$$\begin{aligned}\oint_{PSRQ}\mathbf{a}\cdot d\mathbf{r} &= a_2h_2\,\Delta u_2 + \left[a_3h_3 + \frac{\partial}{\partial u_2}(a_3h_3)\,\Delta u_2\right]\,\Delta u_3\\ &\quad - \left[a_2h_2 + \frac{\partial}{\partial u_3}(a_2h_2)\,\Delta u_3\right]\,\Delta u_2 - a_3h_3\,\Delta u_3\\ &= \left[\frac{\partial}{\partial u_2}(a_3h_3) - \frac{\partial}{\partial u_3}(a_2h_2)\right]\,\Delta u_2\,\Delta u_3.\end{aligned}$$

Therefore from (11.17) the component of $\nabla\times\mathbf{a}$ in the direction $\hat{\mathbf{e}}_1$ at P is given by

$$\begin{aligned}(\nabla\times\mathbf{a})_1 &= \lim_{\Delta u_2,\Delta u_3\to 0}\left[\frac{1}{h_2h_3\,\Delta u_2\,\Delta u_3}\oint_{PSRQ}\mathbf{a}\cdot d\mathbf{r}\right]\\ &= \frac{1}{h_2h_3}\left[\frac{\partial}{\partial u_2}(h_3a_3) - \frac{\partial}{\partial u_3}(h_2a_2)\right].\end{aligned}$$

The other two components are found by cyclically permuting the subscripts 1, 2, 3. ◄

Finally, we note that we can also write the ∇^2 operator as a surface integral by setting $\mathbf{a} = \nabla\phi$ in (11.15), to obtain

$$\nabla^2\phi = \nabla\cdot\nabla\phi = \lim_{V\to 0}\left(\frac{1}{V}\oint_S \nabla\phi\cdot d\mathbf{S}\right).$$

11.8 Divergence theorem and related theorems

The divergence theorem relates the total flux of a vector field out of a closed surface S to the integral of the divergence of the vector field over the enclosed volume V; it follows almost immediately from our geometrical definition of divergence (11.15).

Imagine a volume V, in which a vector field $\mathbf{a}$ is continuous and differentiable, to be divided up into a large number of small volumes V_i. Using (11.15), we have for each small volume

$$(\nabla \cdot \mathbf{a})V_i \approx \oint_{S_i} \mathbf{a} \cdot d\mathbf{S},$$

where S_i is the surface of the small volume V_i. Summing over i we find that contributions from surface elements interior to S cancel since each surface element appears in two terms with opposite signs, the outward normals in the two terms being equal and opposite. Only contributions from surface elements that are also parts of S survive. If each V_i is allowed to tend to zero then we obtain the *divergence theorem*,

$$\int_V \nabla \cdot \mathbf{a}\, dV = \oint_S \mathbf{a} \cdot d\mathbf{S}. \tag{11.18}$$

We note that the divergence theorem holds for both simply and multiply connected surfaces, provided that they are closed and enclose some non-zero volume V. The divergence theorem may also be extended to tensor fields (see chapter 26).

The theorem finds most use as a tool in formal manipulations, but sometimes it is of value in transforming surface integrals of the form $\int_S \mathbf{a} \cdot d\mathbf{S}$ into volume integrals or vice versa. For example, setting $\mathbf{a} = \mathbf{r}$ we immediately obtain

$$\int_V \nabla \cdot \mathbf{r}\, dV = \int_V 3\, dV = 3V = \oint_S \mathbf{r} \cdot d\mathbf{S},$$

which gives the expression for the volume of a region found in subsection 11.6.1. The use of the divergence theorem is further illustrated in the following example.

►*Evaluate the surface integral* $I = \int_S \mathbf{a} \cdot d\mathbf{S}$, *where* $\mathbf{a} = (y - x)\,\mathbf{i} + x^2 z\,\mathbf{j} + (z + x^2)\,\mathbf{k}$ *and* S *is the open surface of the hemisphere* $x^2 + y^2 + z^2 = a^2$, $z \geq 0$.

We could evaluate this surface integral directly, but the algebra is somewhat lengthy. We will therefore evaluate it by use of the divergence theorem. Since the latter only holds for closed surfaces enclosing a non-zero volume V, let us first consider the closed surface $S' = S + S_1$, where S_1 is the circular area in the xy-plane given by $x^2 + y^2 \leq a^2$, $z = 0$; S' then encloses a hemispherical volume V. By the divergence theorem we have

$$\int_V \nabla \cdot \mathbf{a}\, dV = \oint_{S'} \mathbf{a} \cdot d\mathbf{S} = \int_S \mathbf{a} \cdot d\mathbf{S} + \int_{S_1} \mathbf{a} \cdot d\mathbf{S}.$$

Now $\nabla \cdot \mathbf{a} = -1 + 0 + 1 = 0$, so we can write

$$\int_S \mathbf{a} \cdot d\mathbf{S} = -\int_{S_1} \mathbf{a} \cdot d\mathbf{S}.$$

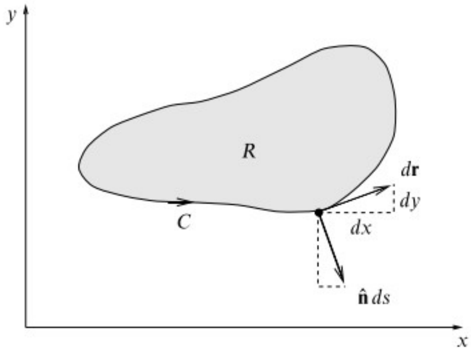

Figure 11.11 A closed curve C in the xy-plane bounding a region R. Vectors tangent and normal to the curve at a given point are also shown.

The surface integral over S_1 is easily evaluated. Remembering that the normal to the surface points outward from the volume, a surface element on S_1 is simply $d\mathbf{S} = -\mathbf{k}\,dx\,dy$. On S_1 we also have $\mathbf{a} = (y - x)\,\mathbf{i} + x^2\,\mathbf{k}$, so that

$$I = -\int_{S_1} \mathbf{a}\cdot d\mathbf{S} = \iint_R x^2\,dx\,dy,$$

where R is the circular region in the xy-plane given by $x^2 + y^2 \le a^2$. Transforming to plane polar coordinates we have

$$I = \iint_{R'} \rho^2\cos^2\phi\;\rho\,d\rho\,d\phi = \int_0^{2\pi}\cos^2\phi\,d\phi\int_0^a \rho^3\,d\rho = \frac{\pi a^4}{4}. \blacktriangleleft$$

It is also interesting to consider the two-dimensional version of the divergence theorem. As an example, let us consider a two-dimensional planar region R in the xy-plane bounded by some closed curve C (see figure 11.11). At any point on the curve the vector $d\mathbf{r} = dx\,\mathbf{i} + dy\,\mathbf{j}$ is a tangent to the curve and the vector $\hat{\mathbf{n}}\,ds = dy\,\mathbf{i} - dx\,\mathbf{j}$ is a normal pointing out of the region R. If the vector field $\mathbf{a}$ is continuous and differentiable in R then the two-dimensional divergence theorem in Cartesian coordinates gives

$$\iint_R \left(\frac{\partial a_x}{\partial x} + \frac{\partial a_y}{\partial y}\right) dx\,dy = \oint \mathbf{a}\cdot\hat{\mathbf{n}}\,ds = \oint_C (a_x\,dy - a_y\,dx).$$

Letting $P = -a_y$ and $Q = a_x$, we recover Green's theorem in a plane, which was discussed in section 11.3.

11.8.1 Green's theorems

Consider two scalar functions ϕ and ψ that are continuous and differentiable in some volume V bounded by a surface S. Applying the divergence theorem to the vector field $\phi\nabla\psi$ we obtain

$$\oint_S \phi\nabla\psi \cdot d\mathbf{S} = \int_V \nabla\cdot(\phi\nabla\psi)\,dV$$
$$= \int_V \left[\phi\nabla^2\psi + (\nabla\phi)\cdot(\nabla\psi)\right]\,dV. \qquad (11.19)$$

Reversing the roles of ϕ and ψ in (11.19) and subtracting the two equations gives

$$\oint_S (\phi\nabla\psi - \psi\nabla\phi)\cdot d\mathbf{S} = \int_V (\phi\nabla^2\psi - \psi\nabla^2\phi)\,dV. \qquad (11.20)$$

Equation (11.19) is usually known as Green's first theorem and (11.20) as his second. Green's second theorem is useful in the development of the Green's functions used in the solution of partial differential equations (see chapter 21).

11.8.2 Other related integral theorems

There exist two other integral theorems which are closely related to the divergence theorem and which are of some use in physical applications. If ϕ is a scalar field and $\mathbf{b}$ is a vector field and both ϕ and $\mathbf{b}$ satisfy our usual differentiability conditions in some volume V bounded by a closed surface S then

$$\int_V \nabla\phi\,dV = \oint_S \phi\,d\mathbf{S}, \qquad (11.21)$$
$$\int_V \nabla\times\mathbf{b}\,dV = \oint_S d\mathbf{S}\times\mathbf{b}. \qquad (11.22)$$

►*Use the divergence theorem to prove (11.21).*

In the divergence theorem (11.18) let $\mathbf{a} = \phi\mathbf{c}$, where $\mathbf{c}$ is a constant vector. We then have

$$\int_V \nabla\cdot(\phi\mathbf{c})\,dV = \oint_S \phi\mathbf{c}\cdot d\mathbf{S}.$$

Expanding out the integrand on the LHS we have

$$\nabla\cdot(\phi\mathbf{c}) = \phi\nabla\cdot\mathbf{c} + \mathbf{c}\cdot\nabla\phi = \mathbf{c}\cdot\nabla\phi,$$

since $\mathbf{c}$ is constant. Also, $\phi\mathbf{c}\cdot d\mathbf{S} = \mathbf{c}\cdot\phi d\mathbf{S}$, so we obtain

$$\int_V \mathbf{c}\cdot(\nabla\phi)\,dV = \oint_S \mathbf{c}\cdot\phi\,d\mathbf{S}.$$

Since $\mathbf{c}$ is constant we may take it out of both integrals to give

$$\mathbf{c}\cdot\int_V \nabla\phi\,dV = \mathbf{c}\cdot\oint_S \phi\,d\mathbf{S},$$

and since $\mathbf{c}$ is arbitrary we obtain the stated result (11.21). ◄

Equation (11.22) may be proved in a similar way by letting $\mathbf{a} = \mathbf{b}\times\mathbf{c}$ in the divergence theorem, where $\mathbf{c}$ is again a constant vector.

11.8.3 Physical applications of the divergence theorem

The divergence theorem is useful in deriving many of the most important partial differential equations in physics (see chapter 20). The basic idea is to use the divergence theorem to convert an integral form, often derived from observation, into an equivalent differential form (used in theoretical statements).

►*For a compressible fluid with time-varying position-dependent density $\rho(\mathbf{r}, t)$ and velocity field $v(\mathbf{r}, t)$, in which fluid is neither being created nor destroyed, show that*

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0.$$

For an arbitrary volume V in the fluid, the conservation of mass tells us that the rate of increase or decrease of the mass M of fluid in the volume must equal the net rate at which fluid is entering or leaving the volume, i.e.

$$\frac{dM}{dt} = -\oint_S \rho \mathbf{v} \cdot d\mathbf{S},$$

where S is the surface bounding V. But the mass of fluid in V is simply $M = \int_V \rho\, dV$, so we have

$$\frac{d}{dt}\int_V \rho\, dV + \oint_S \rho \mathbf{v} \cdot d\mathbf{S} = 0.$$

Taking the derivative inside the first integral on the RHS and using the divergence theorem to rewrite the second integral, we obtain

$$\int_V \frac{\partial \rho}{\partial t}\, dV + \int_V \nabla \cdot (\rho \mathbf{v})\, dV = \int_V \left[\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v})\right] dV = 0.$$

Since the volume V is arbitrary, the integrand (which is assumed continuous) must be identically zero, so we obtain

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0.$$

This is known as the *continuity equation*. It can also be applied to other systems, for example those in which ρ is the density of electric charge or the heat content, etc. For the flow of an incompressible fluid, $\rho =$ constant and the continuity equation becomes simply $\nabla \cdot \mathbf{v} = 0$. ◄

In the previous example, we assumed that there were no sources or sinks in the volume V, i.e. that there was no part of V in which fluid was being created or destroyed. We now consider the case where a finite number of *point* sources and/or sinks are present in an incompressible fluid. Let us first consider the simple case where a single source is located at the origin, out of which a quantity of fluid flows radially at a rate Q ($\mathrm{m}^3\ \mathrm{s}^{-1}$). The velocity field is given by

$$\mathbf{v} = \frac{Q\mathbf{r}}{4\pi r^3} = \frac{Q\hat{\mathbf{r}}}{4\pi r^2}.$$

Now, for a sphere S_1 of radius r centred on the source, the flux across S_1 is

$$\oint_{S_1} \mathbf{v} \cdot d\mathbf{S} = |\mathbf{v}| 4\pi r^2 = Q.$$

Since $\mathbf{v}$ has a singularity at the origin it is not differentiable there, i.e. $\nabla \cdot \mathbf{v}$ is not defined there, but at all other points $\nabla \cdot \mathbf{v} = 0$, as required for an incompressible fluid. Therefore, from the divergence theorem, for any closed surface S_2 that does not enclose the origin we have

$$\oint_{S_2} \mathbf{v} \cdot d\mathbf{S} = \int_V \nabla \cdot \mathbf{v}\, dV = 0.$$

Thus we see that the surface integral $\oint_S \mathbf{v} \cdot d\mathbf{S}$ has value Q or zero depending on whether or not S encloses the source. In order that the divergence theorem is valid for *all* surfaces S, irrespective of whether they enclose the source, we write

$$\nabla \cdot \mathbf{v} = Q\delta(\mathbf{r}),$$

where $\delta(\mathbf{r})$ is the three-dimensional Dirac delta function. The properties of this function are discussed fully in chapter 13, but for the moment we note that it is defined in such a way that

$$\delta(\mathbf{r} - \mathbf{a}) = 0 \qquad \text{for } \mathbf{r} \neq \mathbf{a},$$

$$\int_V f(\mathbf{r})\delta(\mathbf{r} - \mathbf{a})\, dV = \begin{cases} f(\mathbf{a}) & \text{if } \mathbf{a} \text{ lies in } V \\ 0 & \text{otherwise} \end{cases}$$

for any well-behaved function $f(\mathbf{r})$. Therefore, for any volume V containing the source at the origin, we have

$$\int_V \nabla \cdot \mathbf{v}\, dV = Q \int_V \delta(\mathbf{r})\, dV = Q,$$

which is consistent with $\oint_S \mathbf{v} \cdot d\mathbf{S} = Q$ for a closed surface enclosing the source. Hence, by introducing the Dirac delta function the divergence theorem can be made valid even for non-differentiable point sources.

The generalisation to several sources and sinks is straightforward. For example, if a source is located at $\mathbf{r} = \mathbf{a}$ and a sink at $\mathbf{r} = \mathbf{b}$ then the velocity field is

$$\mathbf{v} = \frac{(\mathbf{r} - \mathbf{a})Q}{4\pi|\mathbf{r} - \mathbf{a}|^3} - \frac{(\mathbf{r} - \mathbf{b})Q}{4\pi|\mathbf{r} - \mathbf{b}|^3}$$

and its divergence is given by

$$\nabla \cdot \mathbf{v} = Q\delta(\mathbf{r} - \mathbf{a}) - Q\delta(\mathbf{r} - \mathbf{b}).$$

Therefore, the integral $\oint_S \mathbf{v} \cdot d\mathbf{S}$ has the value Q if S encloses the source, $-Q$ if S encloses the sink and 0 if S encloses neither the source nor sink or encloses them both. This analysis also applies to other physical systems – for example, in electrostatics we can regard the sources and sinks as positive and negative point charges respectively and replace $\mathbf{v}$ by the electric field $\mathbf{E}$.

11.9 Stokes' theorem and related theorems

Stokes' theorem is the 'curl analogue' of the divergence theorem and relates the integral of the curl of a vector field over an open surface S to the line integral of the vector field around the perimeter C bounding the surface.

Following the same lines as for the derivation of the divergence theorem, we can divide the surface S into many small areas S_i with boundaries C_i and unit normals $\hat{\mathbf{n}}_i$. Using (11.17), we have for each small area

$$(\nabla \times \mathbf{a}) \cdot \hat{\mathbf{n}}_i \; S_i \approx \oint_{C_i} \mathbf{a} \cdot d\mathbf{r}.$$

Summing over i we find that on the RHS all parts of all interior boundaries that are not part of C are included twice, being traversed in opposite directions on each occasion and thus contributing nothing. Only contributions from line elements that are also parts of C survive. If each S_i is allowed to tend to zero then we obtain Stokes' theorem,

$$\int_S (\nabla \times \mathbf{a}) \cdot d\mathbf{S} = \oint_C \mathbf{a} \cdot d\mathbf{r}. \qquad (11.23)$$

We note that Stokes' theorem holds for both simply and multiply connected open surfaces, provided that they are two-sided. Stokes' theorem may also be extended to tensor fields (see chapter 26).

Just as the divergence theorem (11.18) can be used to relate volume and surface integrals for certain types of integrand, Stokes' theorem can be used in evaluating surface integrals of the form $\oint_S (\nabla \times \mathbf{a}) \cdot d\mathbf{S}$ as line integrals or vice versa.

►*Given the vector field* $\mathbf{a} = y\,\mathbf{i} - x\,\mathbf{j} + z\,\mathbf{k}$, *verify Stokes' theorem for the hemispherical surface* $x^2 + y^2 + z^2 = a^2$, $z \geq 0$.

Let us first evaluate the surface integral

$$\int_S (\nabla \times \mathbf{a}) \cdot d\mathbf{S}$$

over the hemisphere. It is easily shown that $\nabla \times \mathbf{a} = -2\,\mathbf{k}$, and the surface element is $d\mathbf{S} = a^2 \sin\theta \, d\theta \, d\phi \; \hat{\mathbf{r}}$ in spherical polar coordinates. Therefore

$$\begin{aligned}\int_S (\nabla \times \mathbf{a}) \cdot d\mathbf{S} &= \int_0^{2\pi} d\phi \int_0^{\pi/2} d\theta \, \left(-2a^2 \sin\theta\right) \hat{\mathbf{r}} \cdot \mathbf{k} \\ &= -2a^2 \int_0^{2\pi} d\phi \int_0^{\pi/2} \sin\theta \left(\frac{z}{a}\right) d\theta \\ &= -2a^2 \int_0^{2\pi} d\phi \int_0^{\pi/2} \sin\theta \cos\theta \, d\theta = -2\pi a^2.\end{aligned}$$

We now evaluate the line integral around the perimeter curve C of the surface, which is the circle $x^2 + y^2 = a^2$ in the xy-plane. This is given by

$$\oint_C \mathbf{a}\cdot d\mathbf{r} = \oint_C (y\,\mathbf{i} - x\,\mathbf{j} + z\,\mathbf{k})\cdot(dx\,\mathbf{i} + dy\,\mathbf{j} + dz\,\mathbf{k})$$
$$= \oint_C (y\,dx - x\,dy).$$

Using plane polar coordinates, on C we have $x = a\cos\phi$, $y = a\sin\phi$ so that $dx = -a\sin\phi\,d\phi$, $dy = a\cos\phi\,d\phi$, and the line integral becomes

$$\oint_C (y\,dx - x\,dy) = -a^2\int_0^{2\pi}(\sin^2\phi + \cos^2\phi)\,d\phi = -a^2\int_0^{2\pi} d\phi = -2\pi a^2.$$

Since the surface and line integrals have the same value, we have verified Stokes' theorem in this case. ◄

The two-dimensional version of Stokes' theorem also yields Green's theorem in a plane. Consider the region R in the xy-plane shown in figure 11.11, in which a vector field $\mathbf{a}$ is defined. Since $\mathbf{a} = a_x\,\mathbf{i} + a_y\,\mathbf{j}$, we have $\nabla\times\mathbf{a} = (\partial a_y/\partial x - \partial a_x/\partial y)\,\mathbf{k}$, and Stokes' theorem becomes

$$\iint_R \left(\frac{\partial a_y}{\partial x} - \frac{\partial a_x}{\partial y}\right) dx\,dy = \oint_C (a_x\,dx + a_y\,dy).$$

Letting $P = a_x$ and $Q = a_y$ we recover Green's theorem in a plane, (11.4).

11.9.1 Related integral theorems

As for the divergence theorem, there exist two other integral theorems that are closely related to Stokes' theorem. If ϕ is a scalar field and $\mathbf{b}$ is a vector field, and both ϕ and $\mathbf{b}$ satisfy our usual differentiability conditions on some two-sided open surface S bounded by a closed perimeter curve C, then

$$\int_S d\mathbf{S}\times\nabla\phi = \oint_C \phi\,d\mathbf{r}, \tag{11.24}$$

$$\int_S (d\mathbf{S}\times\nabla)\times\mathbf{b} = \oint_C d\mathbf{r}\times\mathbf{b}. \tag{11.25}$$

►*Use Stokes' theorem to prove (11.24).*

In Stokes' theorem, (11.23), let $\mathbf{a} = \phi\mathbf{c}$, where $\mathbf{c}$ is a constant vector. We then have

$$\int_S [\nabla\times(\phi\mathbf{c})]\cdot d\mathbf{S} = \oint_C \phi\mathbf{c}\cdot d\mathbf{r}. \tag{11.26}$$

Expanding out the integrand on the LHS we have

$$\nabla\times(\phi\mathbf{c}) = \nabla\phi\times\mathbf{c} + \phi\nabla\times\mathbf{c} = \nabla\phi\times\mathbf{c},$$

since $\mathbf{c}$ is constant, and the scalar triple product on the LHS of (11.26) can therefore be written

$$[\nabla\times(\phi\mathbf{c})]\cdot d\mathbf{S} = (\nabla\phi\times\mathbf{c})\cdot d\mathbf{S} = \mathbf{c}\cdot(d\mathbf{S}\times\nabla\phi).$$

Substituting this into (11.26) and taking **c** out of both integrals because it is constant, we find

$$\mathbf{c}\cdot\int_S d\mathbf{S}\times\nabla\phi=\mathbf{c}\cdot\oint_C \phi\, d\mathbf{r}.$$

Since **c** is an arbitrary constant vector we therefore obtain the stated result (11.24). ◄

Equation (11.25) may be proved in a similar way, by letting $\mathbf{a}=\mathbf{b}\times\mathbf{c}$ in Stokes' theorem, where **c** is again a constant vector. We also note that by setting $\mathbf{b}=\mathbf{r}$ in (11.25) we find

$$\int_S (d\mathbf{S}\times\nabla)\times\mathbf{r}=\oint_C d\mathbf{r}\times\mathbf{r}.$$

Expanding out the integrand on the LHS gives

$$(d\mathbf{S}\times\nabla)\times\mathbf{r}=d\mathbf{S}-d\mathbf{S}(\nabla\cdot\mathbf{r})=d\mathbf{S}-3\,d\mathbf{S}=-2\,d\mathbf{S}.$$

Therefore, as we found in subsection 11.5.2, the vector area of an open surface S is given by

$$\mathbf{S}=\int_S d\mathbf{S}=\frac{1}{2}\oint_C \mathbf{r}\times d\mathbf{r}.$$

11.9.2 Physical applications of Stokes' theorem

Like the divergence theorem, Stokes' theorem is useful in converting integral equations into differential equations.

►*From Ampère's law, derive Maxwell's equation in the case where the currents are steady, i.e.* $\nabla\times\mathbf{B}-\mu_0\mathbf{J}=\mathbf{0}$.

Ampère's rule for a distributed current with current density **J** is

$$\oint_C \mathbf{B}\cdot d\mathbf{r}=\mu_0\int_S \mathbf{J}\cdot d\mathbf{S},$$

for any circuit C bounding a surface S. Using Stokes' theorem, the LHS can be transformed into $\int_S(\nabla\times\mathbf{B})\cdot d\mathbf{S}$; hence

$$\int_S(\nabla\times\mathbf{B}-\mu_0\mathbf{J})\cdot d\mathbf{S}=0$$

for *any* surface S. This can only be so if $\nabla\times\mathbf{B}-\mu_0\mathbf{J}=\mathbf{0}$, which is the required relation. Similarly, from Faraday's law of electromagnetic induction we can derive Maxwell's equation $\nabla\times\mathbf{E}=-\partial\mathbf{B}/\partial t$. ◄

In subsection 11.8.3 we discussed the flow of an incompressible fluid in the presence of several sources and sinks. Let us now consider *vortex* flow in an incompressible fluid with a velocity field

$$\mathbf{v}=\frac{1}{\rho}\hat{\mathbf{e}}_\phi,$$

in cylindrical polar coordinates ρ, ϕ, z. For this velocity field $\nabla\times\mathbf{v}$ equals zero everywhere except on the axis $\rho = 0$, where $\mathbf{v}$ has a singularity. Therefore $\oint_C \mathbf{v} \cdot d\mathbf{r}$ equals zero for any path C that does not enclose the vortex line on the axis and 2π if C does enclose the axis. In order for Stokes' theorem to be valid for all paths C, we therefore set

$$\nabla \times \mathbf{v} = 2\pi\delta(\rho),$$

where $\delta(\rho)$ is the Dirac delta function, to be discussed in subsection 13.1.3. Now, since $\nabla \times \mathbf{v} = \mathbf{0}$, except on the axis $\rho = 0$, there exists a scalar potential ψ such that $\mathbf{v} = \nabla\psi$. It may easily be shown that $\psi = \phi$, the polar angle. Therefore, if C does not enclose the axis then

$$\oint_C \mathbf{v} \cdot d\mathbf{r} = \oint d\phi = 0,$$

and if C does enclose the axis,

$$\oint_C \mathbf{v} \cdot d\mathbf{r} = \Delta\phi = 2\pi n,$$

where n is the number of times we traverse C. Thus ϕ is a multivalued potential.

Similar analyses are valid for other physical systems – for example, in magnetostatics we may replace the vortex lines by current-carrying wires and the velocity field $\mathbf{v}$ by the magnetic field $\mathbf{B}$.

11.10 Exercises

11.1 The vector field $\mathbf{F}$ is defined by

$$\mathbf{F} = 2xz\mathbf{i} + 2yz^2\mathbf{j} + (x^2 + 2y^2z - 1)\mathbf{k}.$$

Calculate $\nabla \times \mathbf{F}$ and deduce that $\mathbf{F}$ can be written $F = \nabla\phi$. Determine the form of ϕ.

11.2 The vector field $\mathbf{Q}$ is defined by

$$\mathbf{Q} = \left[3x^2(y+z) + y^3 + z^3\right]\mathbf{i} + \left[3y^2(z+x) + z^3 + x^3\right]\mathbf{j} + \left[3z^2(x+y) + x^3 + y^3\right]\mathbf{k}.$$

Show that $\mathbf{Q}$ is a conservative field, construct its potential function and hence evaluate the integral $J = \int \mathbf{Q} \cdot d\mathbf{r}$ along any line connecting the point A at $(1, -1, 1)$ to B at $(2, 1, 2)$.

11.3 $\mathbf{F}$ is a vector field $xy^2\mathbf{i} + 2\mathbf{j} + x\mathbf{k}$, and L is a path parameterised by $x = ct$, $y = c/t$, $z = d$ for the range $1 \le t \le 2$. Evaluate (a) $\int_L \mathbf{F}\,dt$, (b) $\int_L \mathbf{F}\,dy$ and (c) $\int_L \mathbf{F} \cdot d\mathbf{r}$.

11.4 By making an appropriate choice for the functions $P(x, y)$ and $Q(x, y)$ that appear in Green's theorem in a plane, show that the integral of $x - y$ over the upper half of the unit circle centred on the origin has the value $-\frac{2}{3}$. Show the same result by direct integration in Cartesian coordinates.

11.5 Determine the point of intersection P, in the first quadrant, of the two ellipses

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \quad \text{and} \quad \frac{x^2}{b^2} + \frac{y^2}{a^2} = 1.$$

Taking $b < a$, consider the contour L that bounds the area in the first quadrant that is common to the two ellipses. Show that the parts of L that lie along the coordinate axes contribute nothing to the line integral around L of $x\,dy - y\,dx$. Using a parameterisation of each ellipse similar to that employed in the example

Representation theory

As indicated at the start of the previous chapter, significant conclusions can often be drawn about a physical system simply from the study of its symmetry properties. That chapter was devoted to setting up a formal mathematical basis, group theory, with which to describe and classify such properties; the current chapter shows how to implement the consequences of the resulting classifications and obtain concrete physical conclusions about the system under study. The connection between the two chapters is akin to that between working with coordinate-free vectors, each denoted by a single symbol, and working with a coordinate system in which the same vectors are expressed in terms of components.

The 'coordinate systems' that we will choose will be ones that are expressed in terms of matrices; it will be clear that ordinary numbers would not be sufficient, as they make no provision for any non-commutation amongst the elements of a group. Thus, in this chapter the group elements will be *represented* by matrices that have the same commutation relations as the members of the group, whatever the group's original nature (symmetry operations, functional forms, matrices, permutations, etc.). For some abstract groups it is difficult to give a written description of the elements and their properties without recourse to such representations. Most of our applications will be concerned with representations of the groups that consist of the symmetry operations on molecules containing two or more identical atoms.

Firstly, in section 29.1, we use an elementary example to demonstrate the kind of conclusions that can be reached by arguing purely on symmetry grounds. Then in sections 29.2–29.10 we develop the formal side of representation theory and establish general procedures and results. Finally, these are used in section 29.11 to tackle a variety of problems drawn from across the physical sciences.

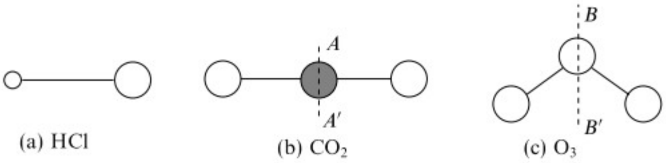

Figure 29.1 Three molecules, (a) hydrogen chloride, (b) carbon dioxide and (c) ozone, for which symmetry considerations impose varying degrees of constraint on their possible electric dipole moments.

29.1 Dipole moments of molecules

Some simple consequences of *symmetry* can be demonstrated by considering whether a permanent electric dipole moment can exist in any particular molecule; three simple molecules, hydrogen chloride, carbon dioxide and ozone, are illustrated in figure 29.1. Even if a molecule is electrically neutral, an electric dipole moment will exist in it if the centres of gravity of the positive charges (due to protons in the atomic nuclei) and of the negative charges (due to the electrons) do not coincide.

For hydrogen chloride there is no reason why they should coincide; indeed, the normal picture of the binding mechanism in this molecule is that the electron from the hydrogen atom moves its average position from that of its proton nucleus to somewhere between the hydrogen and chlorine nuclei. There is no compensating movement of positive charge, and a net dipole moment is to be expected – and is found experimentally.

For the linear molecule carbon dioxide it seems obvious that it cannot have a dipole moment, because of its symmetry. Putting this rather more rigorously, we note that any rotation about the long axis of the molecule leaves it totally unchanged; consequently, any component of a permanent electric dipole perpendicular to that axis must be zero (a non-zero component would rotate although no physical change had taken place in the molecule). That only leaves the possibility of a component parallel to the axis. However, a rotation of π radians about the axis AA' shown in figure 29.1(b) carries the molecule into itself, as does a reflection in a plane through the carbon atom and perpendicular to the molecular axis (i.e. one with its normal parallel to the axis). In both cases the two oxygen atoms change places but, as they are identical, the molecule is indistinguishable from the original. Either 'symmetry operation' would reverse the sign of any dipole component directed parallel to the molecular axis; this can only be compatible with the indistinguishability of the original and final systems if the parallel component is zero. Thus on symmetry grounds carbon dioxide cannot have a permanent electric dipole moment.

Finally, for ozone, which is angular rather than linear, symmetry does not place such tight constraints. A dipole-moment component parallel to the axis BB' (figure 29.1(c)) is possible, since there is no symmetry operation that reverses the component in that direction and at the same time carries the molecule into an indistinguishable copy of itself. However, a dipole moment perpendicular to BB' is not possible, since a rotation of π about BB' would both reverse any such component and carry the ozone molecule into itself – two contradictory conclusions unless the component is zero.

In summary, symmetry requirements appear in the form that some or all components of permanent electric dipoles in molecules are forbidden; they do not show that the other components do exist, only that they may. The greater the symmetry of the molecule, the tighter the restrictions on potentially non-zero components of its dipole moment.

In section 23.11 other, more complicated, physical situations will be analysed using results derived from representation theory. In anticipation of these results, and since it may help the reader to understand where the developments in the next nine sections are leading, we make here a broad, powerful, but rather formal, statement as follows.

If a physical system is such that after the application of particular rotations or reflections (or a combination of the two) the final system is indistinguishable from the original system then its behaviour, and hence the functions that describe its behaviour, must have the corresponding property of invariance when subjected to the same rotations and reflections.

29.2 Choosing an appropriate formalism

As mentioned in the introduction to this chapter, the elements of a finite group $\mathcal{G}$ can be *represented* by matrices; this is done in the following way. A suitable column matrix u, known as a *basis vector*,[§] is chosen and is written in terms of its components u_i, the *basis functions*, as $\mathsf{u} = (u_1\ u_2\ \cdots\ u_n)^{\mathrm{T}}$. The u_i may be of a variety of natures, e.g. numbers, coordinates, functions or even a set of labels, though for any one basis vector they will all be of the same kind.

Once chosen, the basis vector can be used to generate an n-dimensional *representation* of the group as follows. An element X of the group is selected and its effect on each basis function u_i is determined. If the action of X on u_1 is to produce u_1', etc. then the set of equations

$$u_i' = Xu_i \tag{29.1}$$

[§] This usage of the term *basis vector* is not exactly the same as that introduced in subsection 8.1.1.

of simple pair interchanges to which a permutation is equivalent. That these assignments are in accord with the group multiplication table 28.8 should be checked.

Thus the three irreps of the group $\mathcal{G}$ (i.e. the group $3m$ or C_{3v} or S_3), are, using the conventional notation A_1, A_2, E (see section 29.8), as follows:

		Element					
		I	A	B	C	D	E
Irrep	A_1	1	1	1	1	1	1
	A_2	1	1	1	-1	-1	-1
	E	M_I	M_A	M_B	M_C	M_D	M_E

(29.12)

where

$$\mathsf{M}_I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \qquad \mathsf{M}_A = \begin{pmatrix} -\frac{1}{2} & \frac{\sqrt{3}}{2} \\ -\frac{\sqrt{3}}{2} & -\frac{1}{2} \end{pmatrix}, \qquad \mathsf{M}_B = \begin{pmatrix} -\frac{1}{2} & -\frac{\sqrt{3}}{2} \\ \frac{\sqrt{3}}{2} & -\frac{1}{2} \end{pmatrix},$$

$$\mathsf{M}_C = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \mathsf{M}_D = \begin{pmatrix} \frac{1}{2} & -\frac{\sqrt{3}}{2} \\ -\frac{\sqrt{3}}{2} & -\frac{1}{2} \end{pmatrix}, \quad \mathsf{M}_E = \begin{pmatrix} \frac{1}{2} & \frac{\sqrt{3}}{2} \\ \frac{\sqrt{3}}{2} & -\frac{1}{2} \end{pmatrix}.$$

29.5 The orthogonality theorem for irreducible representations

We come now to the central theorem of representation theory, a theorem that justifies the relatively routine application of certain procedures to determine the restrictions that are inherent in physical systems that have some degree of rotational or reflection symmetry. The development of the theorem is long and quite complex when presented in its entirety, and the reader will have to refer elsewhere for the proof.[§]

The theorem states that, in a certain sense, the irreps of a group $\mathcal{G}$ are as orthogonal as possible, as follows. If, for each irrep, the elements in any one position in each of the g matrices are used to make up g-component column matrices then

(i) any two such column matrices coming from different irreps are orthogonal;
(ii) any two such column matrices coming from different positions in the matrices of the same irrep are orthogonal.

This orthogonality is in addition to the irreps' being in the form of orthogonal (unitary) matrices and thus each comprising mutually orthogonal rows and columns.

[§] See, e.g., H. F. Jones, *Groups, Representations and Physics* (Bristol: Institute of Physics, 1998); J. F. Cornwell, *Group Theory in Physics*, vol 2 (London: Academic Press, 1984); J-P. Serre, *Linear Representations of Finite Groups* (New York: Springer, 1977).

More mathematically, if we denote the entry in the ith row and jth column of a matrix $\mathsf{D}(X)$ by $[\mathsf{D}(X)]_{ij}$, and $\hat{\mathsf{D}}^{(\lambda)}$ and $\hat{\mathsf{D}}^{(\mu)}$ are two irreps of $\mathcal{G}$ having dimensions n_λ and n_μ respectively, then

$$\sum_X \left[\hat{\mathsf{D}}^{(\lambda)}(X)\right]^*_{ij} \left[\hat{\mathsf{D}}^{(\mu)}(X)\right]_{kl} = \frac{g}{n_\lambda}\delta_{ik}\delta_{jl}\delta_{\lambda\mu}. \tag{29.13}$$

This rather forbidding-looking equation needs some further explanation.

Firstly, the asterisk indicates that the complex conjugate should be taken if necessary, though all our representations so far have involved only real matrix elements. Each Kronecker delta function on the right-hand side has the value 1 if its two subscripts are equal and has the value 0 otherwise. Thus the right-hand side is only non-zero if $i = k$, $j = l$ and $\lambda = \mu$, all at the same time.

Secondly, the summation over the group elements X means that g contributions have to be added together, each contribution being a product of entries drawn from the representative matrices in the two irreps $\hat{\mathsf{D}}^{(\lambda)} = \{\hat{\mathsf{D}}^{(\lambda)}(X)\}$ and $\hat{\mathsf{D}}^{(\mu)} = \{\hat{\mathsf{D}}^{(\mu)}(X)\}$. The g contributions arise as X runs over the g elements of $\mathcal{G}$.

Thus, putting these remarks together, the summation will produce zero if either

(i) the matrix elements are not taken from exactly the same position in every matrix, including cases in which it is not possible to do so because the irreps $\hat{\mathsf{D}}^{(\lambda)}$ and $\hat{\mathsf{D}}^{(\mu)}$ have different dimensions, or

(ii) even if $\hat{\mathsf{D}}^{(\lambda)}$ and $\hat{\mathsf{D}}^{(\mu)}$ do have the same dimensions and the matrix elements are from the same positions in every matrix, they are different irreps, i.e. $\lambda \neq \mu$.

Some numerical illustrations based on the irreps A_1, A_2 and E of the group $3m$ (or C_{3v} or S_3) will probably provide the clearest explanation (see (29.12)).

(a) Take $i = j = k = l = 1$, with $\hat{\mathsf{D}}^{(\lambda)} = A_1$ and $\hat{\mathsf{D}}^{(\mu)} = A_2$. Equation (29.13) then reads

$$1(1) + 1(1) + 1(1) + 1(-1) + 1(-1) + 1(-1) = 0,$$

as expected, since $\lambda \neq \mu$.

(b) Take (i, j) as $(1, 2)$ and (k, l) as $(2, 2)$, corresponding to different matrix positions within the same irrep $\hat{\mathsf{D}}^{(\lambda)} = \hat{\mathsf{D}}^{(\mu)} = $ E. Substituting in (29.13) gives

$$0(1) + \left(-\tfrac{\sqrt{3}}{2}\right)\left(-\tfrac{1}{2}\right) + \left(\tfrac{\sqrt{3}}{2}\right)\left(-\tfrac{1}{2}\right) + 0(1) + \left(-\tfrac{\sqrt{3}}{2}\right)\left(-\tfrac{1}{2}\right) + \left(\tfrac{\sqrt{3}}{2}\right)\left(-\tfrac{1}{2}\right) = 0.$$

(c) Take (i, j) as $(1, 2)$, and (k, l) as $(1, 2)$, corresponding to the same matrix positions within the same irrep $\hat{\mathsf{D}}^{(\lambda)} = \hat{\mathsf{D}}^{(\mu)} = $ E. Substituting in (29.13) gives

$$0(0) + \left(-\tfrac{\sqrt{3}}{2}\right)\left(-\tfrac{\sqrt{3}}{2}\right) + \left(\tfrac{\sqrt{3}}{2}\right)\left(\tfrac{\sqrt{3}}{2}\right) + 0(0) + \left(-\tfrac{\sqrt{3}}{2}\right)\left(-\tfrac{\sqrt{3}}{2}\right) + \left(\tfrac{\sqrt{3}}{2}\right)\left(\tfrac{\sqrt{3}}{2}\right) = \tfrac{6}{2}.$$

(d) No explicit calculation is needed to see that if $i = j = k = l = 1$, with $\hat{\mathsf{D}}^{(\lambda)} = \hat{\mathsf{D}}^{(\mu)} = \mathrm{A}_1$ (or A_2), then each term in the sum is either 1^2 or $(-1)^2$ and the total is 6, as predicted by the right-hand side of (29.13) since $g = 6$ and $n_\lambda = 1$.

29.6 Characters

The actual matrices of general representations and irreps are cumbersome to work with, and they are not unique since there is always the freedom to change the coordinate system, i.e. the components of the basis vector (see section 29.3), and hence the entries in the matrices. However, one thing that does not change for a matrix under such an equivalence (similarity) transformation – i.e. under a change of basis – is the trace of the matrix. This was shown in chapter 8, but is repeated here. The trace of a matrix A is the sum of its diagonal elements,

$$\mathrm{Tr}\,\mathsf{A} = \sum_{i=1}^{n} \mathsf{A}_{ii}$$

or, using the summation convention (section 26.1), simply A_{ii}. Under a similarity transformation, again using the summation convention,

$$\begin{aligned}
[\mathsf{D}_{\mathsf{Q}}(X)]_{ii} &= [\mathsf{Q}^{-1}]_{ij}[\mathsf{D}(X)]_{jk}[\mathsf{Q}]_{ki} \\
&= [\mathsf{D}(X)]_{jk}[\mathsf{Q}]_{ki}[\mathsf{Q}^{-1}]_{ij} \\
&= [\mathsf{D}(X)]_{jk}[\mathsf{I}]_{kj} \\
&= [\mathsf{D}(X)]_{jj},
\end{aligned}$$

showing that the traces of equivalent matrices are equal.

This fact can be used to greatly simplify work with representations, though with some partial loss of the information content of the full matrices. For example, using trace values alone it is not possible to distinguish between the two groups known as $4mm$ and $\bar{4}2m$, or as C_{4v} and D_{2d} respectively, even though the two groups are not isomorphic. To make use of these simplifications we now define the characters of a representation.

Definition. *The* characters $\chi(\mathsf{D})$ *of a representation* D *of a group* $\mathcal{G}$ *are defined as the traces of the matrices* $\mathsf{D}(X)$*, one for each element* X *of* $\mathcal{G}$.

At this stage there will be g characters, but, as we noted in subsection 28.7.3, elements A, B of $\mathcal{G}$ in the same conjugacy class are connected by equations of the form $B = X^{-1}AX$. It follows that their matrix representations are connected by corresponding equations of the form $\mathsf{D}(B) = \mathsf{D}(X^{-1})\mathsf{D}(A)\mathsf{D}(X)$, and so by the argument just given their representations will have equal traces and hence equal characters. Thus *elements in the same conjugacy class have the same characters,*

$3m$	I	A, B	C, D, E	
A_1	1	1	1	z; z^2; $x^2 + y^2$
A_2	1	1	-1	R_z
E	2	-1	0	(x, y); (xz, yz); (R_x, R_y); $(x^2 - y^2, 2xy)$

Table 29.1 The character table for the irreps of group $3m$ (C_{3v} or S_3). The right-hand column lists some common functions that transform according to the irrep against which each is shown (see text).

though, in general, these will vary from one representation to another. However, it might also happen that two or more conjugacy classes have the same characters in a representation – indeed, in the trivial irrep A_1, see (29.12), every element inevitably has the character 1.

For the irrep A_2 of the group $3m$, the classes $\{I\}$, $\{A, B\}$ and $\{C, D, E\}$ have characters 1, 1 and -1, respectively, whilst they have characters 2, -1 and 0 respectively in irrep E.

We are thus able to draw up a *character table* for the group $3m$ as shown in table 29.1. This table holds in compact form most of the important information on the behaviour of functions under the two-dimensional rotational and reflection symmetries of an equilateral triangle, i.e. under the elements of group $3m$. The entry under I for any irrep gives the dimension of the irrep, since it is equal to the trace of the unit matrix whose dimension is equal to that of the irrep. In other words, for the λth irrep $\chi^{(\lambda)}(I) = n_\lambda$, where n_λ is its dimension.

In the extreme right-hand column we list some common functions of Cartesian coordinates that transform, under the group $3m$, according to the irrep on whose line they are listed. Thus, as we have seen, z, z^2, and $x^2 + y^2$ are all unchanged by the group operations (though x and y individually are affected) and so are listed against the one-dimensional irrep A_1. Each of the pairs (x, y), (xz, yz), and $(x^2 - y^2, 2xy)$, however, is mixed as a pair by some of the operations, and so these pairs are listed against the two-dimensional irrep E: each pair forms a basis set for this irrep.

The quantities R_x, R_y and R_z refer to rotations about the indicated axes; they transform in the same way as the corresponding components of angular momentum **J**, and their behaviour can be established by examining how the components of $\mathbf{J} = \mathbf{r} \times \mathbf{p}$ transform under the operations of the group. To do this explicitly is beyond the scope of this book. However, it can be noted that R_z, being listed opposite the one-dimensional A_2, is unchanged by I and by the rotations A and B but changes sign under the mirror reflections C, D, and E, as would be expected.

29.6.1 Orthogonality property of characters

Some of the most important properties of characters can be deduced from the orthogonality theorem (29.13),

$$\sum_X \left[\hat{\mathsf{D}}^{(\lambda)}(X)\right]^*_{ij} \left[\hat{\mathsf{D}}^{(\mu)}(X)\right]_{kl} = \frac{g}{n_\lambda}\delta_{ik}\delta_{jl}\delta_{\lambda\mu}.$$

If we set $j = i$ and $l = k$, so that both factors in any particular term in the summation refer to diagonal elements of the representative matrices, and then sum both sides over i and k, we obtain

$$\sum_X \sum_{i=1}^{n_\lambda} \sum_{k=1}^{n_\mu} \left[\hat{\mathsf{D}}^{(\lambda)}(X)\right]^*_{ii} \left[\hat{\mathsf{D}}^{(\mu)}(X)\right]_{kk} = \frac{g}{n_\lambda} \sum_{i=1}^{n_\lambda} \sum_{k=1}^{n_\mu} \delta_{ik}\delta_{ik}\delta_{\lambda\mu}.$$

Expressed in term of characters, this reads

$$\sum_X \left[\chi^{(\lambda)}(X)\right]^* \chi^{(\mu)}(X) = \frac{g}{n_\lambda} \sum_{i=1}^{n_\lambda} \delta_{ii}^2 \delta_{\lambda\mu} = \frac{g}{n_\lambda} \sum_{i=1}^{n_\lambda} 1 \times \delta_{\lambda\mu} = g\delta_{\lambda\mu}. \tag{29.14}$$

In words, the (g-component) 'vectors' formed from the characters of the various irreps of a group are mutually orthogonal, but each one has a squared magnitude (the sum of the squares of its components) equal to the order of the group.

Since, as noted in the previous subsection, group elements in the same class have the same characters, (29.14) can be written as a sum over classes rather than elements. If c_i denotes the number of elements in class $\mathcal{C}_i$ and X_i any element of $\mathcal{C}_i$, then

$$\sum_i c_i \left[\chi^{(\lambda)}(X_i)\right]^* \chi^{(\mu)}(X_i) = g\delta_{\lambda\mu}. \tag{29.15}$$

Although we do not prove it here, there also exists a 'completeness' relation for characters. It makes a statement about the products of characters for a fixed pair of group elements, X_1 and X_2, when the products are summed over all possible irreps of the group. This is the converse of the summation process defined by (29.14). The completeness relation states that

$$\sum_\lambda \left[\chi^{(\lambda)}(X_1)\right]^* \chi^{(\lambda)}(X_2) = \frac{g}{c_1}\delta_{\mathcal{C}_1\mathcal{C}_2}, \tag{29.16}$$

where element X_1 belongs to conjugacy class $\mathcal{C}_1$ and X_2 belongs to $\mathcal{C}_2$. Thus the sum is zero unless X_1 and X_2 belong to the same class. For table 29.1 we can verify that these results are valid.

(i) For $\hat{\mathsf{D}}^{(\lambda)} = \hat{\mathsf{D}}^{(\mu)} = \mathrm{A}_1$ or A_2, (29.15) reads

$$1(1) + 2(1) + 3(1) = 6,$$

whilst for $\hat{\mathsf{D}}^{(\lambda)} = \hat{\mathsf{D}}^{(\mu)} = \mathrm{E}$, it gives

$$1(2^2) + 2(1) + 3(0) = 6.$$

(ii) For $\hat{\mathsf{D}}^{(\lambda)} = \mathrm{A}_2$ and $\hat{\mathsf{D}}^{(\mu)} = \mathrm{E}$, say, (29.15) reads

$$1(1)(2) + 2(1)(-1) + 3(-1)(0) = 0.$$

(iii) For $X_1 = A$ and $X_2 = D$, say, (29.16) reads

$$1(1) + 1(-1) + (-1)(0) = 0,$$

whilst for $X_1 = C$ and $X_2 = E$, both of which belong to class $\mathcal{C}_3$ for which $c_3 = 3$,

$$1(1) + (-1)(-1) + (0)(0) = 2 = \frac{6}{3}.$$

29.7 Counting irreps using characters

The expression of a general representation $\mathsf{D} = \{\mathsf{D}(X)\}$ in terms of irreps, as given in (29.11), can be simplified by going from the full matrix form to that of characters. Thus

$$\mathsf{D}(X) = m_1\hat{\mathsf{D}}^{(1)}(X) \oplus m_2\hat{\mathsf{D}}^{(2)}(X) \oplus \cdots \oplus m_N\hat{\mathsf{D}}^{(N)}(X)$$

becomes, on taking the trace of both sides,

$$\chi(X) = \sum_{\lambda=1}^{N} m_\lambda \chi^{(\lambda)}(X). \qquad (29.17)$$

Given the characters of the irreps of the group $\mathcal{G}$ to which the elements X belong, and the characters of the representation $\mathsf{D} = \{\mathsf{D}(X)\}$, the g equations (29.17) can be solved as simultaneous equations in the m_λ, either by inspection or by multiplying both sides by $\left[\chi^{(\mu)}(X)\right]^*$ and summing over X, making use of (29.14) and (29.15), to obtain

$$m_\mu = \frac{1}{g}\sum_X \left[\chi^{(\mu)}(X)\right]^* \chi(X) = \frac{1}{g}\sum_i c_i \left[\chi^{(\mu)}(X_i)\right]^* \chi(X_i). \qquad (29.18)$$

That an unambiguous formula can be given for each m_λ, once the *character set* (the set of characters of each of the group elements or, equivalently, of each of the conjugacy classes) of D is known, shows that, for any particular group, two representations with the same characters are equivalent. This strongly suggests something that can be shown, namely, *the number of irreps = the number of conjugacy classes*. The argument is as follows. Equation (29.17) is a set of simultaneous equations for N unknowns, the m_λ, some of which may be zero. The value of N is equal to the number of irreps of $\mathcal{G}$. There are g different values of X, but the number of *different* equations is only equal to the number of distinct conjugacy classes, since any two elements of $\mathcal{G}$ in the same class have the same character set and therefore generate the same equation. For a unique solution to simultaneous equations in N unknowns, exactly N independent equations are needed. Thus N is also the number of classes, establishing the stated result.

►*Determine the irreps contained in the representation of the group 3m in the vector space spanned by the functions x^2, y^2, xy.*

We first note that although these functions are not orthogonal they form a basis set for a representation, since they are linearly independent quadratic forms in x and y and any other quadratic form can be written (uniquely) in terms of them. We must establish how they transform under the symmetry operations of group $3m$. We need to do so only for a representative element of each conjugacy class, and naturally we take the simplest in each case.

The first class contains only I (as always) and clearly $\mathsf{D}(I)$ is the 3×3 unit matrix.

The second class contains the rotations, A and B, and we choose to find $\mathsf{D}(A)$. Since, under A,

$$x \;\to\; -\frac{1}{2}x + \frac{\sqrt{3}}{2}y \qquad \text{and} \qquad y \;\to\; -\frac{\sqrt{3}}{2}x - \frac{1}{2}y,$$

it follows that

$$x^2 \;\to\; \tfrac{1}{4}x^2 - \tfrac{\sqrt{3}}{2}xy + \tfrac{3}{4}y^2, \qquad\qquad y^2 \;\to\; \tfrac{3}{4}x^2 + \tfrac{\sqrt{3}}{2}xy + \tfrac{1}{4}y^2 \tag{29.19}$$

and

$$xy \;\to\; \tfrac{\sqrt{3}}{4}x^2 - \tfrac{1}{2}xy - \tfrac{\sqrt{3}}{4}y^2. \tag{29.20}$$

Hence $\mathsf{D}(A)$ can be deduced and is given below.

The third and final class contains the reflections, C, D and E; of these C is much the easiest to deal with. Under C, $x \to -x$ and $y \to y$, causing xy to change sign but leaving x^2 and y^2 unaltered. The three matrices needed are thus

$$\mathsf{D}(I) = \mathsf{I}_3, \quad \mathsf{D}(C) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \quad \mathsf{D}(A) = \begin{pmatrix} \frac{1}{4} & \frac{3}{4} & -\frac{\sqrt{3}}{2} \\ \frac{3}{4} & \frac{1}{4} & \frac{\sqrt{3}}{2} \\ \frac{\sqrt{3}}{4} & -\frac{\sqrt{3}}{4} & -\frac{1}{2} \end{pmatrix};$$

their traces are respectively 3, 1 and 0.

It should be noticed that much more work has been done here than is necessary, since the traces can be computed immediately from the effects of the symmetry operations on the basis functions. All that is needed is the weight of each basis function in the transformed expression for that function; these are clearly 1, 1, 1 for I, and $\frac{1}{4}$, $\frac{1}{4}$, $-\frac{1}{2}$ for A, from (29.19) and (29.20), and 1, 1, -1 for C, from the observations made just above the displayed matrices. The traces are then the sums of these weights. The off-diagonal elements of the matrices need not be found, nor need the matrices be written out.

From (29.17) we now need to find a superposition of the characters of the irreps that gives representation D in the bottom line of table 29.2.

By inspection it is obvious that $\mathsf{D} = \mathrm{A}_1 \oplus \mathrm{E}$, but we can use (29.18) formally:

$$\begin{aligned} m_{A_1} &= \tfrac{1}{6}[1(1)(3) + 2(1)(0) + 3(1)(1)] = 1, \\ m_{A_2} &= \tfrac{1}{6}[1(1)(3) + 2(1)(0) + 3(-1)(1)] = 0, \\ m_E &= \tfrac{1}{6}[1(2)(3) + 2(-1)(0) + 3(0)(1)] = 1. \end{aligned}$$

Thus A_1 and E appear once each in the reduction of D, and A_2 not at all. Table 29.1 gives the further information, not needed here, that it is the combination $x^2 + y^2$ that transforms as a one-dimensional irrep and the pair $(x^2 - y^2,\ 2xy)$ that forms a basis of the two-dimensional irrep, E. ◄

	Classes		
Irrep	I	AB	CDE
A_1	1	1	1
A_2	1	1	-1
E	2	-1	0
D	3	0	1

Table 29.2 The characters of the irreps of the group $3m$ and of the representation D, which must be a superposition of some of them.

29.7.1 *Summation rules for irreps*

The first summation rule for irreps is a simple restatement of (29.14), with μ set equal to λ; it then reads

$$\sum_X \left[\chi^{(\lambda)}(X)\right]^* \chi^{(\lambda)}(X) = g.$$

In words, the sum of the squares (modulus squared if necessary) of the characters of an irrep taken over all elements of the group adds up to the order of the group. For group $3m$ (table 29.1), this takes the following explicit forms:

for A_1, $\quad 1(1^2) + 2(1^2) + 3(1^2) = 6;$
for A_2, $\quad 1(1^2) + 2(1^2) + 3(-1)^2 = 6;$
for E, $\quad 1(2^2) + 2(-1)^2 + 3(0^2) = 6.$

We next prove a theorem that is concerned not with a summation within an irrep but with a summation over irreps.

Theorem. *If n_μ is the dimension of the μth irrep of a group $\mathcal{G}$ then*

$$\sum_\mu n_\mu^2 = g,$$

where g is the order of the group.

Proof. Define a representation of the group in the following way. Rearrange the rows of the multiplication table of the group so that whilst the elements in a particular order head the columns, their inverses in the same order head the rows. In this arrangement of the $g \times g$ table, the leading diagonal is entirely occupied by the identity element. Then, for each element X of the group, take as representative matrix the multiplication-table array obtained by replacing X by 1 and all other element symbols by 0. The matrices $\mathsf{D}^{\text{reg}}(X)$ so obtained form the *regular representation* of $\mathcal{G}$; they are each $g \times g$, have a single non-zero entry '1' in each row and column and (as will be verified by a little experimentation) have

(a)

	I	A	B
I	I	A	B
A	A	B	I
B	B	I	A

(b)

	I	A	B
I	I	A	B
B	B	I	A
A	A	B	I

Table 29.3 (a) The multiplication table of the cyclic group of order 3, and (b) its reordering used to generate the regular representation of the group.

the same multiplication structure as the group $\mathcal{G}$ itself, i.e. they form a faithful representation of $\mathcal{G}$.

Although not part of the proof, a simple example may help to make these ideas more transparent. Consider the cyclic group of order 3. Its multiplication table is shown in table 29.3(a) (a repeat of table 28.10(a) of the previous chapter), whilst table 29.3(b) shows the same table reordered so that the columns are still labelled in the order I, A, B but the rows are now labelled in the order $I^{-1} = I$, $A^{-1} = B$, $B^{-1} = A$. The three matrices of the regular representation are then

$$\mathsf{D}^{\rm reg}(I) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \mathsf{D}^{\rm reg}(A) = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}, \quad \mathsf{D}^{\rm reg}(B) = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

An alternative, more mathematical, definition of the regular representation of a group is

$$\left[\mathsf{D}^{\rm reg}(G_k)\right]_{ij} = \begin{cases} 1 & \text{if } G_k G_j = G_i, \\ 0 & \text{otherwise.} \end{cases}$$

We now return to the proof. With the construction given, the regular representation has characters as follows:

$$\chi^{\rm reg}(I) = g, \qquad \chi^{\rm reg}(X) = 0 \quad \text{if } X \neq I.$$

We now apply (29.18) to $\mathsf{D}^{\rm reg}$ to obtain for the number m_μ of times that the irrep $\hat{\mathsf{D}}^{(\mu)}$ appears in $\mathsf{D}^{\rm reg}$ (see 29.11))

$$m_\mu = \frac{1}{g} \sum_X \left[\chi^{(\mu)}(X)\right]^* \chi^{\rm reg}(X) = \frac{1}{g} \left[\chi^{(\mu)}(I)\right]^* \chi^{\rm reg}(I) = \frac{1}{g} n_\mu g = n_\mu.$$

Thus an irrep $\hat{\mathsf{D}}^{(\mu)}$ of dimension n_μ appears n_μ times in $\mathsf{D}^{\rm reg}$, and so by counting the total number of basis functions, or by considering $\chi^{\rm reg}(I)$, we can conclude that

$$\sum_{\mu} n_{\mu}^2 = g. \tag{29.21}$$

This completes the proof.

As before, our standard demonstration group $3m$ provides an illustration. In this case we have seen already that there are two one-dimensional irreps and one two-dimensional irrep. This is in accord with (29.21) since

$$1^2 + 1^2 + 2^2 = 6, \qquad \text{which is the order } g \text{ of the group.}$$

Another straightforward application of the relation (29.21), to the group with multiplication table 29.3(a), yields immediate results. Since $g = 3$, none of its irreps can have dimension 2 or more, as $2^2 = 4$ is too large for (29.21) to be satisfied. Thus all irreps must be one-dimensional and there must be three of them (consistent with the fact that each element is in a class of its own, and that there are therefore three classes). The three irreps are the sets of 1×1 matrices (numbers)

$$\mathrm{A}_1 = \{1, 1, 1\} \qquad \mathrm{A}_2 = \{1, \omega, \omega^2\} \qquad \mathrm{A}_2^* = \{1, \omega^2, \omega\},$$

where $\omega = \exp(2\pi i/3)$; since the matrices are 1×1, the same set of nine numbers would be, of course, the entries in the character table for the irreps of the group. The fact that the numbers in each irrep are all cube roots of unity is discussed below. As will be noticed, two of these irreps are complex – an unusual occurrence in most applications – and form a complex conjugate pair of one-dimensional irreps. In practice, they function much as a two-dimensional irrep, but this is to be ignored for formal purposes such as theorems.

A further property of characters can be derived from the fact that all elements in a conjugacy class have the same order. Suppose that the element X has order m, i.e. $X^m = I$. This implies for a representation D of dimension n that

$$[\mathsf{D}(X)]^m = I_n. \tag{29.22}$$

Representations equivalent to D are generated as before by using similarity transformations of the form

$$\mathsf{D}_{\mathsf{Q}}(X) = \mathsf{Q}^{-1}\mathsf{D}(X)\mathsf{Q}.$$

In particular, if we choose the columns of Q to be the eigenvectors of $\mathsf{D}(X)$ then, as discussed in chapter 8,

$$\mathsf{D}_{\mathsf{Q}}(X) = \begin{pmatrix} \lambda_1 & 0 & \cdots & 0 \\ 0 & \lambda_2 & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \cdots & 0 & \lambda_n \end{pmatrix}$$

where the λ_i are the eigenvalues of $\mathsf{D}(X)$. Therefore, from (29.22), we have that

$$\begin{pmatrix} \lambda_1^m & 0 & \cdots & 0 \\ 0 & \lambda_2^m & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \cdots & 0 & \lambda_n^m \end{pmatrix} = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \cdots & 0 & 1 \end{pmatrix}.$$

Hence all the eigenvalues λ_i are mth roots of unity, and so $\chi(X)$, the trace of $\mathsf{D}(X)$, is the sum of n of these. In view of the implications of Lagrange's theorem (section 28.6 and subsection 28.7.2), the only values of m allowed are the divisors of the order g of the group.

29.8 Construction of a character table

In order to decompose representations into irreps on a routine basis using characters, it is necessary to have available a character table for the group in question. Such a table gives, for each irrep μ of the group, the character $\chi^{(\mu)}(X)$ of the class to which group element X belongs. To construct such a table the following properties of a group, established earlier in this chapter, may be used:

(i) the number of classes equals the number of irreps;
(ii) the 'vector' formed by the characters from a given irrep is orthogonal to the 'vector' formed by the characters from a different irrep;
(iii) $\sum_\mu n_\mu^2 = g$, where n_μ is the dimension of the μth irrep and g is the order of the group;
(iv) the identity irrep (one-dimensional with all characters equal to 1) is present for every group;
(v) $\sum_X \left|\chi^{(\mu)}(X)\right|^2 = g$.
(vi) $\chi^{(\mu)}(X)$ is the sum of n_μ mth roots of unity, where m is the order of X.

►*Construct the character table for the group* 4*mm (or C_{4v}) using the properties of classes, irreps and characters so far established.*

The group 4*mm* is the group of two-dimensional symmetries of a square, namely rotations of 0, $\pi/2$, π and $3\pi/2$ and reflections in the mirror planes parallel to the coordinate axes and along the main diagonals. These are illustrated in figure 29.3. For this group there are eight elements:

- the identity, I;
- rotations by $\pi/2$ and $3\pi/2$, R and R';
- a rotation by π, Q ;
- four mirror reflections m_x, m_y, m_d and $m_{d'}$.

Requirements (i) to (iv) at the start of this section put tight constraints on the possible character sets, as the following argument shows.

The group is non-Abelian (clearly $Rm_x \neq m_xR$), and so there are fewer than eight classes, and hence fewer than eight irreps. But requirement (iii), with $g = 8$, then implies

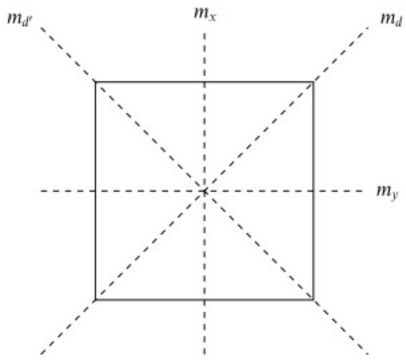

Figure 29.3 The mirror planes associated with $4mm$, the group of two-dimensional symmetries of a square.

that at least one irrep has dimension 2 or greater. However, there can be no irrep with dimension 3 or greater, since $3^2 > 8$, nor can there be more than one two-dimensional irrep, since $2^2 + 2^2 = 8$ would rule out a contribution to the sum in (iii) of 1^2 from the identity irrep, and this must be present. Thus the only possibility is one two-dimensional irrep and, to make the sum in (iii) correct, four one-dimensional irreps.

Therefore using (i) we can now deduce that there are five classes. This same conclusion can be reached by evaluating $X^{-1}YX$ for every pair of elements in $\mathcal{G}$, as in the description of conjugacy classes given in the previous chapter. However, it is tedious to do so and certainly much longer than the above. The five classes are I, Q, $\{R, R'\}$, $\{m_x, m_y\}$, $\{m_d, m_{d'}\}$.

It is straightforward to show that only I and Q commute with every element of the group, so they are the only elements in classes of their own. Each other class must have at least 2 members, but, as there are three classes to accommodate $8 - 2 = 6$ elements, there must be exactly 2 in each class. This does not pair up the remaining 6 elements, but does say that the five classes have 1, 1, 2, 2, and 2 elements. Of course, if we had started by dividing the group into classes, we would know the number of elements in each class directly.

We cannot entirely ignore the group structure (though it sometimes happens that the results are independent of the group structure – for example, all non-Abelian groups of order 8 have the same character table!); thus we need to note in the present case that $m_i^2 = I$ for $i = x,\ y,\ d$ or d' and, as can be proved directly, $Rm_i = m_iR'$ for the same four values of label i. We also recall that for any pair of elements X and Y, $\mathsf{D}(XY) = \mathsf{D}(X)\mathsf{D}(Y)$. We may conclude the following for the one-dimensional irreps.

(a) In view of result (vi), $\chi(m_i) = \mathsf{D}(m_i) = \pm 1$.

(b) Since $R^4 = I$, result (vi) requires that $\chi(R)$ is one of $1,\ i,\ -1,\ -i$. But, since $\mathsf{D}(R)\mathsf{D}(m_i) = \mathsf{D}(m_i)\mathsf{D}(R')$, and the $\mathsf{D}(m_i)$ are just numbers, $\mathsf{D}(R) = \mathsf{D}(R')$. Further

$$\mathsf{D}(R)\mathsf{D}(R) = \mathsf{D}(R)\mathsf{D}(R') = \mathsf{D}(RR') = \mathsf{D}(I) = 1,$$

and so $\mathsf{D}(R) = \pm 1 = \mathsf{D}(R')$.

(c) $\mathsf{D}(Q) = \mathsf{D}(RR) = \mathsf{D}(R)\mathsf{D}(R) = 1$.

If we add this to the fact that the characters of the identity irrep A_1 are all unity then we can fill in those entries in character table 29.4 shown in bold.

Suppose now that the three missing entries in a one-dimensional irrep are p, q and r, where each can only be ± 1. Then, allowing for the numbers in each class, orthogonality

8H & - KKK
+ @ / C - ! (3 -
! , 2

$4mm$	I	Q	R, R'	m_x, m_y	$m_d, m_{d'}$
A_1	**1**	**1**	**1**	**1**	**1**
A_2	**1**	**1**	1	-1	-1
B_1	**1**	**1**	-1	1	-1
B_2	**1**	**1**	-1	-1	1
E	**2**	-2	0	0	0

Table 29.4 The character table deduced for the group $4mm$. For an explanation of the entries in bold see the text.

with the characters of A_1 requires that

$$1(1)(1) + 1(1)(1) + 2(1)(p) + 2(1)(q) + 2(1)(r) = 0.$$

The only possibility is that two of p, q, and r equal -1 and the other equals $+1$. This can be achieved in three different ways, corresponding to the need to find three further different one-dimensional irreps. Thus the first four lines of entries in character table 29.4 can be completed. The final line can be completed by requiring it to be orthogonal to the other four. Property (v) has not been used here though it could have replaced part of the argument given. ◀

29.9 Group nomenclature

The nomenclature of published character tables, as we have said before, is erratic and sometimes unfortunate; for example, often E is used to represent, not only a two-dimensional irrep, but also the identity operation, where we have used I. Thus the symbol E might appear in both the column and row headings of a table, though with quite different meanings in the two cases. In this book we use roman capitals to denote irreps.

One-dimensional irreps are regularly denoted by A and B, B being used if a rotation about the principal axis of $2\pi/n$ has character -1. Here n is the highest integer such that a rotation of $2\pi/n$ is a symmetry operation of the system, and the principal axis is the one about which this occurs. For the group of operations on a square, $n = 4$, the axis is the perpendicular to the square and the rotation in question is R. The names for the group, $4mm$ and C_{4v}, derive from the fact that here n is equal to 4. Similarly, for the operations on an equilateral triangle, $n = 3$ and the group names are $3m$ and C_{3v}, but because the rotation by $2\pi/3$ has character $+1$ in all its one-dimensional irreps (see table 29.1), only A appears in the irrep list.

Two-dimensional irreps are denoted by E, as we have already noted, and three-dimensional irreps by T, although in many cases the symbols are modified by primes and other alphabetic labels to denote variations in behaviour from one irrep to another in respect of mirror reflections and parity inversions. In the study of molecules, alternative names based on molecular angular momentum properties are common. It is beyond the scope of this book to list all these variations, or to give a large selection of character tables; our aim is to demonstrate and justify the use of those found in the literature specifically dedicated to crystal physics or molecular chemistry.

Variations in notation are not restricted to the naming of groups and their irreps, but extend to the symbols used to identify a typical element, and hence all members, of a conjugacy class in a group. In physics these are usually of the types n_z, $\bar{n}_z$ or m_x. The first of these denotes a rotation of $2\pi/n$ about the z-axis, and the second the same thing followed by parity inversion (all vectors $\mathbf{r}$ go to $-\mathbf{r}$), whilst the third indicates a mirror reflection in a plane, in this case the plane $x = 0$.

Typical chemistry symbols for classes are NC_n, NC_n^2, NC_n^x, NS_n, σ_v, σ^{xy}. Here the first symbol N, where it appears, shows that there are N elements in the class (a useful feature). The subscript n has the same meaning as in the physics notation, but σ rather than m is used for a mirror reflection, subscripts v, d or h or superscripts xy, xz or yz denoting the various orientations of the relevant mirror planes. Symmetries involving parity inversions are denoted by S; thus S_n is the chemistry analogue of $\bar{n}$. None of what is said in this and the previous paragraph should be taken as definitive, but merely as a warning of common variations in nomenclature and as an initial guide to corresponding entities. Before using any set of group character tables, the reader should ensure that he or she understands the precise notation being employed.

29.10 Product representations

In quantum mechanical investigations we are often faced with the calculation of what are called matrix elements. These normally take the form of integrals over all space of the product of two or more functions whose analytic forms depend on the microscopic properties (usually angular momentum and its components) of the electrons or nuclei involved. For 'bonding' calculations involving 'overlap integrals' there are usually two functions involved, whilst for transition probabilities a third function, giving the spatial variation of the interaction Hamiltonian, also appears under the integral sign.

If the environment of the microscopic system under investigation has some symmetry properties, then sometimes these can be used to establish, without detailed evaluation, that the multiple integral must have zero value. We now express the essential content of these ideas in group theoretical language.

Suppose we are given an integral of the form

$$J = \int \Psi\phi \, d\tau \quad \text{or} \quad J = \int \Psi\xi\phi \, d\tau$$

to be evaluated over all space in a situation in which the physical system is invariant under a particular group $\mathcal{G}$ of symmetry operations. For the integral to be non-zero the integrand must be invariant under each of these operations. In group theoretical language, *the integrand must transform as the identity, the one-dimensional representation* A_1 *of* $\mathcal{G}$; more accurately, some non-vanishing part of the integrand must do so.

An alternative way of saying this is that if under the symmetry operations of $\mathcal{G}$ the integrand transforms according to a representation D and D does not contain A_1 amongst its irreps then the integral J is necessarily zero. It should be noted that the converse is not true; J may be zero even if A_1 is present, since the integral, whilst showing the required invariance, may still have the value zero.

It is evident that we need to establish how to find the irreps that go to make up a representation of a double or triple product when we already know the irreps according to which the factors in the product transform. The method is established by the following theorem.

Theorem. *For each element of a group the character in a product representation is the product of the corresponding characters in the separate representations.*

Proof. Suppose that $\{u_i\}$ and $\{v_j\}$ are two sets of basis functions, that transform under the operations of a group $\mathcal{G}$ according to representations $\mathsf{D}^{(\lambda)}$ and $\mathsf{D}^{(\mu)}$ respectively. Denote by u and v the corresponding basis vectors and let X be an element of the group. Then the functions generated from u_i and v_j by the action of X are calculated as follows, using (29.1) and (29.4):

$$u_i' = Xu_i = \left[\left(\mathsf{D}^{(\lambda)}(X)\right)^{\mathrm{T}} \mathsf{u}\right]_i = \left[\mathsf{D}^{(\lambda)}(X)\right]_{ii} u_i + \sum_{l\neq i} \left[\left(\mathsf{D}^{(\lambda)}(X)\right)^{\mathrm{T}}\right]_{il} u_l,$$

$$v_j' = Xv_j = \left[\left(\mathsf{D}^{(\mu)}(X)\right)^{\mathrm{T}} \mathsf{v}\right]_j = \left[\mathsf{D}^{(\mu)}(X)\right]_{jj} v_j + \sum_{m\neq j} \left[\left(\mathsf{D}^{(\mu)}(X)\right)^{\mathrm{T}}\right]_{jm} v_m.$$

Here $[\mathsf{D}(X)]_{ij}$ is just a single element of the matrix $\mathsf{D}(X)$ and $[\mathsf{D}(X)]_{kk} = [\mathsf{D}^{\mathrm{T}}(X)]_{kk}$ is simply a diagonal element from the matrix – the repeated subscript does not indicate summation. Now, if we take as basis functions for a product representation $\mathsf{D}^{\mathrm{prod}}(X)$ the products $w_k = u_i v_j$ (where the $n_\lambda n_\mu$ various possible pairs of values i, j are labelled by k), we have also that

$$\begin{aligned} w_k' &= Xw_k = Xu_iv_j = (Xu_i)(Xv_j) \\ &= \left[\mathsf{D}^{(\lambda)}(X)\right]_{ii} \left[\mathsf{D}^{(\mu)}(X)\right]_{jj} u_iv_j + \text{terms not involving the product } u_iv_j. \end{aligned}$$

This is to be compared with

$$w_k' = Xw_k = \left[\left(\mathsf{D}^{\mathrm{prod}}(X)\right)^{\mathrm{T}} \mathsf{w}\right]_k = \left[\mathsf{D}^{\mathrm{prod}}(X)\right]_{kk} w_k + \sum_{n\neq k} \left[\left(\mathsf{D}^{\mathrm{prod}}(X)\right)^{\mathrm{T}}\right]_{kn} w_n,$$

where $\mathsf{D}^{\mathrm{prod}}(X)$ is the product representation matrix for element X of the group. The comparison shows that

$$\left[\mathsf{D}^{\mathrm{prod}}(X)\right]_{kk} = \left[\mathsf{D}^{(\lambda)}(X)\right]_{ii} \left[\mathsf{D}^{(\mu)}(X)\right]_{jj}.$$

It follows that

$$\begin{aligned}
\chi^{\text{prod}}(X) &= \sum_{k=1}^{n_\lambda n_\mu} \left[\mathsf{D}^{\text{prod}}(X)\right]_{kk} \\
&= \sum_{i=1}^{n_\lambda} \sum_{j=1}^{n_\mu} \left[\mathsf{D}^{(\lambda)}(X)\right]_{ii} \left[\mathsf{D}^{(\mu)}(X)\right]_{jj} \\
&= \left\{ \sum_{i=1}^{n_\lambda} \left[\mathsf{D}^{(\lambda)}(X)\right]_{ii} \right\} \left\{ \sum_{j=1}^{n_\mu} \left[\mathsf{D}^{(\mu)}(X)\right]_{jj} \right\} \\
&= \chi^{(\lambda)}(X)\ \chi^{(\mu)}(X). \qquad (29.23)
\end{aligned}$$

This proves the theorem, and a similar argument leads to the corresponding result for integrands in the form of a product of three or more factors.

An immediate corollary is that *an integral whose integrand is the product of two functions transforming according to two different irreps is necessarily zero.* To see this, we use (29.18) to determine whether irrep A_1 appears in the product character set $\chi^{\text{prod}}(X)$:

$$m_{A_1} = \frac{1}{g} \sum_X \left[\chi^{(A_1)}(X)\right]^* \chi^{\text{prod}}(X) = \frac{1}{g} \sum_X \chi^{\text{prod}}(X) = \frac{1}{g} \sum_X \chi^{(\lambda)}(X)\chi^{(\mu)}(X).$$

We have used the fact that $\chi^{(A_1)}(X) = 1$ for all X but now note that, by virtue of (29.14), the expression on the right of this equation is equal to zero unless $\lambda = \mu$.

Any complications due to non-real characters have been ignored – in practice, they are handled automatically as it is usually $\Psi^*\phi$, rather than $\Psi\phi$, that appears in integrands, though many functions are real in any case, and nearly all characters are.

Equation (29.23) is a general result for integrands but, specifically in the context of chemical bonding, it implies that for the possibility of bonding to exist, the two quantum wavefunctions must transform according to the same irrep. This is discussed further in the next section.

29.11 Physical applications of group theory

As we indicated at the start of chapter 28 and discussed in a little more detail at the beginning of the present chapter, some physical systems possess symmetries that allow the results of the present chapter to be used in their analysis. We consider now some of the more common sorts of problem in which these results find ready application.

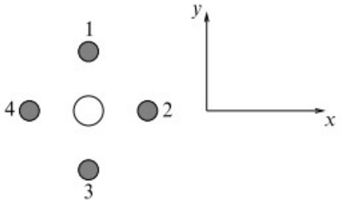

Figure 29.4 A molecule consisting of four atoms of iodine and one of manganese.

29.11.1 Bonding in molecules

We have just seen that whether chemical bonding can take place in a molecule is strongly dependent upon whether the wavefunctions of the two atoms forming a bond transform according to the same irrep. Thus it is sometimes useful to be able to find a wavefunction that does transform according to a particular irrep of a group of transformations. This can be done if the characters of the irrep are known and a sensible starting point can be guessed. We state without proof that starting from any n-dimensional basis vector $\Psi \equiv (\Psi_1 \; \Psi_2 \; \cdots \; \Psi_n)^{\mathrm{T}}$, where $\{\Psi_i\}$ is a set of wavefunctions, the new vector $\Psi^{(\lambda)} \equiv (\Psi_1^{(\lambda)} \; \Psi_2^{(\lambda)} \; \cdots \; \Psi_n^{(\lambda)})^{\mathrm{T}}$ generated by

$$\Psi_i^{(\lambda)} = \sum_X \chi^{(\lambda)^*}(X) X \Psi_i \tag{29.24}$$

will transform according to the λth irrep. If the randomly chosen Ψ happens not to contain any component that transforms in the desired way then the $\Psi^{(\lambda)}$ so generated is found to be a zero vector and it is necessary to select a new starting vector. An illustration of the use of this 'projection operator' is given in the next example.

►*Consider a molecule made up of four iodine atoms lying at the corners of a square in the xy-plane, with a manganese atom at its centre, as shown in figure 29.4. Investigate whether the molecular orbital given by the superposition of p-state (angular momentum* $l = 1$*) atomic orbitals*

$$\Psi_1 = \Psi_y(\mathbf{r} - \mathbf{R}_1) + \Psi_x(\mathbf{r} - \mathbf{R}_2) - \Psi_y(\mathbf{r} - \mathbf{R}_3) - \Psi_x(\mathbf{r} - \mathbf{R}_4)$$

can bond to the d-state atomic orbitals of the manganese atom described by either (i) $\phi_1 = (3z^2 - r^2)f(r)$ *or* (ii) $\phi_2 = (x^2 - y^2)f(r)$, *where* $f(r)$ *is a function of r and so is unchanged by any of the symmetry operations of the molecule. Such linear combinations of atomic orbitals are known as ring orbitals.*

We have eight basis functions, the atomic orbitals $\Psi_x(N)$ and $\Psi_y(N)$, where $N = 1, 2, 3, 4$ and indicates the position of an iodine atom. Since the wavefunctions are those of p-states they have the forms $xf(r)$ or $yf(r)$ and lie in the directions of the x- and y-axes shown in the figure. Since r is not changed by any of the symmetry operations, $f(r)$ can be treated as a constant. The symmetry group of the system is $4mm$, whose character table is table 29.4.

Case (i). The manganese atomic orbital $\phi_1 = (3z^2 - r^2)f(r)$, lying at the centre of the molecule, is not affected by any of the symmetry operations since z and r are unchanged by them. It clearly transforms according to the identity irrep A_1. We therefore need to know which combination of the iodine orbitals $\Psi_x(N)$ and $\Psi_y(N)$, if any, also transforms according to A_1.

We use the projection operator (29.24). If we choose $\Psi_x(1)$ as the arbitrary one-dimensional starting vector, we unfortunately obtain zero (as the reader may wish to verify), but $\Psi_y(1)$ is found to generate a new non-zero one-dimensional vector transforming according to A_1. The results of acting on $\Psi_y(1)$ with the various symmetry elements X can be written down by inspection (see the discussion in section 29.2). So, for example, the $\Psi_y(1)$ orbital centred on iodine atom 1 and aligned along the positive y-axis is changed by the anticlockwise rotation of $\pi/2$ produced by R' into an orbital centred on atom 4 and aligned along the negative x-axis; thus $R'\Psi_y(1) = -\Psi_x(4)$. The complete set of group actions on $\Psi_y(1)$ is:

$$I,\ \Psi_y(1); \quad Q,\ -\Psi_y(3); \quad R,\ \Psi_x(2); \quad R',\ -\Psi_x(4);$$

$$m_x,\ \Psi_y(1); \quad m_y,\ -\Psi_y(3); \quad m_d,\ \Psi_x(2); \quad m_{d'},\ -\Psi_x(4).$$

Now $\chi^{(\mathrm{A}_1)}(X) = 1$ for all X, so (29.24) states that the sum of the above results for $X\Psi_y(1)$, all with weight 1, gives a vector (here, since the irrep is one-dimensional, just a wavefunction) that transforms according to A_1 and is therefore capable of forming a chemical bond with the manganese wavefunction ϕ_1. It is

$$\Psi^{(\mathrm{A}_1)} = 2[\Psi_y(1) - \Psi_y(3) + \Psi_x(2) - \Psi_x(4)],$$

though, of course, the factor 2 is irrelevant. This is precisely the ring orbital Ψ_1 given in the problem, but here it is generated rather than guessed beforehand.

Case (ii). The atomic orbital $\phi_2 = (x^2 - y^2)f(r)$ behaves as follows under the action of typical conjugacy class members:

$$I,\ \phi_2; \quad Q,\ \phi_2; \quad R,\ (y^2 - x^2)f(r) = -\phi_2; \quad m_x,\ \phi_2; \quad m_d,\ -\phi_2.$$

From this we see that ϕ_2 transforms as a one-dimensional irrep, but, from table 29.4, that irrep is B_1 not A_1 (the irrep according to which Ψ_1 transforms, as already shown). Thus ϕ_2 and Ψ_1 cannot form a bond. ◄

The original question did not ask for the the ring orbital to which ϕ_2 may bond, but it can be generated easily by using the values of $X\Psi_y(1)$ calculated in case (i) and now weighting them according to the characters of B_1:

$$\begin{aligned}\Psi^{(\mathrm{B}_1)} &= \Psi_y(1) - \Psi_y(3) + (-1)\Psi_x(2) - (-1)\Psi_x(4) \\ &\quad + \Psi_y(1) - \Psi_y(3) + (-1)\Psi_x(2) - (-1)\Psi_x(4) \\ &= 2[\Psi_y(1) - \Psi_x(2) - \Psi_y(3) + \Psi_x(4)].\end{aligned}$$

Now we will find the other irreps of $4mm$ present in the space spanned by the basis functions $\Psi_x(N)$ and $\Psi_y(N)$; at the same time this will illustrate the important point that since we are working with characters we are only interested in the diagonal elements of the representative matrices. This means (section 29.2) that if we work in the natural representation $\mathsf{D}^{\mathrm{nat}}$ we need consider only those functions that transform, wholly or partially, into themselves. Since we have no need to write out the matrices explicitly, their size (8×8) is no drawback. All the irreps spanned by the basis functions $\Psi_x(N)$ and $\Psi_y(N)$ can be determined by considering the actions of the group elements upon them, as follows.

(i) Under I all eight basis functions are unchanged, and $\chi(I) = 8$.

(ii) The rotations R, R' and Q change the value of N in every case and so all diagonal elements of the natural representation are zero and $\chi(R) = \chi(Q) = 0$.

(iii) m_x takes x into $-x$ and y into y and, for $N = 1$ and 3, leaves N unchanged, with the consequences (remember the forms of $\Psi_x(N)$ and $\Psi_y(N)$) that

$$\begin{aligned} &\Psi_x(1) \rightarrow -\Psi_x(1), \quad \Psi_x(3) \rightarrow -\Psi_x(3), \\ &\Psi_y(1) \rightarrow \Psi_y(1), \qquad \Psi_y(3) \rightarrow \Psi_y(3). \end{aligned}$$

Thus $\chi(m_x)$ has four non-zero contributions, -1, -1, 1 and 1, together with four zero contributions. The total is thus zero.

(iv) m_d and $m_{d'}$ leave no atom unchanged and so $\chi(m_d) = 0$.

The character set of the natural representation is thus 8, 0, 0, 0, 0, which, either by inspection or by applying formula (29.18), shows that

$$\mathsf{D}^{\text{nat}} = \text{A}_1 \oplus \text{A}_2 \oplus \text{B}_1 \oplus \text{B}_2 \oplus 2\text{E},$$

i.e. that all possible irreps are present. We have constructed previously the combinations of $\Psi_x(N)$ and $\Psi_y(N)$ that transform according to A_1 and B_1. The others can be found in the same way.

29.11.2 Matrix elements in quantum mechanics

In section 29.10 we outlined the procedure for determining whether a matrix element that involves the product of three factors as an integrand is necessarily zero. We now illustrate this with a specific worked example.

►*Determine whether a 'dipole' matrix element of the form*

$$J = \int \Psi_{d_1} x \Psi_{d_2}\, d\tau,$$

where Ψ_{d_1} and Ψ_{d_2} are d-state wavefunctions of the forms $xyf(r)$ and $(x^2 - y^2)g(r)$ respectively, can be non-zero (i) *in a molecule with symmetry C_{3v} (or 3m), such as ammonia, and* (ii) *in a molecule with symmetry C_{4v} (or 4mm), such as the MnI$_4$ molecule considered in the previous example.*

We will need to make reference to the character tables of the two groups. The table for C_{3v} is table 29.1 (section 29.6); that for C_{4v} is reproduced as table 29.5 from table 29.4 but with the addition of another column showing how some common functions transform.

We make use of (29.23), extended to the product of three functions. No attention need be paid to $f(r)$ and $g(r)$ as they are unaffected by the group operations.

Case (i). From the character table 29.1 for C_{3v}, we see that each of xy, x and $x^2 - y^2$ forms part of a basis set transforming according to the two-dimensional irrep E. Thus we may fill in the array of characters (using chemical notation for the classes, except that we continue to use I rather than E) as shown in table 29.6. The last line is obtained by

$4mm$	I	Q	R, R'	m_x, m_y	$m_d, m_{d'}$	
A_1	1	1	1	1	1	z; z^2; $x^2 + y^2$
A_2	1	1	1	−1	−1	R_z
B_1	1	1	−1	1	−1	$x^2 - y^2$
B_2	1	1	−1	−1	1	xy
E	2	−2	0	0	0	(x, y); (xz, yz); (R_x, R_y)

Table 29.5 The character table for the irreps of group $4mm$ (or C_{4v}). The right-hand column lists some common functions, or, for the two-dimensional irrep E, pairs of functions, that transform according to the irrep against which they are shown.

Function	Irrep	Classes		
		I	$2C_3$	$3\sigma_v$
xy	E	2	−1	0
x	E	2	−1	0
$x^2 - y^2$	E	2	−1	0
product		8	−1	0

Table 29.6 The character sets, for the group C_{3v} (or $3mm$), of three functions and of their product $x^2y(x^2 - y^2)$.

Function	Irrep	Classes				
		I	C_2	$2C_6$	$2\sigma_v$	$2\sigma_d$
xy	B_2	1	1	−1	−1	1
x	E	2	−2	0	0	0
$x^2 - y^2$	B_1	1	1	−1	1	−1
product		2	−2	0	0	0

Table 29.7 The character sets, for the group C_{4v} (or $4mm$), of three functions, and of their product $x^2y(x^2 - y^2)$.

multiplying together the corresponding characters for each of the three elements. Now, by inspection, or by applying (29.18), i.e.

$$m_{A_1} = \tfrac{1}{6}[1(1)(8) + 2(1)(-1) + 3(1)(0)] = 1,$$

we see that irrep A_1 does appear in the reduced representation of the product, and so J is not necessarily zero.

Case (ii). From table 29.5 we find that, under the group C_{4v}, xy and $x^2 - y^2$ transform as irreps B_2 and B_1 respectively and that x is part of a basis set transforming as E. Thus the calculation table takes the form of table 29.7 (again, chemical notation for the classes has been used).

Here inspection is sufficient, as the product is exactly that of irrep E and irrep A_1 is certainly not present. Thus J is necessarily zero and the dipole matrix element vanishes. ◄

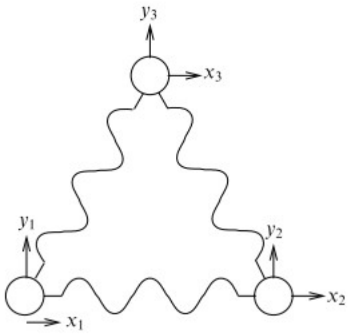

Figure 29.5 An equilateral array of masses and springs.

29.11.3 Degeneracy of normal modes

As our final area for illustrating the usefulness of group theoretical results we consider the normal modes of a vibrating system (see chapter 9). This analysis has far-reaching applications in physics, chemistry and engineering. For a given system, normal modes that are related by some symmetry operation have the same frequency of vibration; the modes are said to be *degenerate*. It can be shown that such modes span a vector space that transforms according to some irrep of the group $\mathcal{G}$ of symmetry operations of the system. Moreover, the degeneracy of the modes equals the dimension of the irrep. As an illustration, we consider the following example.

►*Investigate the possible vibrational modes of the equilateral triangular arrangement of equal masses and springs shown in figure 29.5. Demonstrate that two are degenerate.*

Clearly the symmetry group is that of the symmetry operations on an equilateral triangle, namely $3m$ (or C_{3v}), whose character table is table 29.1. As on a previous occasion, it is most convenient to use the natural representation D^{nat} of this group (it almost always saves having to write out matrices explicitly) acting on the six-dimensional vector space $(x_1, y_1, x_2, y_2, x_3, y_3)$. In this example the natural and regular representations coincide, but this is not usually the case.

We note that in table 29.1 the second class contains the rotations A (by $\pi/3$) and B (by $2\pi/3$), also known as R and R'. This class is known as 3_z in crystallographic notation, or C_3 in chemical notation, as explained in section 29.9. The third class contains C, D, E, the three mirror reflections.

Clearly $\chi(I) = 6$. Since all position labels are changed by a rotation, $\chi(3_z) = 0$. For the mirror reflections the simplest representative class member to choose is the reflection m_y in the plane containing the y_3-axis, since then only label 3 is unchanged; under m_y, $x_3 \to -x_3$ and $y_3 \to y_3$, leading to the conclusion that $\chi(m_y) = 0$. Thus the character set is 6, 0, 0.

Using (29.18) and the character table 29.1 shows that

$$\mathsf{D}^{\text{nat}} = \mathrm{A}_1 \oplus \mathrm{A}_2 \oplus 2\mathrm{E}.$$

However, we have so far allowed x_i, y_i to be completely general, and we must now identify and remove those irreps that do not correspond to vibrations. These will be the irreps corresponding to bodily translations of the triangle and to its rotation without relative motion of the three masses.

Bodily translations are linear motions of the centre of mass, which has coordinates

$$x = (x_1 + x_2 + x_3)/3 \quad \text{and} \quad y = (y_1 + y_2 + y_3)/3).$$

Table 29.1 shows that such a coordinate pair (x, y) transforms according to the two-dimensional irrep E; this accounts for one of the two such irreps found in the natural representation.

It can be shown that, as stated in table 29.1, planar bodily rotations of the triangle – rotations about the z-axis, denoted by R_z – transform as irrep A_2. Thus, when the linear motions of the centre of mass, and pure rotation about it, are removed from our reduced representation, we are left with $E \oplus A_1$. So, E and A_1 must be the irreps corresponding to the internal vibrations of the triangle – one doubly degenerate mode and one non-degenerate mode.

The physical interpretation of this is that two of the normal modes of the system have the same frequency and one normal mode has a different frequency (barring accidental coincidences for other reasons). It may be noted that in quantum mechanics the energy quantum of a normal mode is proportional to its frequency. ◀

In general, group theory does not tell us what the frequencies are, since it is entirely concerned with the symmetry of the system and not with the values of masses and spring constants. However, using this type of reasoning, the results from representation theory can be used to predict the degeneracies of atomic energy levels and, given a perturbation whose Hamiltonian (energy operator) has some degree of symmetry, the extent to which the perturbation will resolve the degeneracy. Some of these ideas are explored a little further in the next section and in the exercises.

29.11.4 Breaking of degeneracies

If a physical system has a high degree of symmetry, invariant under a group $\mathcal{G}$ of reflections and rotations, say, then, as implied above, it will normally be the case that some of its eigenvalues (of energy, frequency, angular momentum etc.) are degenerate. However, if a perturbation that is invariant only under the operations of the elements of a smaller symmetry group (a subgroup of $\mathcal{G}$) is added, some of the original degeneracies may be broken. The results derived from representation theory can be used to decide the extent of the degeneracy-breaking.

The normal procedure is to use an N-dimensional basis vector, consisting of the N degenerate eigenfunctions, to generate an N-dimensional representation of the symmetry group of the perturbation. This representation is then decomposed into irreps. In general, eigenfunctions that transform according to different irreps no longer share the same frequency of vibration. We illustrate this with the following example.

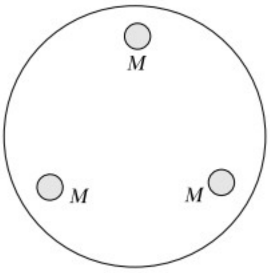

Figure 29.6 A circular drumskin loaded with three symmetrically placed masses.

►*A circular drumskin has three equal masses placed on it at the vertices of an equilateral triangle, as shown in figure 29.6. Determine which degenerate normal modes of the drumskin can be split in frequency by this perturbation.*

When no masses are present the normal modes of the drum-skin are either non-degenerate or two-fold degenerate (see chapter 21). The degenerate eigenfunctions Ψ of the nth normal mode have the forms

$$J_n(kr)(\cos n\theta)e^{\pm i\omega t} \qquad \text{or} \qquad J_n(kr)(\sin n\theta)e^{\pm i\omega t}.$$

Therefore, as explained above, we need to consider the two-dimensional vector space spanned by $\Psi_1 = \sin n\theta$ and $\Psi_2 = \cos n\theta$. This will generate a two-dimensional representation of the group $3m$ (or C_{3v}), the symmetry group of the perturbation. Taking the easiest element from each of the three classes (identity, rotations, and reflections) of group $3m$, we have

$$\begin{aligned}
&I\Psi_1 = \Psi_1, \qquad I\Psi_2 = \Psi_2,\\
&A\Psi_1 = \sin\left[n\left(\theta - \tfrac{2}{3}\pi\right)\right] = \left(\cos\tfrac{2}{3}n\pi\right)\Psi_1 - \left(\sin\tfrac{2}{3}n\pi\right)\Psi_2,\\
&A\Psi_2 = \cos\left[n\left(\theta - \tfrac{2}{3}\pi\right)\right] = \left(\cos\tfrac{2}{3}n\pi\right)\Psi_2 + \left(\sin\tfrac{2}{3}n\pi\right)\Psi_1,\\
&C\Psi_1 = \sin[n(\pi - \theta)] = -(\cos n\pi)\Psi_1,\\
&C\Psi_2 = \cos[n(\pi - \theta)] = (\cos n\pi)\Psi_2.
\end{aligned}$$

The three representative matrices are therefore

$$\mathsf{D}(I) = \mathsf{I}_2, \quad \mathsf{D}(A) = \begin{pmatrix} \cos\frac{2}{3}n\pi & -\sin\frac{2}{3}n\pi \\ \sin\frac{2}{3}n\pi & \cos\frac{2}{3}n\pi \end{pmatrix}, \quad \mathsf{D}(C) = \begin{pmatrix} -\cos n\pi & 0 \\ 0 & \cos n\pi \end{pmatrix}.$$

The characters of this representation are $\chi(I) = 2$, $\chi(A) = 2\cos(2n\pi/3)$ and $\chi(C) = 0$. Using (29.18) and table 29.1, we find that

$$\begin{aligned}
m_{\mathrm{A}_1} &= \tfrac{1}{6}\left(2 + 4\cos\tfrac{2}{3}n\pi\right) = m_{\mathrm{A}_2}\\
m_{\mathrm{E}} &= \tfrac{1}{6}\left(4 - 4\cos\tfrac{2}{3}n\pi\right).
\end{aligned}$$

Thus

$$\mathsf{D} = \begin{cases} \mathrm{A}_1 \oplus \mathrm{A}_2 & \text{if } n = 3,\ 6,\ 9,\ \ldots,\\ \mathrm{E} & \text{otherwise.} \end{cases}$$

Hence the normal modes $n = 3,\ 6,\ 9,\ \ldots$ each transform under the operations of $3m$

as the sum of two one-dimensional irreps and, using the reasoning given in the previous example, are therefore split in frequency by the perturbation. For other values of n the representation is irreducible and so the degeneracy cannot be split. ◄

29.12 Exercises

29.1 A group $\mathcal{G}$ has four elements I, X, Y and Z, which satisfy $X^2 = Y^2 = Z^2 = XYZ = I$. Show that $\mathcal{G}$ is Abelian and hence deduce the form of its character table.

Show that the matrices

$$\mathsf{D}(I) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \qquad \mathsf{D}(X) = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix},$$
$$\mathsf{D}(Y) = \begin{pmatrix} -1 & -p \\ 0 & 1 \end{pmatrix}, \qquad \mathsf{D}(Z) = \begin{pmatrix} 1 & p \\ 0 & -1 \end{pmatrix},$$

where p is a real number, form a representation D of $\mathcal{G}$. Find its characters and decompose it into irreps.

29.2 Using a square whose corners lie at coordinates $(\pm 1, \pm 1)$, form a natural representation of the dihedral group $\mathcal{D}_4$. Find the characters of the representation, and, using the information (and class order) in table 29.4 (p. 1102), express the representation in terms of irreps.

Now form a representation in terms of eight 2×2 orthogonal matrices, by considering the effect of each of the elements of $\mathcal{D}_4$ on a general vector (x, y). Confirm that this representation is one of the irreps found using the natural representation.

29.3 The quaternion group $\mathcal{Q}$ (see exercise 28.20) has eight elements $\{\pm 1, \pm i, \pm j, \pm k\}$ obeying the relations

$$i^2 = j^2 = k^2 = -1, \quad ij = k = -ji.$$

Determine the conjugacy classes of $\mathcal{Q}$ and deduce the dimensions of its irreps. Show that $\mathcal{Q}$ is homomorphic to the four-element group $\mathcal{V}$, which is generated by two distinct elements a and b with $a^2 = b^2 = (ab)^2 = I$. Find the one-dimensional irreps of $\mathcal{V}$ and use these to help determine the full character table for $\mathcal{Q}$.

29.4 Construct the character table for the irreps of the permutation group S_4 as follows.

(a) By considering the possible forms of its cycle notation, determine the number of elements in each conjugacy class of the permutation group S_4, and show that S_4 has five irreps. Give the logical reasoning that shows they must consist of two three-dimensional, one two-dimensional, and two one-dimensional irreps.

(b) By considering the odd and even permutations in the group S_4, establish the characters for one of the one-dimensional irreps.

(c) Form a natural matrix representation of 4×4 matrices based on a set of objects $\{a, b, c, d\}$, which may or may not be equal to each other, and, by selecting one example from each conjugacy class, show that this natural representation has characters 4, 2, 1, 0, 0. In the four-dimensional vector space in which each of the four coordinates takes on one of the four values a, b, c or d, the one-dimensional subspace consisting of the four points with coordinates of the form $\{a, a, a, a\}$ is invariant under the permutation group and hence transforms according to the invariant irrep A_1. The remaining three-dimensional subspace is irreducible; use this and the characters deduced above to establish the characters for one of the three-dimensional irreps, T_1.

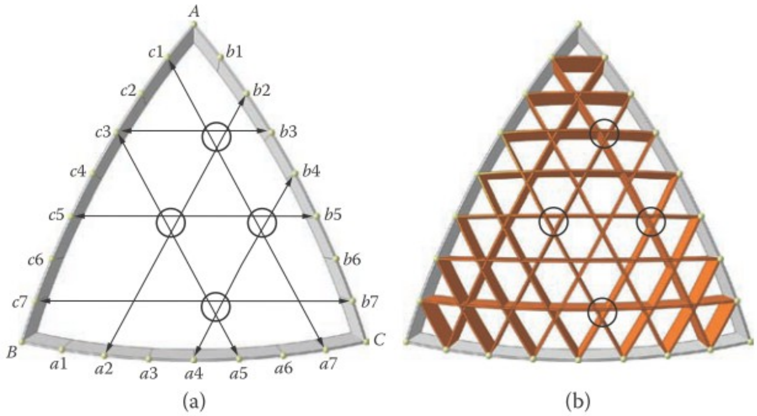
8.5.7 Equal-Arcs (Three Great Circles)

The previous example cast some doubts on the advantages of using equal-arc reference points to define great circle intersections. However, when three intersecting great circles are used to define grid points instead of two, the results are outstanding, yielding the most uniform tessellation gird of the three schemas thus far. Like the previous Equal-arcs (two great circles) schema, this one is not without its surprises, but they are easy to deal with.

In this schema, equal-arc reference points along the PPT's edges are selected so that pairs of them define three great circle arcs approximately parallel to their respective PPT edge. Unlike Equal-chords schemas where great circles reference equal-chord points, those based on equal-arc references do not intersect at a single line. Each pair of great circles intersects at a different line and defines its own pair of antipodal points. With three intersecting great circles, six antipodal points are created and three of them (one from each antipodal pair) fall on the surface of the PPT. Figure 8.17(a) illustrates the result.

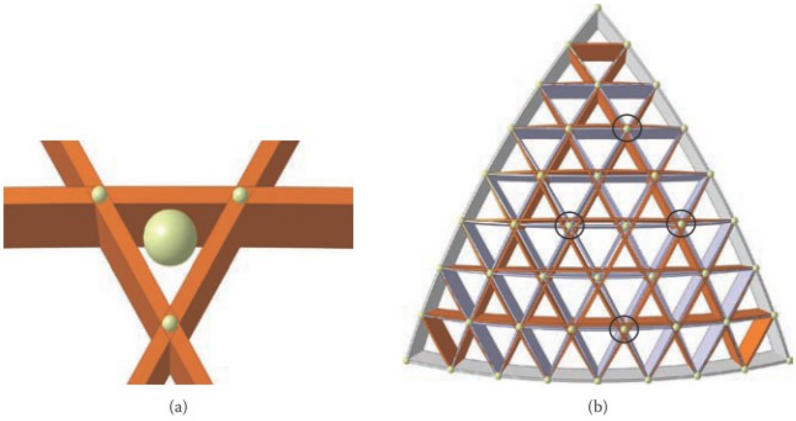
In Figure 8.17(a), examples of four three-way intersections are circled. Taking just one of these examples, the great circle arcs between *c*3-*b*3, *c*1-*a*7 and *b*2-*a*2 intersect at three different places, creating three different points within the PPT. These points are on the surface of the sphere but they form a small window triangle rather than the single tessellation vertex we need. Figure 8.17(b) shows the 21 window triangles that result when the entire PPT is subdivided. Notice that the windows become larger and larger towards the center of the PPT; the smallest ones are the ones nearest the PPT's three apices.

Each window is actually a small triangle whose planar surface is just inside the sphere; only the apices of the window triangle are actually on the surface of the sphere. Figure 8.18(a) shows a detail of the window and its vertices. The red arcs represent the great circle arcs, and the small balls represent their intersection points. What is needed is a single point that summarizes the three window vertices. The triangle's centroid is the most appropriate choice because if the triangle were continuously scaled down while maintaining the proportions of its sides, its geometry would converge at a single point at its centroid. The centroid of a triangle is defined as the intersection of its medians. The average of its three



(a) (b)

Figure 8.17. Equal-arcs (three great circles) schema.



(a) (b)

Figure 8.18. Equal-arcs windows and tessellation vertices.

vertex coordinates produces the same point we call C. To find the window's centroid point:

$$Cx = \frac{(x_1 + x_2 + x_3)}{3},$$
$$Cy = \frac{(y_1 + y_2 + y_3)}{3},$$
$$Cz = \frac{(z_1 + z_2 + z_3)}{3}.$$

We are almost done; only one small detail remains. The window's centroid is on the plane of the triangle, which is inside the sphere. The point must be projected from the origin to the surface of the sphere to create the final tessellation vertex we need. This is a simple matter of normalizing—creating a unit vector length—for the point. Appendix C explains this simple procedure. Figure 8.18(b) shows the tessellation vertices that result when all the centroids of the window triangles are found and projected to the sphere's surface. The original great circle arcs are shown in red, the final grid in blue-green. This figure highlights intersections that were used as examples in previous figures.

Figure 8.19 shows the completed PPT with the surface and panel treatments we have been using. The results are highly uniform, and are the best yet. The final grid resembles Equal-chords to some extent. The largest and smallest triangles are in the same positions as Equal-chords. The mid-PPT face triangle is also equilateral, and just as in Equal-chords, triangle areas increase as you move from the PPT apex to mid-edge, and from mid-edge to midface. The main differences between the Equal-chords and Equal-arcs (three great circles) schema are chord lengths and face angles. We compare the two schemas in the next chapter.

Figure 8.20 shows a complete sphere based on the PPT just created. Notice that its part counts are the same as the other schemas. The subdivision method did not change this fact,

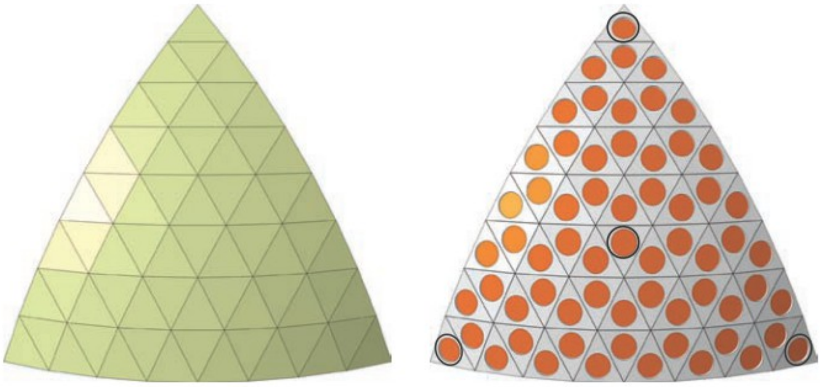


Figure 8.19. Equal-arcs (three great circles) tessellated PPT.

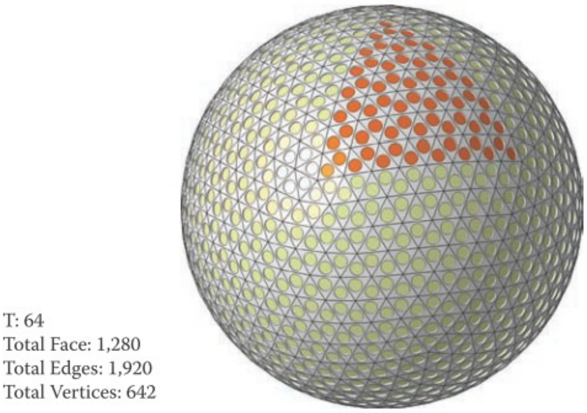

Figure 8.20. Equal-arcs (three great circles) tessellated sphere.

since the schemas all have the same *b*,*c* specification. Certainly, Equal-arcs (three great circles) involves more computation than either of the previous two schemas, but the results are worthwhile. Analysis will show that it has the best distribution of points and the least variation in chord lengths, angles, and face angles of any Class I schema.

8.5.8 Mid-Arcs

The earliest work with Mid-arcs was done by Jeffrey Lindsay in the early 1950s. At that time, the technique was referred to as the alternate method. We call the technique Mid-arcs because it is more descriptive of how the technique works. Deltahedra spherical faces are all equilateral. Mid-arcs takes advantage of this fact and subdivides a PPT by creating one mid-arc reference point on each of its edges. Each pair of mid-arc points defines a great

circle arc across the triangle and these three arcs subdivide the triangle into four smaller ones. There is no need to intersect great circles. We use the same method of defining four new triangles within an existing one until we have subdivided the entire PPT. Each time we subdivide all the triangles in a PPT this way, we double the PPT's frequency. Mid-arcs is very easy to understand and to calculate. It is popular with cartographers and astronomers[15] who have devised ways to reference individual triangles on the sphere by taking advantage of the schema's hierarchical nesting of triangles within triangles.[16] Often, they subdivide a spherical octahedron rather than an icosahedron because the octahedron results in natural great circles that can be aligned with the earth's equator and Greenwich Meridian.

Figure 8.21 shows how Mid-arcs work. The pattern of triangles within triangles is evident. Each successive layer of triangles is based on the mid-arc points of an outer triangle. This recursive nesting of triangles within triangles is the essence of Mid-arcs.[17]

Figure 8.22 applies the schema to the same icosahedral PPT we have been using all along. We number the vertices from top to bottom, left to right so that Figure 8.21 and Figure 8.22 can be compared. As usual, subdivision begins at the PPT edges, where each has a single mid-arc reference point.[18] In Figure 21(a), they are numbered 11, 15, and 41. These points can be found by projecting the mid-chord point between 1 and 37 to the surface of the sphere or finding the middle of the arc between the PPT's apices. Either way, great circle arcs between these points define four new subtriangles (1-11-15, 11-37-41, 11-41-15, and 15-41-45), each of which has mid-arc points (4, 6, 13, 22, 24, 26, 28, 39, and 43); see Figure 8.22(b). These new mid-arc points define 12 more edges and 30 new vertex points when all edges are considered (c). This process repeats itself once again until a total of 42 tessellation vertices and 108 edges are defined. Figure 8.22(d) shows the complete tessellation. Keep in mind that all of these vertices and edges were derived from the apices of

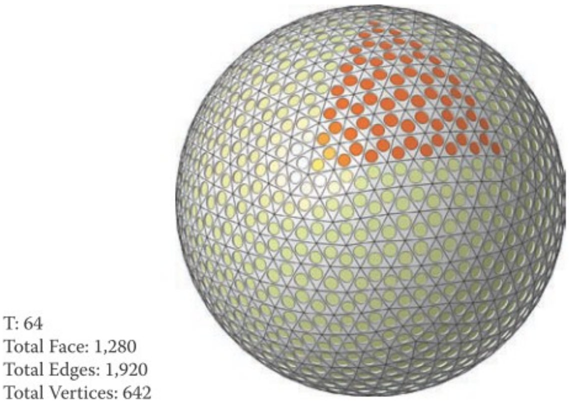

Figure 8.23. Mid-arcs tessellated sphere.

---

[15] (Dutton 1996, 1991) and (Szalay et al. 2005).

[16] (Fekete 1990)

[17] Cartographers sometimes use quaternary subdivision meshing schemas that hierarchically subdivide equilateral triangles similar to Mid-arcs (Dutton 1996). See also Section 3.3.

[18] The edge midpoints of the icosahedron (or of the dodecahedron) are the vertices of the icosidodecahedron (20 triangular faces and 12 pentagonal faces). See Chapter 6 for examples.

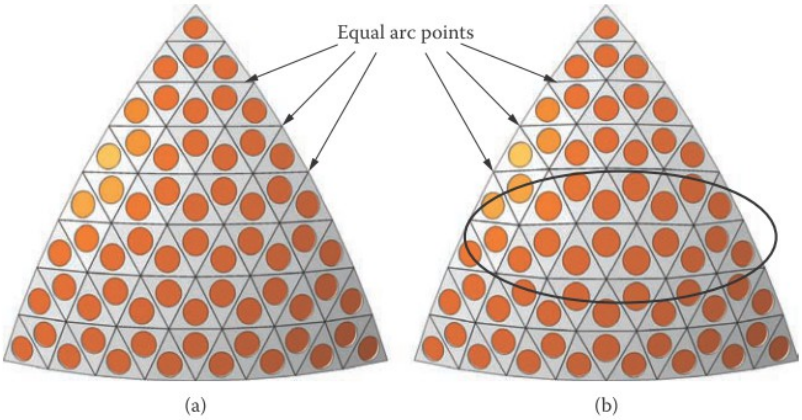

Figure 8.24. Equal-arcs versus Mid-arcs PPT tessellations.

the original PPT and the mid-arc reference point along each edge. Calculations have to be precise; otherwise, errors will accumulate. Our example stops at 8^v, but we could keep on subdividing each triangle indefinitely, doubling the frequency each time.

The Mid-arcs schema is straightforward and easy to calculate. However, there are some limitations. Unlike the other Class I schemas, Mid-arcs can only tessellate frequencies that are powers of 2 (i.e. 2^v, 4^v, 8^v, 16^v, 32^v, etc.). Any even or odd frequency is possible with the other Class I schemas, but only even ones are possible with Mid-arcs. The second drawback concerns the tessellation faces themselves. Despite the fact that we start with an equilateral PPT face and place reference points only in the middle of each of its edges, the vast majority of subdivision triangles created in the final tessellation are not equilateral. Only those faces whose centroids are tangent to the PPT's own centroid are equilateral; all others are slightly isosceles or acute. In this example, only triangles 1-37-45, 11-15-41, 13-24-26, and 18-25-19 are equilateral.

A few numbers illustrate this last point. The icosahedron's PPT edges are each 63.43495º. The first new mid-arc triangle (11-15-41) is also equilateral with 36º edges (its centroid is tangent to the PPT's centroid), but the other three triangles created (1-11-15, 11-27-41, and 15-41-45) are slightly isosceles. Two of their edges are 31.71747º, and the other edge shared with the mid-PPT triangle is 36º. Although other Class I schemas have this same characteristic, Mid-arcs produce more variation in chord length and triangle area than others do. We will see this later in the next chapter. Figure 8.23 shows a full sphere subdivided by the Mid-arcs technique along with its part counts. The PPT we subdivided is highlighted.

Figure 8.24 illustrates another disadvantage of Mid-arcs tessellation (left) by comparing its grid side by side with an Equal-arcs (three great circles) tessellation for the same PPT. Although the PPT edge reference points are the same in both schemas, Mid-arcs faces increase in size more quickly as they approach the center of the PPT, and the chords change length faster as they approach the middle of the PPT. As a result, sequences of chords that cross the PPT are not as smooth in transition as they are with Equal-arcs. An example run of chords showing this difference is circled. Figure 8.25 makes the same comparison, but

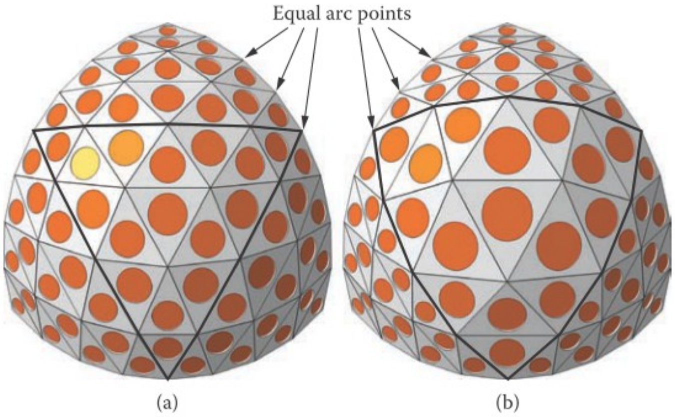

Figure 8.25. Tetrahedral Equal-arcs versus Mid-arcs PPT tessellations.

uses tetrahedral PPTs instead. Tetrahedron PPTs are four times larger than an icosahedron's face (not to scale in the figure), and this makes it easier to see the differences between the two schemas. The first-level subdivision of the PPT is highlighted in each illustration, and the differences are pronounced. Mid-arcs central PPT face is noticeably larger and the faces near the PPT apices are smaller than they are in Equal-arcs tessellations. In Figure 8.25(b) the tetrahedron's central equilateral triangle (highlighted) has three times as much area as the ones at each apex. The tetrahedron's equilateral faces have significantly more spherical excess than the icosahedron's and highlight these differences.

Mid-arcs is the simplest subdivision technique presented thus far. The fact that frequencies are always powers of 2 and the repetitive definition of triangles within triangles offers a natural hierarchy that can be exploited to reference individual triangles on the sphere.[19] Mid-arcs also demonstrates a basic spherical principle—there are no similar triangles on a sphere. You cannot subdivide a spherical equilateral triangle around its mid-edge points and define four other equilaterals as you can in plane geometry.

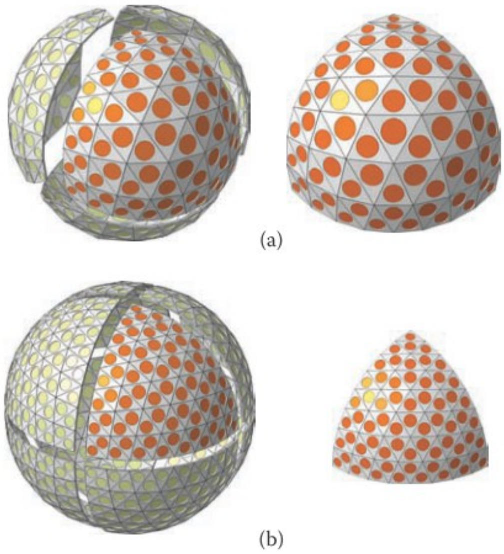
8.5.9 Subdividing Other Deltahedra

We have developed four different Class I schemas in this chapter. Although each example subdivides a spherical icosahedron, the same methodology applies to tetrahedra and octahedra. The only difference is the initial PPT's characteristics (vertex angle, edge arc length, and vertex coordinates) used to start the process. Use the values in Table 8.2 to subdivide the others.

Figure 8.26 shows examples of 8*v* equal-arc schemas for the tetrahedron and octahedron (geodesic notation $\{3,3+\}_{0,8}$ and $\{3,4+\}_{0,8}$, respectively). They are shown in a partially disassembled state and with mixed surface treatments. Both of these polyhedra have larger PPT areas than the icosahedron for the same radius sphere. As a result, their tessellation triangles show much more variation in tessellation triangle area and shape, as the incenter circles clearly show. The tetrahedron shows the greatest variation of the two. These examples clearly demonstrate how important the choice of foundation polyhedra is when the

---

[19] (Fekete 1990)



(a)

(b)

Figure 8.26. Equal-arc (three great circles) tessellations of tetrahedra and octahedra.

goal is to create the most uniform subdivision possible. It is no wonder the icosahedron is the most frequently used polyhedral base.

8.5.10 Summary

Class I schemas were among the first spherical polyhedra subdivision methods developed. They apply to any deltahedra. Except for Mid-arcs, which is limited to frequencies that are powers of 2, any even or odd frequency is possible and, depending on prime factors, may contain subgrids at harmonic frequencies. Class I subdivisions maintain the polyhedron's edge as part of the final tessellation grid, though the edge is segmented. The geodesic notation for Class I is distinctive: either the *b* or *c* coefficient is always 0.

Class I tessellations begin with Equal-chords or Equal-arcs reference points along the PPT's edges. Pairs of points (and the origin) define intersecting great circles that are approximately parallel to the PPT's edges. Grid points result where their line of intersection pierces the sphere's surface:

- *Equal-chords*. Based on equal-chord reference points, great circles parallel to the PPT's edges are intersected and their intersection points define points on the tessellation grid within the PPT's surface. Two intersect at the same line as three.

- *Equal-arcs (two great circles)*. Based on equal-arc reference points, two great circles are intersected. They intersect at a single line and define individual tessellation points on the PPT's surface. This procedure is computationally simple, but the resulting tessellation vertices are not rotationally symmetric and only mirror symmetric around one of the PPT's altitude axis.

- *Analysis, visualization, and data extractions*. Demonstrates what can be done with the completed sphere.

- *Summary*. Recaps the highlights of the design example.

Each of our design examples start with a reference model that is used to define the spherical design's theoretical framework (points, lines, planes, and surfaces). The reference model does not contain any geometric information regarding a real connector, panel, or strut. For example, the reference model might contain a line indicating where the center line of a pipe will be, but in the final design, it does not contain the geometry of the pipe itself. The reference model might also contain planes. They might indicate the limits of a surface or pad in the final design.

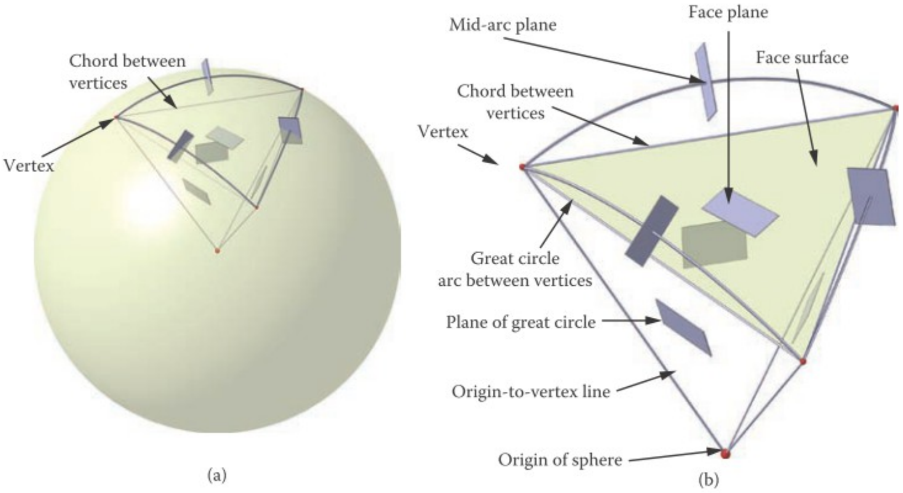
In the next step, the reference model is used to build up the actual spherical design parts, such as struts, connectors, surfaces, or panels. For example, in this step, a pipe of a particular diameter, length, and wall thickness is created using the center line in the reference model. Most of the time, spherical designers develop parts for only a single LCD or PPT. When the final design of this small area is complete, it is instantiated many times. When a part is instantiated, it is not copied. Instead, a reference to the part's original geometry is created and new location information is added, which describes how the original part (the one referred to) is to be transformed (moved, rotated, scaled, etc.) to position it somewhere else. Instancing allows us to cover the entire sphere with a design based on just one LCD or PPT. Each instance of the small part is positioned side by side and aligned properly on the sphere by applying constraints between points and edges of adjacent parts. A group of constrained parts defines an assembly (of LCD or PPT parts). Due to the symmetry in most spherical designs, the assembly itself can be instanced many times and constraints applied to make still larger assemblies. For instance, there are 120 LCDs in a spherical icosahedron. A single spherical design for one LCD could be instanced six times to make a single assembly for one icosahedral PPT. This assembly, in turn, could be instanced 20 more times. Constraints between each instance positions them to cover the entire sphere. This scenario is only one possibility. We will demonstrate some designs where there are several levels of assemblies and subassemblies.

In a sense, what we have just described is using CAD such as a digital brick layer. We design one brick—a very precise and intricate one—and then lay instances of this brick (references to the original brick, plus geometric transformation information describing its new location) side by side to make a wall. Our bricks and wall, however, are spherical triangles, hexagons, and hyperbolic surfaces. Mathematical constraints between assemblies act as mortar. The reference methodology we use here is applicable to any spherical polyhedron, subdivision method, design layout, or frequency. It exploits the high degree of symmetry and repetition found in spherical designs. Our method begins with reference models.

10.4.1 Start with a Few Good Points

Reference models greatly facilitate spherical design. Every example in this chapter uses one. The first three examples reuse the same reference model, while the last two use a different one. A reference model is made with CATIA and it contains only points, lines, surfaces, and planes. There are no physical design elements in the reference model; that is, it does not contain elements such as connectors, panels, or struts.

The reference model is highly precise, and its layout is carefully chosen to include only the minimum number of elements that will define the reference geometry needed



(a) (b)

Figure 10.16. Simple spherical reference model.

to build our parts. Reference models might seem an unnecessary step, but they are well worth the effort. If they are accurate, every spherical design, based on them, will be accurate as well.

Reference models can be reused repeatedly to make a surprising variety of spherical designs. Our first three examples all use the same reference model, but their physical designs could not be more different. Figure 10.16 shows an overall (a) and detailed (b) view of a very simple spherical triangle reference model. None of this reference geometry is visible, but we have used small spheres, cylinders, pads, and coloring to indicate where points, lines, planes, and surfaces are located.

To build this model, we calculated four precise points. Three points lay on the surface of the sphere and define the triangle's vertices. They have the exact angular relationship to one another we want, and they are perfectly tangent to the surface of the sphere. The forth point defines the sphere's origin. The points used in this figure are the vertices of a standard spherical icosahedron face; thus, this model also describes a spherical equilateral triangle.

Using just these four points, CATIA part design and surfacing tools will define everything else. A line tool defines vertex-to-vertex lines (the triangle's edges or chords) and vertex-to-origin reference lines. A plane tool defines planes at the triangle's face and at the three great circles, which make the sides of the spherical triangle. Three more planes are defined normal to both the triangle's mid-chord and mid-arc sides. A circle tool defines great circle arcs on the planes between vertex points.

The reference model is now complete and includes one spherical surface (only shown in Figure 10.16(a)), three points on the spherical surface (which define the icosahedron's face triangle), one origin point, three vertex-to-vertex chord lines, three vertex-to-origin lines, one triangle face plane, one triangular surface, three great circle planes, and three mid-chord/arc normal planes. CATIA defined all of these elements from the initial four input points.

Most of the time, the number of starter points is quite modest, and you can calculate them with a scientific calculator, using the equations provided in previous chapters. In other cases, you may find it easier to use the CAD program itself to calculate the points. We use both techniques in this chapter. Regardless of the input method you use, you may be surprised at how few points are actually needed to build the reference model of a complex spherical design.

The spherical designs in this chapter are based on equal-arc (thee great circles),triacon, and skew subdivisions. A triacon reference model of a single-edge diamond, or even half-diamond, is usually enough to describe a design covering the entire sphere. For equal-arc subdivisions, a single LCD or PPT is used.

Most CAD systems have reflection or mirroring tools. Any geometry can be copied and reflected around a specified plane. Thus, the reference geometry for a left-handed LCD can be reflected to make a right-handed LCD with minimum work. If the design was completely symmetrical around one great circle, the design model for one hemisphere can be reflected to complete the other hemisphere. Reflection is just one of many labor-saving CAD tools.

Some subdivisions result in enantiomorphic shapes. For example, triangular, pentagonal, or hexagonal shapes that do not have equal-length sides often reoccur in other parts of the subdivision as left- or right-handed versions. Copy-reflecting can solve most of these cases. The Ford hex-triangle example, developed later in this chapter, demonstrates enantiomorphic conditions, which are easily solved by mirroring the proper reference model geometry.

10.4.2 Spherical Assembly

The octet truss example introduced constraints and their role in assembling 3D models. In that example, individual octet truss connectors were assembled, along with their rivet fasteners, into a large, nine-way connector.

Spherical assembly makes use of the same techniques, but because the number of parts is so much bigger, even greater productivity gains are possible with careful assembly techniques. A complex and detailed section of the sphere can automatically define every other location on the entire sphere. This is usually accomplished by assembling basic design units into a larger unit and then assembling those units into an even larger assembly.

There are many benefits to using assemblies. Any change to the basic design unit instantly propagates wherever the unit is instanced. This benefit alone makes spherical assembly worth using. There are no restrictions. Automatic drawings can be made, analysis performed, and all the usual visualizations and space analysis can be performed.

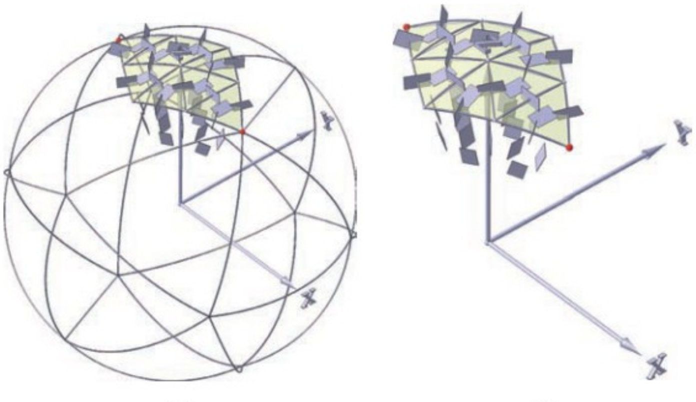
Spherical assemblies result in surprisingly small CAD models. This is because they contain just the geometry of the basic design unit, its reference model (which could be deleted after the design unit is created), and the mathematical constraints, which define how the design units are instanced and constrained in larger assemblies. In other words, the design model is not copied repeatedly; it is instanced. This is a key concept, because without it, CAD geometric models would be huge and keeping them consistent would be a major task. There is only one copy of the basic design part, plus some administrative overhead (mostly constraints and visualization options, such as colors or materials), which apply to each instance. The CAD user will certainly notice when spherical assemblies are used; system response does not degrade much, even as he or she works with increasingly large frequencies and more complex part detail. Any spherist anticipating using CAD would be well advised to understand spherical assemblies and to use them wherever there is a high degree of symmetry in the application.

10.5 Three Class II Triacon Designs

Next we will develop three Class II triacon designs. All of them are based on icosahedral 4^v triacon breakdowns and are easily visualized. We will make one comprehensive reference model and reuse it to make very different spherical designs.

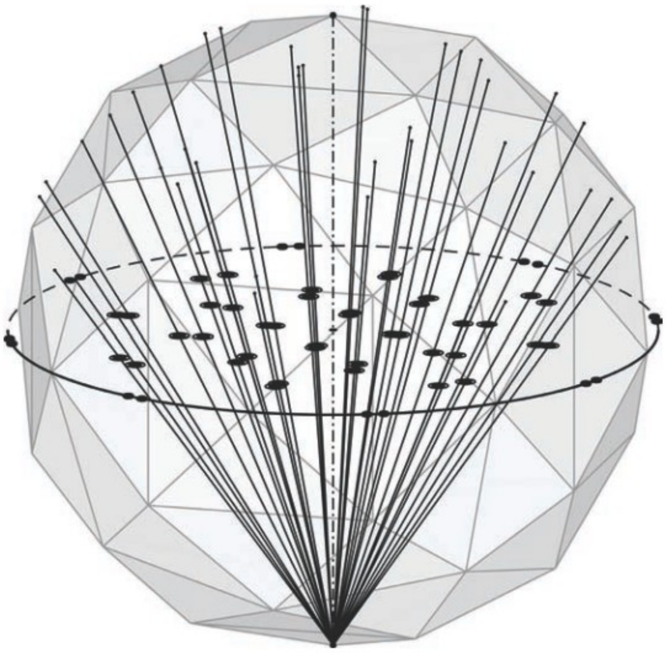
The standard unit of symmetry in triacon breakdowns is the polyhedral edge-symmetric diamond. Two of the diamond's vertices are tangent to adjacent polyhedra vertices. The other two diamond vertices are tangent to the polyhedron's face midpoint (see Section 8.6). Figure 10.17 (a) shows a 4^v triacon edge-zenith diamond in the context of a complete spherical icosahedron reference model. Again, the small planes, arcs, and colored surfaces, shown in the figure, simply serve to make these reference elements visible. Only one diamond reference diamond model is needed because the 29 others around the sphere (one diamond straddles each of the icosahedron's 30 edges) are identical except for their absolute vertex coordinate values. Thus, we can create a single design unit based on this one diamond and then copy it to all the other positions on the sphere. Figure 10.17 (b) is a close-up view of just the edge-zenith triacon reference model. The surface of the sphere is shown in gold, spotlighting the diamond's key elements. The *xyz*-axis is shown again to help associate illustrations (a) and (b).

This model contains the same reference elements as the spherical triangle example, shown in Figure 10.16, except that there are more of them: 9 spherical surface points, 1 origin point, 8 triangular surfaces, 16 vertex-to-vertex edges and arcs, and 16 great circle planes (one of every vertex-to-vertex arc). Small red spheres indicate the two diamond points that are tangent to the icosahedron's vertices. Notice that the triacon diamond is symmetrical around both the *zx*- and *zy*-planes. This means you could start building this reference model with as few as five or six points and use the CAD system to complete the



(a) (b)

Figure 10.17. Icosahedron 4^v triacon reference model.



B

Stereographic Projection

In many spherical designs, it is helpful to visualize points and great and lesser circles in two dimensions or as a flat drawing. As the illustrations in this book demonstrate, there are many ways to project spherical geometry onto a 2D surface. However, there is one projection method in particular that offers both visualization and direct analysis capabilities. *Stereographic projection* is a way to show the 3D relationship of points and arcs on a sphere in a 2D diagram called a stereogram. Geodesic subdivisions distribute many points and arcs on the surface of a sphere, and stereographic projection is the best way to represent them in a 2D way that preserves angular relationships.

Stereograms are like maps or graphs of the points and arcs on a sphere. We use stereographics to visualize how well a particular subdivision schema performs and to make comparisons among schemas. With experience, stereograms are easy to read. They immediately show symmetry, if it exists; they also show whether points are well distributed or if the subdivision faces are oriented uniformly. Often, you can identify the subdivision schema and the base spherical polyhedra being used simply by inspecting the stereogram.

Stereographics were studied by ancient Greek mathematicians and used to solve spherical trigonometry problems. Later, they were used to make astronomical instruments, such as the astrolabe. Today, the technique is used by cartographers, who make maps of the earth or maps from satellite images of moons and planets. Geologists and civil engineers use stereographics to analyze large-scale rock formations, while crystallographers use the technique to study small crystals and their chemical composition.

B.1 Points on a Sphere

Stereographic projections depict points and arcs on the surface of the sphere. Points on the surface of the sphere are positions in 3D space, and we identify each of these points with the vector that points from the center of the sphere to this point. A vector has direction and magnitude. A line established by the point and the origin of the sphere define the direction. The magnitude is the length or distance between the point and the origin. For almost every case example in this book, the magnitude is one unit because we choose to work with a generalized sphere of one radius unit. That unit can be one millimeter or one mile; it does not matter.

In the geodesic applications developed here, points on the sphere can be the vertices of triangular grids or vectors that are normal to each face. Face normals are very useful vectors because their direction passes through the origin and is perpendicular to the face, or more precisely, to the plane of the face. The face normal has a magnitude as well. This magnitude is directly proportional to the distance of the face from the origin. However, we can project (or scale) the normal point and define a new point that *does* lie on the surface of the unit sphere. The new point is called a unit normal and maintains the original direction of the normal; thus, it remains on a line from the origin and remains perpendicular to the plane of the face. The stereographic projection of either geodesic tessellation vertices, or the unit normals of their faces, is the best way of representing the inter-relationship of their directions and orientations on a plane.

B.2 Stereographic Properties

Many techniques exist for projecting shapes on a sphere onto 2D surfaces. Cartographers have invented scores. But unlike other projection methods, stereographic projection is particularly suitable when analyzing and comparing spherical subdivisions.

First, stereographic projections are conformal. That is, the stereogram preserves the angular relationship between points or intersecting arcs on the surface of the sphere. If lines of latitude and longitude, which meet at right angles on a globe, are projected, they will meet at right angles on the stereoprojection. This also means that the angles between points or between crossing arcs can be directly measured on the stereogram. *Conformality* is an important property because it preserves the general shape of projected objects.

Second, circles on the sphere project as circles on the projection plane. If a great circle passes through the center of a projection, it projects as a straight line (a segment of a circle with an infinite radius). Other spherical projections can display angular relationships between poles on the sphere, but the stereographic projection is the only one that projects any circle on the surface of the sphere into a circle on the projection.[1] Geodesics distribute many great circle arcs and spherical caps, lesser circles around points on the sphere, and are often used to analyze how uniformly points are distributed. All of them project as circles on the stereogram.

---

[1] Some circles project as straight lines or circles with an infinite radius.

Projections can be made from either the north or south pole of the sphere, and the projection plane, called the primitive, can be the equator (actually any great circle) or tangent to the sphere at either pole (or any plane passing through the sphere). Each combination changes the appearance of the stereogram, but the information it contains and how it is used remain the same. These choices make stereographic projection flexible, although some combinations are more useful to geodesic work than others. We discuss some of these choices in this section, and we adopt some standard uses that we use to analyze subdivisions.

B.3 A History of Diverse Uses

The stereographic projection has its origins no later than the third century BC. Appollonius of Perga included theorems with direct application to proving circle preservation in his *Conics*, which dates from the late third century BC. Applications of the stereographic projection are certain to have been made by the Greeks no later than about 225 BC in the form of the anaphoric clock, which has a disk with stereographically projected stars rotating behind a grid including a stereographically projected horizon and tropics. Hipparchus certainly used the stereographic projection to make star maps and is incorrectly (in my opinion) credited by Ptolemy as being the originator of the projection method. Ptolemy‘s *Planisphaerium* demonstrates that a solid theoretical foundation for the projection was in place before 150 AD.

The Greeks called the process of representing a sphere on a plane “unfolding the sphere.” The stereographic projection was named by François d’Aguilon (Franciscus Aguilonius) in *Opticorum libri sex* (Antwerp, 1613) from στερεοζ (solid). Hence, stereographic means “drawing solids (on a plane).” It is clear that the Greeks did not prove the conformal properties of the projection, but may have assumed it. It is equally clear that the Greeks did know and use the preservation of circles property. Preservation of angles (conformality) under the stereographic projection was first proved by Thomas Harriot (1560–1621).

Islamic astronomers used the projection and proved its basic properties no later than the ninth century. A notable entirely European contribution was *De plana spera*, an early thirteenth-century work by Jordanus de Nemore that presented the theoretical foundation for the stereographic projection. The stereographic projection was applied to astrolabes, quadrants, and other astronomical instruments in both Islamic countries and in Christian Europe in medieval times. Claudius Ptolemy (ca. 150 AD) wrote extensively on stereographics in his work entitled *Planisphaerium*, and in 1613, François d’Aguilon gave the technique its name, “stereographic.”

B.4 The Astrolabe

Stereoprojection is a natural choice for star charts and reference grids for familiar objects or patterns in the night sky. Stereographics was the fundamental projection in the most important astronomy instrument ever devised: the astrolabe. An astrolabe is used to solve problems related to time and the positions of the sun and stars. The first astrolabes date to before 400 AD, and they remained very popular in Europe and the Islamic world into the seventeenth century. No other instrument enjoyed such a long life. The earliest astrolabes

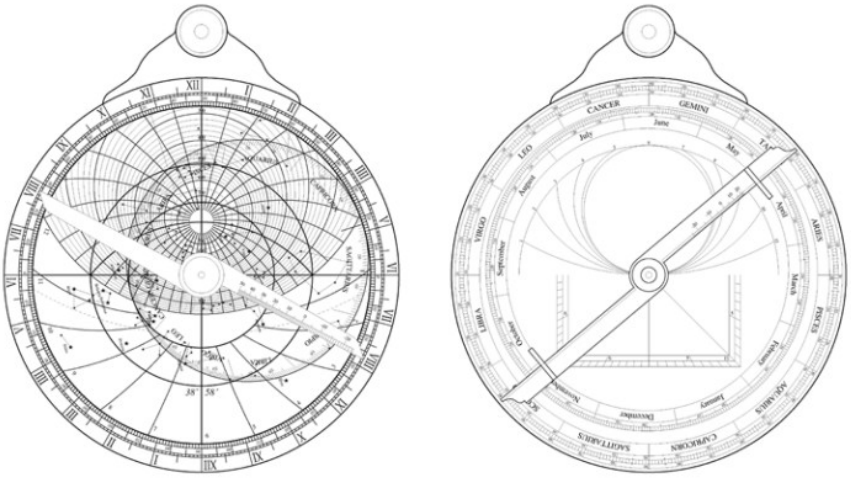


Figure B.1. Astrolabe front and back.

that evolved in Greek antiquity were refined in the Islamic world and were virtually perfected by the tenth century AD. They were introduced into Europe in the eleventh century from Moslem Spain (al-Andalus). Figure B.1 shows the front and back sides of a classic astrolabe.[2]

The earliest known astrolabes, brass disks 6 to 12 inches in diameter, were made in Alexandria. Muslims first encountered the astrolabe in the eighth century in Harran, currently in Turkey near the Syrian border. Even the earliest designs were highly sophisticated instruments. Every part was carefully designed and engraved with scales for specific functions. The main body, the *mater* (Latin for "mother"), was a round plate with a large, hollow circular pocket that accommodated a set of thin, circular disks called *climates*, *plates*, or *tympans* (Latin for "plate"). On the climate disk was engraved a stereoprojection celestial grid of the sky above the observer's local horizon, at the latitude from which the user would make his observations. The center of the climate disk corresponds to the north celestial pole. Well equipped astrolabes would also include a set of climate plates, stored in the mater, each engraved with a sky reference grid for a latitude where the instrument might be used.

Centered over the climate disk is a pierced disk called the *rete* (Latin for "net") which is free to rotate over the climate disk to simulate the daily motion of the stars. It is a frame with openings so the climate disk underneath can be seen. Pointers mark the positions of bright stars. The location of the sun is shown by the projection of the ecliptic as an offset circle on the rete. Scales on the back side of the astrolabe are used to determine the position of the sun on the ecliptic (i.e., the sun's longitude).

Early astronomers believed the earth to be fixed in the heavens and that the stars revolved around it. Although we now know this is not true, the concept is still effectively used today by ocean voyagers who use sextants to navigate. The star's position over the stereographic reference lines indicates where in the sky (azimuth and altitude) the sun or a star can be found.

---

[2] Astrolabe illustrations courtesy of James Morrison.

Many European astrolabes included a rotating rule over the rete. It served many purposes, acting like the hand of a clock, providing an altitude scale, and aiding in the interpretation of the rete's position over the climate. It also was an index to scales engraved on the outer rim, or *limb*, of the astrolabe.

Progressive design refinements and advanced craftsmanship, plus the widespread dissemination of astrolabes in Europe in the fifteenth and sixteenth centuries, led to instrument refinements and contributed to the astrolabe being applied to surveying, orienteering, and timekeeping along with astronomical uses. Many of these additional features required engraved scales to be added to the back of the instrument. The astrolabe's popularity for casting horoscopes guaranteed its continued use even to the present day, and astrolabes were even available in paper and other affordable forms. The astrolabe was truly the most elegant and widely used scientific instrument ever made. Despite its many design variations, the fundamental use of stereoprojection remained constant.

B.5 Crystallography and Geology

New uses for stereographics have been found in the fields of crystallography, civil engineering, and structural geology. Crystallographers study the atomic structure of solids. Before the use of X-ray diffraction techniques, stereographic techniques were used to graph and analyze the geometry of crystals. Stereograms are made of the orientation of a crystal's planes and the angles between them. In order to make the stereogram, crystal is located inside an imaginary sphere. Points on the sphere are located directly above each face (on an axis normal to the face). These points are then stereoprojected from a pole in the hemisphere opposite the point. Figure B.2 shows the basic arrangement. The result is the dot-like pattern on the primitive, the equatorial plane where points are projected. Each dot is the projection of a point on the sphere directly above a crystal's face. The angles between dots indicate the angles between crystal faces. Other dot patterns indicate symmetrical relationships between vertices, edges, and crystal faces.

in 2D and 3D are covered. They are represented using homogeneous vectors, but we will give a Euclidean interpretation for the vectors of every entity. At the end of this section, we will see that the chosen representations are special cases of the Plücker coordinates, a representation of subspaces within a projective space.

2.2.1 Points and Lines in 2D

Given a *2D point* $\boldsymbol{x} = (x, y)^\mathsf{T} \in \mathbb{R}^2$ on the Euclidean plane, one may obtain a homogeneous representation using equation (2.3):

$$\mathbf{x} = \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} \cong \begin{pmatrix} wx \\ wy \\ w \end{pmatrix} \cong \begin{pmatrix} u \\ v \\ w \end{pmatrix}$$

see also figure 2.1(d) on page 21.

A Euclidean representation of a 2D point is straight forward by specifying two coordinates, but the Euclidean representation of a *2D line* can be manifold:

slope-intercept form	$y = m\,x + b$
axis-intercept form	$\frac{x}{a} + \frac{y}{b} = 1$
angle-distance form	$x\,cos(\varphi) + y\,sin(\varphi) = d$
homogeneous form	$a\,x + b\,y + c = 0$
determinant form	$\begin{vmatrix} x_1 & x_2 & x \\ y_1 & y_2 & y \\ 1 & 1 & 1 \end{vmatrix} = 0$
point-angle form	$(x - x_0)\,cos(\varphi) + (y - y_0)\,sin(\varphi) = 0$

Some of these representations do not cover all possible cases (e.g. vertical lines for the slope-intercept form) and some require more parameters than necessary: the determinant form requires two points $\boldsymbol{x}_1$, $\boldsymbol{x}_2$ hence four parameters opposed to the fact that only two parameters are necessary, for example angle and distance.

We will start with the homogeneous form $a\,x+b\,y+c = 0$, then the parameters can be written in a homogeneous vector

$$\mathbf{l} = \begin{pmatrix} a \\ b \\ c \end{pmatrix}$$

If we multiply the homogeneous form with a scalar w and use the homogeneous vector $\mathbf{x} = (wx, wy, w)^\mathsf{T} \cong (u, v, w)^\mathsf{T}$ for a point, we obtain

$$a\,u + b\,v + c\,w = \mathbf{l}^\mathsf{T}\mathbf{x} = \mathbf{x}^\mathsf{T}\mathbf{l} = 0 \qquad (2.12)$$

which is the 2D case for equation (2.10) for hyperplanes.

A *line segment* $\mathbf{s}_l$ is a finite segment of an (infinite) line. It can be represented by a triple $(\mathbf{l}_{fs}, \mathbf{x}_{fs}, l)$, the infinite line $\mathbf{l}_{fs}$, a mid-point $\mathbf{x}_{fs}$ of the line segment and a length l. This is equivalent compared to defining two enclosing points on the line, cf. definition 1 on page 6.

2.2.1.1 Homogeneous and Euclidean Parts From the homogeneous vectors for points it is easy to determine the Euclidean distance from the point to the origin $\boldsymbol{O}$: for a projective point $\mathbf{x} = (u, v, w)^\mathsf{T}$, the Euclidean distance to the origin is given by $d(\mathbf{x}, \boldsymbol{O}) = \sqrt{(u/w)^2 + (v/w)^2} = \sqrt{u^2 + v^2}/|w|$.

The coordinates of the 2D line $\mathbf{l} = (a, b, c)^\mathsf{T}$ may be interpreted by comparing equation (2.12) with the angle-distance form: they are essentially the same up to a multiplication factor $\lambda_l = 1/\sqrt{a^2 + b^2}$:

$$\mathbf{l} = \begin{pmatrix} a \\ b \\ c \end{pmatrix} \cong 1/\sqrt{a^2 + b^2} \begin{pmatrix} a \\ b \\ c \end{pmatrix} = \begin{pmatrix} cos(\varphi) \\ sin(\varphi) \\ -d \end{pmatrix} \tag{2.13}$$

As the scalar d refers to the distance of the line to the origin, we obtain $d(\mathbf{l}, \boldsymbol{O}) = |c|/\sqrt{a^2 + b^2}$. Note that the angle φ is the angle of the normal of the line $\mathbf{l}$.

Motivated by the above observation of computing the distances to the origin and as suggested by BRAND 1966 p. 51ff., we will divide the homogeneous vectors for 2D points and lines into two parts:

- the *Euclidean part* depends upon the position of the Euclidean origin $\boldsymbol{O}$. This part of the homogeneous vector will be indexed with O and is the enumerator of the fractions $d(\mathbf{x}, \boldsymbol{O})$ and $d(\mathbf{l}, \boldsymbol{O})$ as above.
- the *homogeneous part* is independent of the position of the origin $\boldsymbol{O}$. It refers to the denominator of the fractions $d(\mathbf{x}, \boldsymbol{O})$ and $d(\mathbf{l}, \boldsymbol{O})$.

For a 2D point $\mathbf{x}$ and for a 2D line $\mathbf{l}$ the partitioning yields

$$\mathbf{x} = \begin{pmatrix} u \\ v \\ \hline w \end{pmatrix} = \begin{pmatrix} \boldsymbol{x}_O \\ \hline x_h \end{pmatrix} \quad ; \quad \mathbf{l} = \begin{pmatrix} a \\ b \\ \hline c \end{pmatrix} = \begin{pmatrix} \boldsymbol{l}_h \\ \hline l_O \end{pmatrix}$$

2.2.1.2 Normalization to Euclidean Coordinates Dividing the homogeneous vectors by the norm of the homogeneous parts, $\mathbf{x}/|x_h|$ and $\mathbf{l}/|\boldsymbol{l}_h|$, we obtain the Euclidean representation of the 2D entities: the Euclidean coordinates of a 2D point and the angle-distance form of a 2D line. We call this division *Euclidean normalization:* for any homogeneous vector $\mathbf{x}$ representing a geometric entity, the Euclidean normalization $\mathsf{N}_O(\cdot)$ is defined as

$$\mathsf{N}_O(\mathbf{x}) := \mathbf{x}/|\boldsymbol{x}_h| \tag{2.14}$$

where $\boldsymbol{x}_h$ is the homogeneous part of the entity $\mathbf{x}$.

Note that the proposed normalization $\mathsf{N}_O(\cdot)$ is ambiguous with respect to its sign: a Euclidean point $\boldsymbol{x} = (2,3)^\mathsf{T}$ may be represented by $\mathbf{x}_1 = (4,6,2)^\mathsf{T}$ and $\mathrm{x}_2 = (-4,-6,-2)^\mathsf{T}$. This leads to $\mathsf{N}_O(\mathbf{x}_1) = -\mathsf{N}_O(\mathbf{x}_2)$. The same applies to a 2D line with $\varphi = 90°$ and $d = 3$, where two representations $\mathbf{m}_1 = (2,0,6)^\mathsf{T}$ and $\mathbf{m}_2 = (-2,0,-6)^\mathsf{T}$ yield $\mathsf{N}_O(\mathbf{m}_1) = -\mathsf{N}_O(\mathbf{m}_1)$, see figure 2.3.

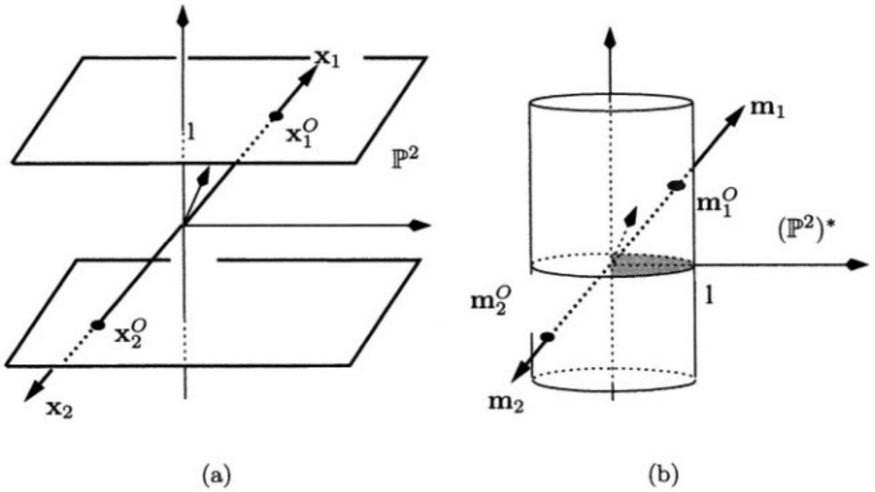

Fig. 2.3. Ambiguous Euclidean normalization of a 2D point $\boldsymbol{x}$ and a 2D line $\boldsymbol{m}$, which can be represented by $\mathbf{x}_1, \mathbf{x}_2$ resp. $\mathbf{m}_1, \mathbf{m}_2$: the normalizations $\mathsf{N}_O(\mathbf{x}_1)$ and $\mathsf{N}_O(\mathbf{x}_2)$ resp. $\mathsf{N}_O(\mathbf{m}_1)$ and $\mathsf{N}_O(\mathbf{m}_2)$ yield different results. We may choose one representation where the homogeneous part is positive oriented, see text for details.

To reach a unique representation, it is possible to demand that the homogeneous part $(\boldsymbol{x}_e)_h$ of any *normalized* homogeneous vector $\mathbf{x}_e = \mathsf{N}_O(\mathbf{x})$ should be *positive oriented:* for points, this means that the homogeneous scale factor x_h is positive, thus for a 2D point $\mathbf{x}$, we skip the norm by $\mathsf{N}_O(\mathbf{x}) = \mathbf{x}/x_h$. For lines, the direction $\boldsymbol{l}_h$ should be on the upper half of the circle S^2, thus $\langle (0,1)^\mathsf{T}, \boldsymbol{l}_h \rangle > 0$, see figure 2.3(b) As for the spherical normalization, the ambiguity may be resolved using oriented projective geometry, STOLFI 1991, but the ambiguity only affects the Euclidean output of the reasoning process: as long as only homogeneous coordinates are used, the sign of the vectors is not important. We will not use Euclidean coordinates directly during the complete reasoning, see chapter 3, thus the ambiguity can be disregarded in our case.

To summarize, we are now able to transfer back and forth between Euclidean and homogeneous representation as in figure 2.2 on page 23. Furthermore, we can easily obtain the distances to the origin:

$$d(\mathbf{x}, \boldsymbol{O}) = \frac{|\boldsymbol{x}_O|}{|x_h|} \quad ; \quad d(\mathbf{l}, \boldsymbol{O}) = \frac{|l_O|}{|\boldsymbol{l}_h|} \tag{2.15}$$

In the next sections, we will define Euclidean and homogeneous parts for 3D entities, too, and we will see that there both parts of the vector play the same role as in the 2D case.

2.2.1.3 Infinite Points and Line As stated earlier, projective geometry allows us to represent entities at infinity. This means that the distance from the origin is not defined in the Euclidean interpretation, thus the formulas in equation (2.15) are not valid anymore. This can only happen when the norm of the enumerator, i.e. the norm of the homogeneous part is zero.

Property 1 *If a homogeneous vector is non-zero, then it represents an entity at infinity if and only if the norm of the homogeneous part is zero.*

Infinite points are of the form $\mathbf{x}_\infty = (u, v, 0)^\mathsf{T}$. Since $\mathbf{x}_\infty$ is a homogeneous vector, this is a one-parameter family of vectors; the parameter is the direction of the infinite point: taking the angle-distance form from equation (2.13), an infinite point $\mathbf{x}_\infty$ lies on a 2D line $\mathbf{l} = \lambda(cos(\varphi), sin(\varphi), -d)$ if and only if the direction angle φ is perpendicular to the directional vector $(u, v)^\mathsf{T}$.
The (unique) 2D line at infinity is of the form $\mathbf{l}_\infty = (0, 0, c)^\mathsf{T}$, and it is obvious that all 2D points $\mathbf{x}_\infty$ at infinity are on the line at infinity.

Table 2.1. Interpretation of the canonical basis $\mathbf{e}_i$ as 2D points and 2D lines.

homogeneous vector	2D point interpretation	2D line interpretation
$\mathbf{e}_1 = (1,0,0)^\mathsf{T}$	infinite point in x-direction	y-axis
$\mathbf{e}_2 = (0,1,0)^\mathsf{T}$	infinite point in y-direction	x-axis
$\mathbf{e}_3 = (0,0,1)^\mathsf{T}$	origin	line at infinity

Canonical Examples As examples for points and lines, we look at the canonical basis vectors $\mathbf{e}_i = (0, \ldots, \underset{i}{1}, \ldots, 0)$ and interpret them as 2D points or lines, see table 2.1. This will be useful when analyzing homogeneous transformations, section 2.3 on page 34 and construction of new entities, section 3.1.1 on page 49.

2.2.2 Points and Planes in 3D

Points in 3D are represented analogously to points in 2D: given a *3D point* $\boldsymbol{X} = (X, Y, Z)^\mathsf{T} \in \mathbb{R}^3$, the homogeneous representation is according to equation (2.3):

$$\mathbf{X} = \begin{pmatrix} X \\ Y \\ Z \\ 1 \end{pmatrix} \cong \begin{pmatrix} TX \\ TY \\ TZ \\ T \end{pmatrix} \cong \begin{pmatrix} U \\ V \\ W \\ T \end{pmatrix}$$

A *plane* in 3D can be represented in several ways, similar to 2D line representations, see table 2.2.1 on page 25. Since 3D planes are hyperplanes for $\mathbb{P}^3$ as 2D lines are hyperplanes for $\mathbb{P}^2$, a plane is represented as a homogeneous vector $\mathbf{A} = (A, B, C, D)^\mathsf{T}$, resembling the homogeneous form $AX + BY + CZ + D = 0$ with a Euclidean point $X = (X,Y,Z)$. Again the homogeneous form can be rewritten with a homogeneous point vector **X:**

$$AU + BV + CW + D = \mathbf{A}^\mathsf{T}\mathbf{X} = \mathbf{X}^\mathsf{T}\mathbf{A}$$

Since we deal with polyhedral objects, a *plane segment* or a *planar patch* can be defined by its polygonal outline: a planar patch $\mathbf{P} = (\mathbf{A}_P, \mathbf{l}_{P1}, \ldots, \mathbf{l}_{Pn})$ is a planar region enclosed by n 2D lines $\mathbf{l}_{Pi}, i = 0 \ldots n$ which lie on the plane $\mathbf{A}_P$, cf. definition 1 on page 6.

2.2.2.1 Homogeneous and Euclidean Parts We can transfer the definition from section 2.2.1 and define the homogeneous and Euclidean parts of a point **X** and a plane **A**

$$\mathbf{X} = \begin{pmatrix} U \\ V \\ W \\ \hline T \end{pmatrix} = \begin{pmatrix} \boldsymbol{X}_O \\ \hline X_h \end{pmatrix} \quad ; \quad \mathbf{A} = \begin{pmatrix} A \\ B \\ C \\ \hline D \end{pmatrix} = \begin{pmatrix} \boldsymbol{A}_h \\ \hline A_O \end{pmatrix}$$

The Euclidean normalization of **X** is then $\mathsf{N}_O(\mathbf{X}) = \mathbf{X}/X_h$ and $\mathsf{N}_O(\mathbf{A}) = \mathbf{A}/|\boldsymbol{A}_h|$. Similar to the 2D case, the ambiguity in the sign of $\mathbf{A}_e = \mathsf{N}_O(\mathbf{A})$ is resolved by testing whether the normalized direction $(\boldsymbol{A}_e)_h$ is on the upper half of the sphere S^3, thus $\langle (0,0,1)^\mathsf{T}, (\boldsymbol{A}_e)_h \rangle > 0$. The Euclidean distance $d(\cdot, \boldsymbol{O})$ to the origin is

$$d(\mathbf{X}, \boldsymbol{O}) = \frac{|\boldsymbol{X}_O|}{|X_h|} = |\mathsf{N}_O(\mathbf{X})| \quad ; \quad d(\mathbf{A}, \boldsymbol{O}) = \frac{|A_O|}{|\boldsymbol{A}_h|} = |\mathsf{N}_O(\mathbf{A})| \qquad (2.16)$$

2.2.2.2 Ideal Points and Plane and Canonical Examples With property 1 on page 28 it is clear that the infinite point $\mathbf{X}_\infty = (U, V, W, 0)^\mathsf{T}$ lies on the infinite plane $\mathbf{A}_\infty = (0, 0, 0, 1)$. The direction of an infinite point $\mathbf{X}_\infty$ is determined by Euclidean part $(\boldsymbol{X}_\infty)_O$.

The interpretation for the canonical vectors $\mathbf{E}_i, i = 1, \ldots, 4$ are listed in table 2.2, it is a direct generalization of table 2.1 on the preceding page.

Table 2.2. Interpretation of the canonical basis $\mathbf{E}_i$ as 3D points and 3D planes.

homogeneous vector	3D point interpretation	3D line interpretation
$\mathbf{E}_1 = (1,0,0,0)^\mathsf{T}$	infinite point in x-direction	yz-plane
$\mathbf{E}_2 = (0,1,0,0)^\mathsf{T}$	infinite point in y-direction	xz-plane
$\mathbf{E}_3 = (0,0,1,0)^\mathsf{T}$	infinite point in z-direction	xy-plane
$\mathbf{E}_4 = (0,0,0,1)^\mathsf{T}$	origin	plane at infinity

2.2.3 Lines in 3D

A *3D line* is different from the previous entities since it is neither a point nor a hyperplane. It is rather a one-dimensional subspace in 3D which can be represented by two (Euclidean) points $\boldsymbol{X}_0$ and $\boldsymbol{Y}_0$, cf. figure 2.4(a). One needs four parameters to represent a line in 3D, as shown in figure 2.4(b): assume two planes have been chosen in advance such as the coordinate planes on the *XY* respectively *XZ* axes. Then the two intersection points of the 3D line and the planes can be described by two parameters each.

There exists a number of other representations for 3D lines, but in the following we will derive a homogeneous vector representation based on two given points, see figure 2.4(a): a 3D line refers to a homogeneous 6-vector

$$\mathbf{L}(\boldsymbol{X}_0, \boldsymbol{Y}_0) = \begin{pmatrix} \boldsymbol{Y}_0 - \boldsymbol{X}_0 \\ \boldsymbol{X}_0 \times \boldsymbol{Y}_0 \end{pmatrix} = \begin{pmatrix} \boldsymbol{L}_h \\ \boldsymbol{L}_O \end{pmatrix}$$

which consists of two parts:

- the first part $\boldsymbol{L}_h$ contains the direction $\boldsymbol{L}_h = \boldsymbol{Y}_0 - \boldsymbol{X}_0$ of the line $\mathbf{L}$ and has 2 degrees of freedom. Note that this part is the *homogeneous part* of the 3D line vector as it is independent from the origin,
- the two points $\boldsymbol{X}_0, \boldsymbol{Y}_0$ and the origin $\boldsymbol{O}$ define a plane, whose normal is given by the cross-product $\boldsymbol{L}_O = \boldsymbol{X}_0 \times \boldsymbol{Y}_0$. With the direction of $\boldsymbol{L}_O$ we have fixed the line $\mathbf{L}(\boldsymbol{X}_0, \boldsymbol{Y}_0)$ in a specific plane. Fixing the plane adds only one additional independent parameter to the existing two of the first part $\boldsymbol{L}_h$, since $\boldsymbol{L}_O$ and $\boldsymbol{L}_h$ are constrained to be perpendicular to each other,

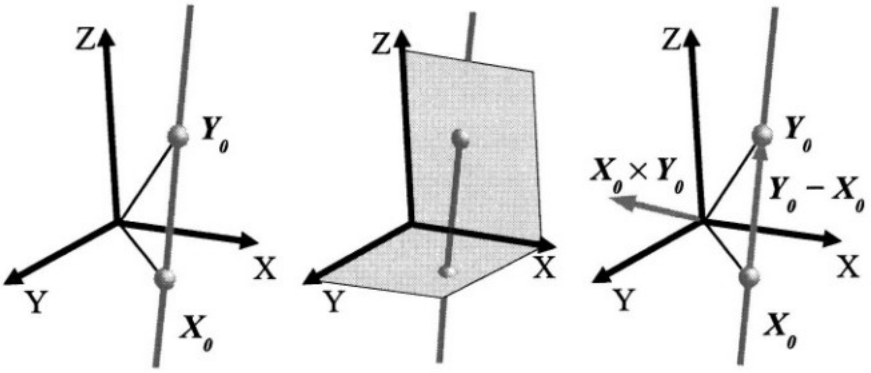
  $$\boldsymbol{L}_O^\mathsf{T} \boldsymbol{L}_h = 0 \qquad (2.17)$$

  This constraint is called the *Plücker constraint* of a 3D line, see below for more details.

  In order to uniquely fix the 3D line we need the minimal distance $d(\mathbf{L}, \boldsymbol{O})$ of the line to the origin as the fourth parameter of the 3D-line. $d(\mathbf{L}, \boldsymbol{O})$ is equivalent to the altitude h of the triangle $(\boldsymbol{O}, \boldsymbol{X}_0, \boldsymbol{Y}_0)$. Because the norm $|\boldsymbol{L}_O|$ of the cross-product $\boldsymbol{X}_0 \times \boldsymbol{Y}_0$ yields twice the area of the triangle and $|\boldsymbol{L}_h|$ is the length of the base of the triangle, we can write

$$d(\mathbf{L}, \boldsymbol{O}) = \frac{|\boldsymbol{L}_O|}{|\boldsymbol{L}_h|} \tag{2.18}$$

Thus the distance as the fourth parameter the 3D line is implicitly given by $\boldsymbol{L}_O$. The 3-vector $\boldsymbol{L}_O = \boldsymbol{X}_0 \times \boldsymbol{Y}_0$ completely depends on the distance of the origin and thus $\boldsymbol{L}_O$ is the *Euclidean part* of the 6-vector $\mathbf{L} = (\boldsymbol{L}_h, \boldsymbol{L}_O)^\mathsf{T}$. The Euclidean part vanishes, i.e. $\boldsymbol{L}_O = \mathbf{0}$, if and only if the line intersects the origin.



(a) (b) (c)

Fig. 2.4. A 3D line may be determined by two points which intersect with two planes of the coordinate system; the two points have 2 degrees of freedom since they are fixed to planes (left). Two Euclidean points $\boldsymbol{X}_0$ and $\boldsymbol{Y}_0$ define a 3D line (middle). In this work we choose two 3-vectors for the representation of $\mathbf{L}$: the direction of the line $\boldsymbol{L}_h = \boldsymbol{X}_0 - \boldsymbol{Y}_0$ and the 3-vector $\boldsymbol{L}_O = \boldsymbol{X}_0 \times \boldsymbol{Y}_0$. We assume $\boldsymbol{L}_O$ to have the length equal to the distance of the 3D line $\mathbf{L}$ to the origin (right).

To summarize the above analysis, a *3D line* is represented by a homogeneous 6-vector $\mathbf{L} = (L_1, L_2, L_3, L_4, L_5, L_6)^\mathsf{T}$, where the homogeneous part $\boldsymbol{L}_h = (L_1, L_2, L_3)^\mathsf{T}$ is constrained to be orthogonal to the Euclidean part $\boldsymbol{L}_O = (L_4, L_5, L_6)^\mathsf{T}$, i.e. $\boldsymbol{L}_h^\mathsf{T} \boldsymbol{L}_O = 0$. Thus the 6-vector $\mathbf{L}$ has 4 degrees of freedom, considering both the orthogonality and homogeneous constraint. As in 2D, a line segment $\mathbf{S}_L$ is a finite fragment of $\mathbf{L}$ and is represented by a triple $(\mathbf{L}, \mathbf{X}_{fs}, L)$, where $\mathbf{X}_{fs}$ is the mid-point of the line segment and L is the length of the segment.

The Euclidean normalization of a 3D line $\mathsf{N}_O(\mathbf{L}) = \mathbf{L}/|\boldsymbol{L}_h|$ uses the formula already known from points and hyperplanes. The ambiguity in the sign of the homogeneous part $(\boldsymbol{L}_e)_h$ of $\mathbf{L}_e = \mathsf{N}_O(\mathbf{L})$ is resolved by deciding whether the normalized direction $(\boldsymbol{L}_e)_h$ is on the upper half of the sphere S^3: $\langle (0,0,1)^\mathsf{T}, (L_e)_h \rangle > 0$.

Some Examples Again, we look at some canonical examples. A line $\mathbf{L} = (\boldsymbol{L}_h, \boldsymbol{L}_O)^\mathsf{T}$ lies at infinity if the homogeneous part vanishes, $\boldsymbol{L}_h = \mathbf{0}$. Thus a line at infinity is defined by the normal direction $\boldsymbol{L}_O$ and has 2 degrees of freedom. Note that a line at infinity can only be computed using equation(2.19).

Taking the canonical 6-vectors $\mathbf{E}_i$, we obtain the coordinate axis and three distinct lines at infinity, namely the lines lying on the canonical planes of the coordinate system, cf. table 2.3.

Table 2.3. Interpretation of the canonical basis $\mathbf{E}_i$ as 3D lines.

homogeneous 6-vector	3D line interpretation
$\mathbf{E}_1 = (1,0,0,0,0,0)^\mathsf{T}$	x-axis
$\mathbf{E}_2 = (0,1,0,0,0,0)^\mathsf{T}$	y-axis
$\mathbf{E}_3 = (0,0,1,0,0,0)^\mathsf{T}$	z-axis
$\mathbf{E}_4 = (0,0,0,1,0,0)^\mathsf{T}$	line at infinity on yz-plane
$\mathbf{E}_6 = (0,0,0,0,0,1)^\mathsf{T}$	line at infinity on xy-plane
$\mathbf{E}_5 = (0,0,0,0,1,0)^\mathsf{T}$	line at infinity on xz-plane

We summarize the representations of points, lines and planes in 2D and 3D in table 2.4

Table 2.4. Homogeneous representation of points, lines and planes in 2D and 3D. A line in 3D is represented with Plücker coordinates, for which the Plücker constraint $\boldsymbol{L}^\mathsf{T}\boldsymbol{L}_O = 0$ holds.

	2D	3D
point	$\mathbf{x}^\mathsf{T} = (u, v; w) = (\boldsymbol{x}_O^\mathsf{T}, x_h)$	$\mathbf{X}^\mathsf{T} = (U, V, W; T) = (\boldsymbol{X}_O^\mathsf{T}, X_h)$
line	$\mathbf{l}^\mathsf{T} = (a, b; c) = (\boldsymbol{l}_h^\mathsf{T}, l_O)$	$\mathbf{L}^\mathsf{T} = (L_1, L_2, L_3; L_4, L_5, L_6) = (\boldsymbol{L}_h^\mathsf{T}, \boldsymbol{L}_O^\mathsf{T})$
plane	-	$\mathbf{A}^\mathsf{T} = (A, B, C; D) = (\boldsymbol{A}_h^\mathsf{T}, A_O)$

2.2.4 Plücker Coordinates

The previous representation of the 3D line is compatible with the representation using the so-called Plücker coordinates. The geometrician Julius Plücker[2] introduced a representation of k-dimensional subspaces within an

---

[2] Julius Plücker, born 1801 in Elberfeld, Germany, died 22 May 1868 in Bonn, Germany. Professor of mathematics at Halle in 1834, at Bonn since 1836.

n-**dimensional** projective space based on $\binom{n+1}{k+1}$ minors of a $(n+1) \times (k+1)$ matrix with given coordinates, cf. FAUGERAS AND LUONG 2001.

An example for Plücker coordinates was already introduced in section 2.1.2, where three points $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ form a 2-dimensional subspace, a hyperplane. From the 4×3 matrix $\mathsf{M}_A = (\mathbf{X}\,\mathbf{Y}\,\mathbf{Z})$ one obtains 4 minors or 4 Plücker coordinates.

Assume now a 3D line $\mathbf{L}$ which was formed by two points $\mathbf{X}$, $\mathbf{Y}$. It is a one-dimensional subspace with $\mathbb{P}^3$ and there are $\binom{n+1}{k+1} = 6$ coordinates, which are derived from 2×2 minors l_{ij} of a 4×2 matrix $\mathsf{M}_L = (\mathbf{X}, \mathbf{Y})$. This matrix consists of two homogeneous vectors of 3D points $\mathbf{X}, \mathbf{Y}$ - we can also use 3D planes, as we will see in section 2.5 on page 40. For M_L we obtain

$$\mathsf{M}_L = \begin{pmatrix} X_1 & Y_1 \\ X_2 & Y_2 \\ X_3 & Y_3 \\ X_4 & Y_4 \end{pmatrix} ; \quad \begin{matrix} l_{12} = \begin{vmatrix} X_1 & Y_1 \\ X_2 & Y_2 \end{vmatrix} & l_{23} = \begin{vmatrix} X_2 & Y_2 \\ X_3 & Y_3 \end{vmatrix} & l_{34} = \begin{vmatrix} X_3 & Y_3 \\ X_4 & Y_4 \end{vmatrix} \\ l_{14} = \begin{vmatrix} X_1 & Y_1 \\ X_4 & Y_4 \end{vmatrix} & l_{24} = \begin{vmatrix} X_2 & Y_2 \\ X_4 & Y_4 \end{vmatrix} & l_{13} = \begin{vmatrix} X_1 & Y_1 \\ X_3 & Y_3 \end{vmatrix} \end{matrix} \tag{2.19}$$

If we assume the homogeneous part of $\mathbf{X}, \mathbf{Y}$ to be fixed as $X_4 = Y_4 = 1$, it is easy to see that the Plücker coordinates l_{ij} directly relate to our 6-vector $\mathbf{L} = (\boldsymbol{L}_h, \boldsymbol{L}_O)^\mathsf{T}$: $\boldsymbol{L}_h = -(l_{14}, l_{24}, l_{34})^\mathsf{T} = (l_{41}, l_{42}, l_{43})^\mathsf{T}$ and $\boldsymbol{L}_O = (l_{23}, -l_{13}, l_{12})^\mathsf{T} = (l_{23}, l_{31}, l_{12})^\mathsf{T}$. Scaling $\mathbf{X}, \mathbf{Y}$ with homogeneous factor λ resp. μ scales the Plücker coordinates by $\lambda \cdot \mu$.

Note that the Plücker coordinates l_{ij} have been expressed according to a particular order of the index pair i, j. We are free though to choose other index pairs, that means any other combination of 2×2 minors. For our choice of $\mathbf{L} = (\boldsymbol{L}_h, \boldsymbol{L}_O)$ we have $(i, j) \in \{(4,1), (4,2), (4,3), (2,3), (3,1), (1,2)\}$. This has only the effect on the ordering and the signs of the Plücker coordinates within a vector, but makes it possible to distinguish clearly between a homogeneous and a Euclidean part. Note that other authors choose different Plücker coordinates for lines, cf. HARTLEY AND ZISSERMAN 2000, STOLFI 1991.

Plücker Constraint In general, the Plücker coordinates are not independent from each other, in fact there is a set of quadratic relations between them. For the cases in 2D and 3D space, a quadratic relation of Plücker coordinates only occurs for line in 3D, we obtain only one condition:

$$l_{41}l_{23} + l_{42}l_{31} + l_{43}l_{12} = 0 \tag{2.20}$$

All 6-vectors $\mathbf{L} = (l_{41}, l_{42}, l_{43}, l_{23}, l_{31}, l_{12})$ satisfying equation (2.20) correspond to valid 3D lines. As mentioned above the Plücker constraint (or Plücker condition) is obviously satisfied with the proposed construction as $\boldsymbol{L}_h^\mathsf{T} \boldsymbol{L}_O = 0$. Note that the constraint (2.20) defines a manifold in $\mathbb{R}^6$, containing all valid 3D-lines. If the vector $\mathbf{L}$ is known to be spherically normalized, the constraint defines a manifold on the sphere S^5.

Thus the vector notation for lines appears to have a disadvantage compared to the vector representation for points and planes: in addition to the homogeneous factor it has another degree of freedom which is constraint by the Plücker condition. This situation can be compared to the fundamental matrix, see section 2.3.3 on page 36, which is a homogeneous 3 × 3 matrix with 7 degrees of freedom. In chapter 3 and 4 we will see that it is easy to cope with the over-parameterization in the context of geometric reasoning.

2.3 Basic Geometric Transformations

After introducing the basic geometric entities, we now review possible geometric transformations on them. One property of these transformations is that they at least preserve straight lines and incidence relations. An in-depth treatment of such geometric transformations on projective entities can be found in HARTLEY AND ZISSERMAN 2000.

Transformations may be applied to points, lines or planes, though usually one refers to point transformations. Reformulating point transformations to transformations of 2D lines and 3D planes is mentioned in section 2.5.2 on page 44.

In the following, we concentrate on the following types of transformations:

- Linear mappings within image space resp. object space, called homographies in 2D and 3D with affine transformations and similarity transformations as special cases
- Linear mapping from object space to image space, called projective camera transformations with affine camera transformations as a special case
- Linear mapping between two different images, called fundamental matrix.

A more detailed analysis and the application of the transformations are introduced in section 3.1.2 on page 56.

Matrix and Vector Representation The transformations will generally be represented by a $n \times m$ matrix M, such that $\boldsymbol{x}' = M\boldsymbol{x}$. If a matrix is a transformation of homogeneous vectors, then it is a homogeneous transformation $\mathsf{M} \cong \lambda\mathsf{M}$ as it is defined up to scale, denoted be upright sans-serif letters.

Alternatively, we will sometimes represent the matrix as a vector $\boldsymbol{m} = \mathrm{vec}(M^{\mathsf{T}})$ where the transposed rows of M are stacked up in a mn-vector, see definition B.2 on page 184.

2.3.1 Homography

Homographies are projective transformations, that linearly map points within a projective space $\mathbb{P}^n$. Thus it can be written as a simple matrix-vector multiplication

$$\mathbf{x}' = \mathsf{H}\mathbf{x}$$

with $\mathbf{x}', \mathbf{x} \in \mathbb{R}^{n+1}$ and the $(n+1) \times (n+1)$ regular matrix H.

An affine transformation H_a is a special case of a homography and combines translation T, rotation R, the scaling of both axes M and skew W of the original space $\mathbb{P}^2$ resp. $\mathbb{P}^3$. For 2D, we obtain

$$\begin{aligned}
\mathsf{H}_a &= \mathsf{W}\,\mathsf{M}\,\mathsf{R}\,\mathsf{T} \\
&= \begin{pmatrix} 1 & s/2 & 0 \\ s/2 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} m_1 & 0 & 0 \\ 0 & m_2 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \cos(\alpha) & \sin(\alpha) & 0 \\ -\sin(\alpha) & \cos(\alpha) & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 & -t_x \\ 0 & 1 & -t_y \\ 0 & 0 & 1 \end{pmatrix} \\
&= \begin{pmatrix} h_{11} & h_{12} & h_{13} \\ h_{21} & h_{22} & h_{23} \\ 0 & 0 & 1 \end{pmatrix}
\end{aligned} \tag{2.21}$$

As an affine transformation in 2D has six degrees of freedom, all six entries in H_a are not constrained. We may constrain the upper left 2×2 matrix $H_a' = \mathsf{H}_a^{(1,2),(1,2)}$ to obtain a similarity transformation by ${H_a'}^{\mathsf{T}} H_a' = m^2 I$. This leads to two independent quadratic constraints in 2D. In a similar way, we obtain five independent quadratic constraints in 3D.

In general, the entries of a homography H can be interpreted using the canonical examples from section 2.2.1.3 on page 28: the multiplication $\mathsf{H}\,\mathbf{e}_i$ with the canonical vectors $\mathbf{e}_i$ yields the i-th column of the homography H. Thus for example the first column $(h_{11}, h_{21}, h_{31})^\mathsf{T}$ is the image of the infinite point in the direction of the x-axis. It is obvious that for an affine transformations H_a infinite points remain at infinity.

The first row $(h_{12}, h_{12}, h_{13})^\mathsf{T}$ of a homography H can be interpreted using lines: as $\mathsf{H}^\mathsf{T}\mathbf{l}' = \mathbf{l}$, cf. equation (2.11), the first row is the line which is mapped to $\mathbf{e}_1$. Thus it is easy to see that for affine transformations, the line at infinity remains at infinity.

2.3.2 Projective Camera

The most common model for cameras is the pinhole camera model: a point $\mathbf{X}$ in 3D space is projected into an image by computing a viewing ray $\mathbf{L}'(\mathbf{x}')$ from the unique projection center $\mathbf{X}_0$ to $\mathbf{X}$ and intersecting this viewing ray with a unique image plane, see figure 2.5. The image formation process described above can also be modeled as a general linear transformation of $\mathbb{P}^3$ to $\mathbb{P}^2$, which again can be written as a matrix-vector multiplication $\mathbf{x}' = \mathsf{P}\mathbf{X}$, where P is a 3×4 matrix.

This time we interpret the *rows* $\mathbf{A}^\mathsf{T}$, $\mathbf{B}^\mathsf{T}$ and $\mathbf{C}^\mathsf{T}$ of the matrix $\mathsf{P} = \begin{pmatrix} \mathbf{A}^\mathsf{T} \\ \mathbf{B}^\mathsf{T} \\ \mathbf{C}^\mathsf{T} \end{pmatrix}$ as planes $\mathbf{A}, \mathbf{B}, \mathbf{C}$ and the multiplication $\mathbf{x}' = \mathsf{P}\,\mathbf{X}$ contains three equations

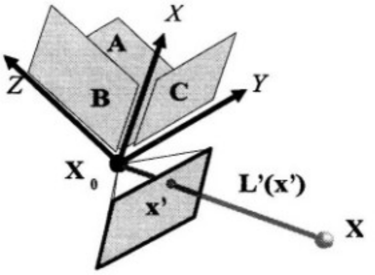


Fig. 2.5. Pinhole camera model and the three camera planes **A**, **B** and **C**.

of the form (2.10) on page 24. If $\mathbf{x}' = (u, v, w)^\mathsf{T}$, then $u = 0$ if and only if $\mathbf{X} \in \mathbf{A}$. Similarly, $v = 0 \Leftrightarrow \mathbf{X} \in \mathbf{B}$ and $w = 0 \Leftrightarrow \mathbf{X} \in \mathbf{C}$, thus a point $\mathbf{x}'$ lies at infinity if $\mathbf{X} \in \mathbf{C}$. The three planes intersect in the projection center $\boldsymbol{X}_0$, as the image point is undefined if $\mathbf{X} = (\boldsymbol{X}_0, 1)^\mathsf{T}$, already observed by DAS 1949.

Given the exterior orientation of a camera with rotation R and projection center $\boldsymbol{X}_0$ and the inner orientation with the calibration matrix K, a Euclidean interpretation of the projection matrix can be formulated as follows:

$$\mathsf{P} = \mathsf{K}R[I| - \boldsymbol{X}_0] \quad \text{with } \mathsf{K} = \begin{pmatrix} c & cs & x_H \\ 0 & c(1+m) & y_h \\ 0 & 0 & 1 \end{pmatrix} \tag{2.22}$$

with skew s, focal length c, principle point $(x_H, y_H)^\mathsf{T}$ and scale difference m between the first and second coordinate axis in the image.

Finally, as in the last section we can fix the last row of the transformation matrix with $\mathbf{C}^\mathsf{T} = (0, 0, 0, 1)^\mathsf{T}$ to obtain a special subclass of projective cameras: the plane $\mathbf{C}$ then lies at infinity and therefore the projection center $\boldsymbol{X}_0$, too. This means that all viewing rays are parallel to each other and we obtain the affine camera

$$\mathsf{P}^a = \begin{pmatrix} p_{11} & p_{12} & p_{13} & p_{14} \\ p_{21} & p_{22} & p_{23} & p_{24} \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

A more detailed description of various camera models can be found in HARTLEY AND ZISSERMAN 2000 or in FÖRSTNER 2001B.

2.3.3 Fundamental Matrix

Assume there are two images given, taken with different cameras P_1 and P_2. Suppose now a point $\mathbf{X}$ in object space is projected in the first and second image, $\mathbf{x}' = \mathsf{P}_1\mathbf{X}$ and $\mathbf{x}'' = \mathsf{P}_2\mathbf{X}$, cf. figure 2.6. It is clear that the projection center $\boldsymbol{X}_{01}$, $\boldsymbol{X}_{02}$ and the point $\mathbf{X}$ define a plane, the so-called epipolar plane.

Now suppose we take two arbitrarily chosen image points $\mathbf{x}'$ and $\mathbf{x}''$ from the first resp. second image. If we want to test whether they are caused by the same object point, one has to test whether the two viewing rays $\mathbf{L}'$ and $\mathbf{L}''$ are coplanar.

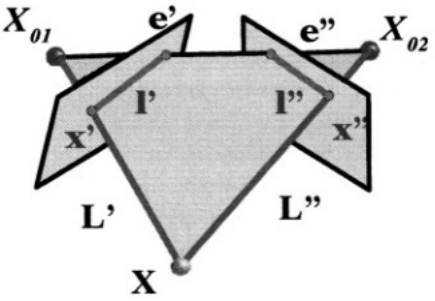

Fig. 2.6. Epipolar geometry: two projection centers $\boldsymbol{X}_{01}$ and $\boldsymbol{X}_{02}$ are connected by an epipolar line, which intersects the image planes at $\mathbf{e}'$ and $\mathbf{e}''$. The two viewing rays $\mathbf{L}'$ and $\mathbf{L}''$ point to the object point $\mathbf{X}$.

But one can also apply this test in 2D by projecting the viewing-ray $\mathbf{L}'$ into the second image, thus obtaining an image line $\mathbf{l}''$, the so-called epipolar line of $\mathbf{x}'$ which in turn has to be incident to the second image point $\mathbf{x}''$. This 2D relationship between the first point $\mathbf{x}'$ and the second point $\mathbf{x}''$ can be expressed as a coplanarity condition with the 3×3 so-called fundamental matrix F:

$$\mathbf{x}'^{\mathsf{T}} \mathsf{F} \mathbf{x}'' = 0 \tag{2.23}$$

Thus the fundamental matrix relates one image to another image. There are many ways to derive an algebraic expression for the fundamental matrix, for a review see HARTLEY AND ZISSERMAN 2000 or FAUGERAS AND LUONG 2001[3]. In section 3.1.3 we will give an explicit formula for computing F given two cameras $\mathsf{P}_1, \mathsf{P}_2$.

The vector defined by $\mathsf{F}\mathbf{x}''$ is actually the homogeneous vector for the epipolar line $\mathbf{l}''$ and by transposing equation 2.23, one also obtains the epipolar line $\mathbf{l}'$, in summary:

$$\mathbf{l}' = \mathbf{l}'(\mathbf{x}'') = \mathsf{F}\mathbf{x}'' \qquad \mathbf{l}'' = \mathbf{l}''(\mathbf{x}') = \mathsf{F}^{\mathsf{T}}\mathbf{x}'$$

Note that the projection of camera center $\boldsymbol{X}_{01}$ into the second image results in a point $\mathbf{e}'$, which is called epipole; likewise we can obtain the second epipole $\mathbf{e}''$. For epipoles, there is no epipolar line defined, thus e.g. $\mathsf{F}\mathbf{e}'' = \mathbf{0}$ and $\mathbf{e}''$ being the nullvector of F.

The fundamental matrix has 7 degrees of freedom: this is due to the fact that the 3×3 matrix is homogeneous and singular, i.e. $\det(\mathsf{F}) = 0$. Thus there are two constraints for the 9 matrix elements.

---

[3] Note that they use the transpose F^{T} as a definition for the fundamental matrix.

If the internal camera parameters K_1 and K_2 are known, only 5 parameters are unknown and the matrix is called *essential matrix,* LONGUET-HIGGINS 1981 and has 5 degrees of freedom.

2.4 Conditioning of Homogeneous Entities

Up to now we have not imposed any restrictions on the homogeneous coordinates of geometric entities nor on the parameters of geometric transformations. As the homogeneous entities are created by Euclidean objects, cf. figure 2.2, their coordinates are expressed with respect to an existing reference coordinate system. In close-range applications, we usually have the reference system nearby the entities. But in aerial imagery, the reference system is usually a geodetic system, like the Gauß-Krüger coordinate system or its international variant, the UTM system (universal-transversal-mercator system), cf. WITTE AND SCHMIDT 1995. For example, the tip of the dome of Aachen has the coordinates $x = 2505940.53[m], y = 5626590.37[m]$. Embedding this point in homogeneous coordinates as in equation (2.3) would yield a difference of seven orders of magnitudes between the Euclidean part $\boldsymbol{X}_O$ and the homogeneous part X_h. When considering subsequent computations with these coordinates, such a coordinate representation is undesirable in terms of numerical stability.

A solution is to define a local coordinate system that is close to the set of given object points, which is advisable to do prior to all methods that are discussed in this work. But if the distances between different points are large with respect to the units, an additional scaling of the coordinates is needed. For homogeneous vectors of geometric entities this means to either choose a larger X_h instead of 1 or equivalently to scale down the Euclidean coordinates by some factor. Both solutions can be achieved by scaling one part appropriately without changing the other part. We call this scaling operation *conditioning* of a geometric entity.

One may choose the second option for conditioning, i.e. scaling the Euclidean part of a geometric entity without scaling its homogeneous part. This has the effect, that the geometric entities of the vectors move closer to the Euclidean origin, cf. section 2.2. The conditioning operation can be represented by a matrix multiplication $\mathbf{x}' = \mathsf{W}(f)\mathbf{x}$, where f is the conditioning factor and W is the identity matrix except of the diagonal elements, which correspond to the Homogeneous part of the vector. The following matrices for 2D and 3D entities are obtained:

$$\begin{aligned} \mathsf{W}_x(f) &= \begin{pmatrix} f\mathsf{I}_2 & \mathbf{0} \\ \mathbf{0}^\mathsf{T} & 1 \end{pmatrix} ; \mathsf{W}_l(f) = \begin{pmatrix} \mathsf{I}_2 & \mathbf{0} \\ \mathbf{0}^\mathsf{T} & f \end{pmatrix} ; \\ \mathsf{W}_X(f) &= \begin{pmatrix} f\mathsf{I}_3 & \mathbf{0} \\ \mathbf{0}^\mathsf{T} & 1 \end{pmatrix} ; \mathsf{W}_L(f) = \begin{pmatrix} \mathsf{I} & \mathsf{0}_3 \\ \mathsf{0}_3 & f\mathsf{I}_3 \end{pmatrix} ; \mathsf{W}_A(f) = \begin{pmatrix} f\mathsf{I}_3 & \mathbf{0} \\ \mathbf{0}^\mathsf{T} & 1 \end{pmatrix} \end{aligned} \tag{2.24}$$

For scaling down the Euclidean part, one has to Choose $f < 1$. To go back to the original coordinates, one simply applies the inverse of the conditioning factor, $\mathbf{x} = \mathsf{W}(\frac{1}{f})$. Given a set of geometric entities, one has to find the entity $\mathbf{x}$ that is furthest away from the origin, and choose a conditioning factor f_{min}, such that $\mathbf{x}' = \mathsf{W}(f_{min})\mathbf{x}$ is sufficiently close to the origin. Then apply the conditioning factor to all other entities.

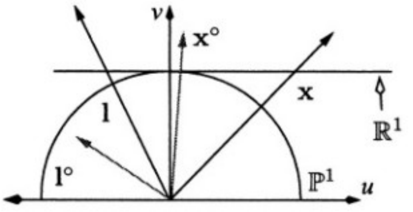

Fig. 2.7. Effect of conditioning of homogeneous vectors: a point $\mathbf{x}$ moves closer to the u-**axis**, a line $\mathbf{l}$ moves closer to the v-**axis**, but the angle between the two new vectors remains invariant.

For the projective axis, the effect of conditioning to the homogeneous vectors is depicted in figure 2.7: for a point $\mathbf{x} = (u, v)^\mathsf{T}$, the first coordinate is scaled by a factor f, the second coordinate remains invariant. The vector is now closer to the v-**axis**, a Euclidean normalization onto $\mathbb{R}^1$ would yield a scalar closer to zero. For a hyperplane $\mathbf{l} = (a, b)^\mathsf{T}$, the second coordinate is assumed to be the Euclidean part and thus the first coordinate is scaled by f, yielding a vector closer to the u-**axis**. Note that the dot-product between $\mathbf{x}$ and $\mathbf{l}$ remains invariant when scaling with the same conditioning factor.

For a transformation, we generally have two different sets of entities $\mathbf{x}_i$ and $\mathbf{x}'_i$, for which two different conditioning factors f and f' have to be computed. A conditioned transformation matrix H° can be obtained by

$$\mathsf{H}^\circ = \mathsf{W}(f')\mathsf{H}\mathsf{W}^{-1}(f) \tag{2.25}$$

The reconditioning of the estimated transformation H° is then given by

$$\mathsf{H} = \mathsf{W}^{-1}(f')\mathsf{H}^\circ\mathsf{W}(f) \tag{2.26}$$

The conditioning operation is not only useful to obtain small coordinates: as we are going to see in the next two chapters, conditioning becomes important when

- computing optimal estimations from a set of observations, cf. section 3.4
- reducing the bias of the statistical representation of uncertain geometric entities, cf. section 4.3.

Algorithm 2.1 shows a method for conditioning of a set of geometric entities. The algorithm is used in section 3.4 on page 80 when constructing an unknown entity by a set of observations and will turn out especially useful

Conditioning a set of geometric entities
Objective: Transform a set of lines, points and planes in 3D such that they move closer to the Euclidean origin.

Given are $n = n_X + n_L + n_A$ entities with n_X 3D points $\mathbf{X}_k$, n_L lines $\mathbf{L}_l$ and n_A planes $\mathbf{A}_m$.

Additionally, the required conditioning factor $f_{min} < 1$ is given, i.e. the minimal ratio between the homogeneous part and the Euclidean part of a geometric entity.

```
1. find the maximum ratio $max_{hO}$ of the norm of the Euclidean
   and homogeneous parts for points, lines and planes
   $max_{hO} := \max_{i,j,k} \frac{|\mathbf{v}_h|}{|\mathbf{v}_O|}$ for $\mathbf{v} \in \{\mathbf{X}_i, \mathbf{L}_j, \mathbf{A}_k\}$
2. determine whether it is necessary to scale the Euclidean parts.
   if $\max_{hO} < f_{min}$ then
      $f := f_{min} \cdot max_{hO}$
      if $f < \epsilon_M$ then $f := f_{min} / max_O$
            with $max_O = \max_{i,j,k} |\mathbf{v}_O|$ for $\mathbf{v} \in \{\mathbf{X}_i, \mathbf{L}_j, \mathbf{A}_k\}$
      $\mathbf{v}^\circ := \mathsf{W}(f)\mathbf{v}$ for $\mathbf{v} \in \{\mathbf{X}_i, \mathbf{L}_j, \mathbf{A}_k\}$
```

Algorithm 2.1: Algorithm for conditioning a set of geometric entities. The conditioning changes the ratio between the norms of the Euclidean and homogeneous part of a vector, which should be smaller than f_{min}. The machine accuracy ϵ_M is the smallest number such that $1.0 + \epsilon_M > 1.0$. The conditioned entity is denoted by $\mathbf{v}^\circ$, for a definition of the matrices $\mathsf{W}(f)$, see equation (2.24).

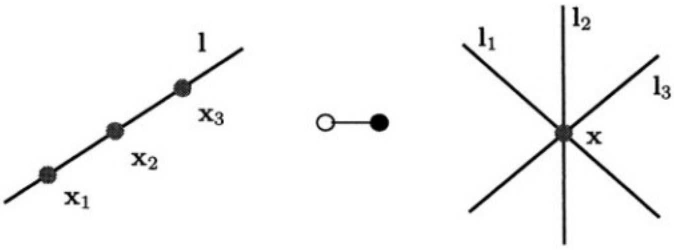
when discussing uncertainty representations of the homogeneous vectors, see section 4.3.3 on page 117.

Note that because we have subdivided all homogeneous vectors of geometric entities into a homogeneous and a Euclidean part, the conditioning of geometric entities is very simple and works consistently for homogeneous vectors for points, lines and planes within a coordinate frame.

2.5 Duality Principle

The duality principle is an important feature of projective geometry as all propositions occur twice: taking the dual of a true proposition yields a new proposition, possibly with a different meaning. As an example for duality, consider the property from section 2.1.2: three 2D points $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3 \in \mathbb{P}^2$ are collinear iff $|\mathbf{x}_1\ \mathbf{x}_2\ \mathbf{x}_3| = 0$. It is possible to replace the points with lines, which are elements of the dual space $(\mathbb{P}^2)^*$. Then we obtain the dual property: three 2D lines $\mathbf{l}_1, \mathbf{l}_2, \mathbf{l}_3$ intersect in one point iff $|\mathbf{l}_1\ \mathbf{l}_2\ \mathbf{l}_3| = 0$, see figure 2.8.

In the following we will discuss dual entities and their transformations. They become important for the geometric constructions described in chapter 3, where we introduce the duality between the join and intersection of entities.



$\mathbf{l}$
$\mathbf{x}_3$
$\mathbf{x}_2$
$\mathbf{x}_1$
$\mathbf{l}_1$
$\mathbf{l}_2$
$\mathbf{l}_3$
$\mathbf{x}$

Fig. 2.8. Checking whether three points are collinear *(left)* is dual to checking whether three lines intersect in one point *(right),* see text for details. The sign ○—● is used here to express the duality between the two geometric situations.

2.5.1 Dual Entities

Dual Points and Hyperplanes As demonstrated by the last example and mentioned in section 2.1.2, points and hyperplanes in 2D and 3D are called dual to each other. As they use the same kind of homogeneous vectors, one can interpret a homogeneous point vector $\mathbf{x}$ as a hyperplane: we denote this change of interpretation by $\overline{\mathbf{x}}$ and call $\overline{\mathbf{x}}$ the dual of $\mathbf{x}$. The vector $\overline{\mathbf{x}}$ has the same coordinates, but now represents a hyperplane instead of a point.

For example, given a 2D point $\mathbf{x} = (x, y, 1)^\mathsf{T}$ its dual $\overline{\mathbf{x}}$ is a 2D line. Setting $\mathbf{l} = \overline{\mathbf{x}}$, we obtain the normalized line $\mathsf{N}_O(\mathbf{l}) = \frac{1}{x^2+y^2}(x, y, 1)^\mathsf{T}$. Thus the distance of the line $\mathbf{l} = \overline{\mathbf{x}}$ is the inverse distance of the point $\mathbf{x}$ to the origin. Additionally, the point and its dual line lie on opposite sides of the origin, see figure 2.9(left). The same reasoning applies to 3D points $\mathbf{X}$, where its dual is a plane $\overline{\mathbf{X}}$, see figure 2.9(middle).

Fig. 2.9. Visualization of dual entities. *Left:* the dual $\overline{\mathbf{x}}$ of a 2D point $\mathbf{x}$ is a 2D line: *middle:* the dual $\overline{\mathbf{X}}$ of a 3D point $\mathbf{X}$ is a plane; *right:* the dual $\overline{\mathbf{L}}$ of a 3D line $\mathbf{L}$ is again a 3D line. the distance d of the dual entities is inverse to the distance of the original entities.

Dual Lines One question has not been answered yet: what is the dual of a 3D line $\mathbf{L}$? To answer this question, we consider again the relationship that was derived between a point and a hyperplane, see equation (2.10). In 3D, a point $\mathbf{U}$ is incident to a plane $\mathbf{A}$ if $\mathbf{U}^\mathsf{T}\mathbf{A} = 0$. If the plane $\mathbf{A}$ was derived by three points $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$, we obtain

$$\mathbf{U}^\mathsf{T}\mathbf{A} = 0 \quad \Leftrightarrow \quad \mathbf{A}^\mathsf{T}\mathbf{U} = 0 \quad \Leftrightarrow \quad |\mathbf{X}, \mathbf{Y}, \mathbf{Z}\ ;\ \mathbf{U}| = 0 \tag{2.27}$$

see equation (2.6). The dot-product $\mathbf{U}^\mathsf{T}\mathbf{A}$ is actually an instance of the so-called cap-product, denoted by $< \mathbf{U}, \mathbf{A} >$: in general the cap-product is defined as a product of elements of two dual projective subspaces onto $\mathbb{R}$. More precisely, the cap-product is defined for the two corresponding *vector* spaces where the sum of the dimensions of the underlying *vector* subspaces is equal to the dimension of the vector space. For example, a 3D point with projective dimension 0 has a vector dimension of 1 as the projective point in $\mathbb{P}^3$ is represented by a line in $\mathbb{R}^4$, cf. figure 2.1(d) for the 2D case. The dual of a 3D point is a 3D plane with projective dimension 2 resp. vector dimension 3. Summing up the vector dimensions yields 1 + 3 = 4 the dimension of $\mathbb{R}^4$. To derive a cap-product involving 3D lines, we can re-interpret the determinant $|\mathbf{X}, \mathbf{Y}, \mathbf{Z}\ ;\ \mathbf{U}|$ by defining two lines $\mathbf{L}(\mathbf{X}, \mathbf{Y})$ and $\mathbf{M}(\mathbf{Z},\mathbf{U})$:

$$|\underbrace{\mathbf{X}\,\mathbf{Y}}_{\mathbf{L}}\ ;\ \underbrace{\mathbf{Z}\,\mathbf{U}}_{\mathbf{M}}| = 0 \tag{2.28}$$

This equation holds if the four points are coplanar or equivalently, if the lines $\mathbf{L}$ and $\mathbf{M}$ intersect in one point. We can expand the determinant in (2.28) to hold the Plücker coordinates of the lines $\mathbf{L}$, $\mathbf{M}$:

$$\begin{aligned}
\begin{vmatrix} X_1 & Y_1 & Z_1 & U_1 \\ X_2 & Y_2 & Z_2 & U_2 \\ X_3 & Y_3 & Z_3 & U_3 \\ X_4 & Y_4 & Z_4 & U_4 \end{vmatrix} &= \begin{vmatrix} X_1 & Y_1 \\ X_4 & Y_4 \end{vmatrix} \begin{vmatrix} Z_2 & U_2 \\ Z_3 & U_3 \end{vmatrix} - \begin{vmatrix} X_2 & Y_2 \\ X_4 & Y_4 \end{vmatrix} \begin{vmatrix} Z_1 & U_1 \\ Z_3 & U_3 \end{vmatrix} + \begin{vmatrix} X_3 & Y_3 \\ X_4 & Y_4 \end{vmatrix} \begin{vmatrix} Z_1 & U_1 \\ Z_2 & U_2 \end{vmatrix} \\
&\quad + \begin{vmatrix} X_2 & Y_2 \\ X_3 & Y_3 \end{vmatrix} \begin{vmatrix} Z_1 & U_1 \\ Z_4 & U_4 \end{vmatrix} - \begin{vmatrix} X_1 & Y_1 \\ X_3 & Y_3 \end{vmatrix} \begin{vmatrix} Z_2 & U_2 \\ Z_4 & U_4 \end{vmatrix} + \begin{vmatrix} X_1 & Y_1 \\ X_2 & Y_2 \end{vmatrix} \begin{vmatrix} Z_3 & U_3 \\ Z_4 & U_4 \end{vmatrix} \qquad (2.29) \\
&= +l_{14}m_{23} - l_{24}m_{13} + l_{34}m_{12} + l_{23}m_{14} - l_{13}m_{24} + l_{12}m_{34} \\
&= -l_{41}m_{23} - l_{42}m_{31} - l_{43}m_{12} - l_{23}m_{41} - l_{31}m_{42} - l_{12}m_{43}
\end{aligned}$$

The 2 × 2 minors are the Plücker coordinates for the lines $\mathbf{L}$ and $\mathbf{M}$, see also section 2.2.4 on page 32. One can check that equation (2.28) is equivalent to

$$-\boldsymbol{L}_h^\mathsf{T}\boldsymbol{M}_O - \boldsymbol{L}_O^\mathsf{T}\boldsymbol{M}_h = 0 \tag{2.30}$$

Thus we have derived a condition for the incidence of two lines $\mathbf{L}$ and $\mathbf{M}$ from the incidence of a plane $\mathbf{A}$ and a point $\mathbf{U}$.

Equation (2.30) defines the cap-product $< \mathbf{L}, \mathbf{M} >$ of two lines in a similar way as $< \mathbf{A}, \mathbf{U} >$ with equation (2.10); the dual of a 3D line is again a 3D line. Interpreting the cap-product by a dot-product of dual entities, we obtain

$$< \mathbf{L}, \mathbf{M} > := -\boldsymbol{L}_h^{\mathsf{T}} \boldsymbol{M}_O - \boldsymbol{L}_O^{\mathsf{T}} \boldsymbol{M}_h = -\mathbf{L}^{\mathsf{T}} \overline{\mathbf{M}} \quad \text{with } \overline{\mathbf{M}} := \begin{pmatrix} \boldsymbol{M}_O \\ \boldsymbol{M}_h \end{pmatrix}$$

where $\overline{\mathbf{M}}$ is the dual of the line $\mathbf{M}$ and is obtained by switching the homogeneous and Euclidean part of the vector $\mathbf{M}$. The visualization of a line and its dual is shown in figure 2.9(left). Note that again the point and its dual line are on opposite sides of the origin and the dual has an inverse distance to the origin with respect to the original entity.

To summarize, the possible cap-products in 2D and 3D are:

entity 1	dim. of vector subspace	dual entity 2	dim. of vector subspace	dim. of vector space	cap-product
point $\mathbf{x}$	1	line $\mathbf{l}$	2	1+2=3	$< \mathbf{x}, \mathbf{l} > \; := \mathbf{x}^{\mathsf{T}} \mathbf{l}$
point $\mathbf{X}$	1	plane $\mathbf{A}$	3	1+3=4	$< \mathbf{X}, \mathbf{A} > \; := \mathbf{X}^{\mathsf{T}} \mathbf{A}$
line $\mathbf{L}$	2	line $\mathbf{M}$	2	2+2=4	$< \mathbf{L}, \mathbf{M} > \; := \mathbf{L}^{\mathsf{T}} \overline{\mathbf{M}}$

Usually the cap-product is defined in the context of the so-called double or Grassmann-Cayley algebra, where operations such as join and intersection form an algebra on projective subspaces. In the next chapter we introduce these operations on the geometric entities defined. Again, for a rigorous treatment of this subject, see FAUGERAS AND LUONG 2001.

An alternative proof that two lines are incident if equation (2.30) does not explicitly use determinants but only analytical geometry and follows BRAND 1966, p. 54: assume a point $(\boldsymbol{X}^{\mathsf{T}}, 1) \in \mathbf{L}^{\mathsf{T}} = (\boldsymbol{L}_h^{\mathsf{T}}, \boldsymbol{L}_O^{\mathsf{T}})$ and $(\boldsymbol{Y}^{\mathsf{T}}, 1) \in \mathbf{M}^{\mathsf{T}} = (\boldsymbol{M}_h^{\mathsf{T}}, \boldsymbol{M}_O^{\mathsf{T}})$. The lines are coplanar if and only if the vectors $(X — Y)$, $\boldsymbol{L}_h$ and $\boldsymbol{M}_h$ are coplanar, or algebraically $(\boldsymbol{X} - \boldsymbol{Y})^{\mathsf{T}} (\boldsymbol{L}_h \times \boldsymbol{M}_h) = 0$. The assertion follows now from the fact that $\boldsymbol{L}_O = \boldsymbol{X} \times \boldsymbol{L}_h$ and $\boldsymbol{M}_O = \boldsymbol{Y} \times \boldsymbol{M}_h$.

Algebraic Expression for Dual Entities As we want to express all operations on entities within linear algebra, we define the dual operator as a linear transformation from one projective subspace to another. For points and lines in 2D and for points and planes in 3D, the dual operator is the identity matrix I_3 resp. I_4:

$$\overline{\mathbf{x}} := I_3 \, \mathbf{x} \quad , \; \overline{\mathbf{l}} := I_3 \, \mathbf{l} \qquad ; \qquad \overline{\mathbf{X}} := I_4 \, \mathbf{X} \quad , \; \overline{\mathbf{A}} := I_4 \, \mathbf{A}$$

For lines in 3D, we define the dual operator as follows, considering our choice for the Plücker-coordinates:

$$\overline{\mathbf{L}} := C\mathbf{L} \quad \text{with } C := \begin{pmatrix} 0&0&0&1&0&0\\ 0&0&0&0&1&0\\ 0&0&0&0&0&1\\ 1&0&0&0&0&0\\ 0&1&0&0&0&0\\ 0&0&1&0&0&0 \end{pmatrix} = \begin{pmatrix} 0 & I_3 \\ I_3 & 0 \end{pmatrix} \tag{2.31}$$

Note that applying the dual operators I_3, I_4 and C changes the interpretation of a homogeneous vector from a projective entity to its dual.

2.5.2 Dual of Point Transformations

The existence of dual entities also has an effect on the transformations mentioned in section 2.3 on page 34, namely homographies, projective transformations and fundamental matrices. There exists a theorem to derive a duality property for linear mappings of all geometric entities. In section 2.1.2 it was already mentioned that given any linear map H from $\mathbb{P}^n$ to $\mathbb{P}^m$, the dual mapping is the transpose H^T that maps the dual spaces $(\mathbb{P}^m)^*$ to $(\mathbb{P}^n)^*$. This behavior can be transferred to any of the proposed geometric entities, see FAUGERAS AND LUONG 2001, p. 154.

For example assume a projective transformation P of a 3D-point $\mathbf{X}$ to 2D point $\mathbf{x}'$, the duality relation for $\mathbf{x}' = \mathsf{P}\mathbf{X}$ can be written as

$$\mathbf{x}' = \mathsf{P}\mathbf{X} \quad \circ\!\!-\!\!\bullet \quad \mathsf{P}^\mathsf{T}\mathbf{l}' = \mathbf{A} \tag{2.32}$$

where again the simplified notation $\overline{\mathbf{x}'} = \mathbf{l}'$ and $\overline{\mathbf{X}} = \mathbf{A}$ holds. The sign $\circ\!\!-\!\!\bullet$ is used here to express the duality between the two expressions.

Since we know how to interpret the elements of the dual spaces $(\mathbb{P}^m)^*$ and $(\mathbb{P}^n)^*$ we can directly apply this to 2D and 3D. In equation (2.32), a 2D image line may be back-projected in 3D using a projective camera matrix P and results in a projective plane $\mathbf{A}$, which intersects the focal point and the 2D line on the image plane.

Similarly, the rules of duality for homographies H, projective transformations P and fundamental matrices F are

$$\begin{aligned} \mathbf{x}' = \mathsf{H}\mathbf{x} \quad &\circ\!\!-\!\!\bullet \quad \mathsf{H}^\mathsf{T}\mathbf{l}' = \mathbf{l} \\ \mathbf{X}' = \mathsf{H}\mathbf{X} \quad &\circ\!\!-\!\!\bullet \quad \mathsf{H}^\mathsf{T}\mathbf{A}' = \mathbf{A} \\ \mathbf{L}' = \mathsf{H}_L\mathbf{L} \quad &\circ\!\!-\!\!\bullet \quad \mathsf{H}_L^\mathsf{T}\overline{\mathbf{L}'} = \overline{\mathbf{L}} \\ \mathbf{x}' = \mathsf{P}\mathbf{X} \quad &\circ\!\!-\!\!\bullet \quad \mathsf{P}^\mathsf{T}\mathbf{l}' = \mathbf{A} \\ \mathbf{l}' = \mathsf{F}\mathbf{x}'' \quad &\circ\!\!-\!\!\bullet \quad \mathsf{F}^\mathsf{T}\mathbf{x}' = \mathbf{l}'' \\ \mathbf{l}' = \mathsf{Q}\mathbf{L} \quad &\circ\!\!-\!\!\bullet \quad \mathsf{Q}^\mathsf{T}\mathbf{x}' = \overline{\mathbf{L}} \end{aligned}$$

The last duality relation involves the projective camera transformation Q for 2D lines, which will be covered in section 3.1.2.2 on page 57.

Right now, the representation of the line transformation $\mathbf{L}' = \mathsf{H}_L\mathbf{L}$ is not obvious as not all homographies $\mathsf{H}_L : \mathbb{P}^5 \rightarrow \mathbb{P}^5$ within the five-dimensional projective space correspond to valid homographies in $\mathbb{P}^3$. We will deal with line transformations H_L in section 3.1.2 on page 56: as soon as we have introduced algebraic expressions for constructions join and intersection, we are able to derive a construction of H_L given a 3D homography H. The same argument applies to projective camera transformations Q for 3D lines, see section 3.1.2.2.

Now apply formula (1). According to (1b), Sec. 161, we have $x_1=2$, $y_1=0$, $z_1=0$, $l_1=3$, $m_1=2$, $n_1=1$, so that

$$\begin{vmatrix} y_0-y_1 & z_0-z_1 \\ m_1 & n_1 \end{vmatrix}=\begin{vmatrix} 0 & 1 \\ 2 & 1 \end{vmatrix}=-2,$$

$$\begin{vmatrix} z_0-z_1 & x_0-x_1 \\ n_1 & l_1 \end{vmatrix}=\begin{vmatrix} 1 & -1 \\ 1 & 3 \end{vmatrix}=4,$$

$$\begin{vmatrix} x_0-x_1 & y_0-y_1 \\ l_1 & m_1 \end{vmatrix}=\begin{vmatrix} -1 & 0 \\ 3 & 2 \end{vmatrix}=-2$$

We obtain

$$d=\frac{\sqrt{(-2)^2+4^2+(-2)^2}}{\sqrt{3^2+2^2+1^2}}=2\sqrt{\frac{3}{7}}$$

163. The Condition for Two Straight Lines Intersecting or Lying in a Single Plane

If the straight lines

$$\frac{x-x_1}{l_1}=\frac{y-y_1}{m_1}=\frac{z-z_1}{n_1}, \tag{1}$$

$$\frac{x-x_2}{l_2}=\frac{y-y_2}{m_2}=\frac{z-z_2}{n_2} \tag{2}$$

lie in a single plane, then

$$\begin{vmatrix} x_2-x_1 & y_2-y_1 & z_2-z_1 \\ l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \end{vmatrix}=0 \tag{3}$$

or, in vector form,

$$(\boldsymbol{r}_2-\boldsymbol{r}_1)\,\boldsymbol{a}_1\boldsymbol{a}_2=0 \tag{3a}$$

Conversely, if Condition (3) is fulfilled, then the straight lines lie in a single plane.

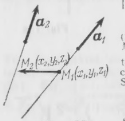

Fig. 177

Explanation. If the straight lines (1) and (2) lie in a single plane, then the straight line M_1M_2 (Fig. 177) also lies in that plane, i. e. the vectors $\overrightarrow{M_1M_2}$, $\boldsymbol{a}_1$, $\boldsymbol{a}_2$ are coplanar (and conversely). This is what Eq. (3) expresses (see Sec. 120).

Note. If $\frac{l_1}{l_2}=\frac{m_1}{m_2}=\frac{n_1}{n_2}$ [here, (3) will definitely be satisfied], then the straight lines are parallel, otherwise the straight lines satisfying Condition (3) intersect.

Example. Determine whether the straight lines

$$\frac{x}{1}=\frac{y}{2}=\frac{z}{3}, \tag{1}$$

$$\frac{x+1}{2}=\frac{y-1}{1}=\frac{z+1}{4} \tag{2}$$

intersect, and if they do, at what point.

Solution. The straight lines (1) and (2) lie in one plane since the determinant (3) equal to $\begin{vmatrix} -1 & 1 & -1 \\ 1 & 2 & 3 \\ 2 & 1 & 4 \end{vmatrix}$ vanishes. These lines are not parallel (the direction numbers are not proportional). In order to find the point of intersection, we have to solve a system of four equations (1), (2) in three unknowns. As a rule, such a system does not have any solutions, but in the given case [because Condition (3) is fulfilled] there is a solution. Solving a system of any three equations, we get $x=1$, $y=2$, $z=3$. The fourth equation is satisfied. The point of intersection is (1, 2, 3).

164. The Equations of a Line Perpendicular to Two Given Straight Lines

The straight line UV intersecting two nonparallel straight lines (L_1 and L_2 in Fig. 178)

$$\frac{x-x_1}{l_1}=\frac{y-y_1}{m_1}=\frac{z-z_1}{n_1},$$

$$\frac{x-x_2}{l_2}=\frac{y-y_2}{m_2}=\frac{z-z_2}{n_2}$$

and perpendicular to them is represented (in vector form) by the equations

$$(\boldsymbol{r}-\boldsymbol{r}_1)\,\boldsymbol{a}_1\boldsymbol{a}=0, \tag{1}$$

$$(\boldsymbol{r}-\boldsymbol{r}_2)\,\boldsymbol{a}_2\boldsymbol{a}=0 \tag{2}$$

where $\boldsymbol{a}_1=\{l_1,\ m_1,\ n_1\}$, $\boldsymbol{a}_2=\{l_2,\ m_2,\ n_2\}$ and $\boldsymbol{a}=\boldsymbol{a}_1\times\boldsymbol{a}_2$.

Taken separately, Eq. (1) is the plane P_1 drawn through the straight line L_1 parallel to the vector $\boldsymbol{a}=\boldsymbol{a}_1\times\boldsymbol{a}_2$ (Sec. 159). Similarly, (2) is plane P_2 drawn through L_2 parallel to $\boldsymbol{a}$.

Point K_1, where UV intersects L_1, is found at the intersection of L_1 with the plane P_2. Similarly, we find, the point K_2 and then the length of the common perpendicular K_1K_2.

Note. If L_1 and L_2 are parallel [then $\boldsymbol{a}=0$ and Eqs. (1), (2) become identities], there is an infinity of straight lines UV. To obtain the equation of one of them, take on L_1 (Fig. 179) an arbitrary point K_1 and form the equation of the straight line passing through K_1 in the direction of the vector $\boldsymbol{a}_1\times\boldsymbol{b}$, where $\boldsymbol{b}=\boldsymbol{a}_1\times(\boldsymbol{r}_2-\boldsymbol{r}_1)$.

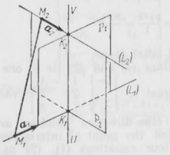

Fig. 178

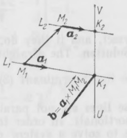

Fig. 179

Example 1. Find the equations of the perpendicular to the straight lines

$$x=2+2t,\qquad y=1+4t,\qquad z=-1-t, \tag{3}$$

$$x=-31+3t',\qquad y=6+2t',\qquad z=3+6t' \tag{4}$$

Solution. We have $\boldsymbol{a}_1=\{2,\ 4,\ -1\}$, $\boldsymbol{a}_2=\{3,\ 2,\ 6\}$, $\boldsymbol{a}=\boldsymbol{a}_1\times\boldsymbol{a}_2=\{26,\ -15,\ -8\}$.

The desired perpendicular is given by the equations

$$\begin{vmatrix} x-2 & y-1 & z+1 \\ 2 & 4 & -1 \\ 26 & -15 & -8 \end{vmatrix}=0,$$

$$\begin{vmatrix} x+31 & y-6 & z-3 \\ 3 & 2 & 6 \\ 26 & -15 & -8 \end{vmatrix}=0$$

or, after simplifying,

$$\begin{cases} 47x+10y+134z+30=0, & (5)\\ 74x+180y-97z+1505=0 & (6)\end{cases}$$

The point K_1 of intersection of the common perpendicular with the straight line (3) is found from the system (3)-(6). We get $K_1(-2,\ -7,\ 1)$. Similarly, we find $K_2(-28,\ 8,\ 9)$. The length d of the common perpendicular is

$$d=\sqrt{(-2+28)^2+(-7-8)^2+(1-9)^2}=\sqrt{965}$$

Example 2. Find the equations of the line perpendicular to the straight lines

$$x=2+2t,\qquad y=3+2t,\qquad z=t, \tag{7}$$

$$x=5+2t',\qquad y=4+2t',\qquad z=1+t' \tag{8}$$

The lines are parallel: $\boldsymbol{a}_1=\boldsymbol{a}_2=\{2,\ 2,\ 1\}$, $\boldsymbol{r}_2-\boldsymbol{r}_1=\{3,\ 1,\ 1\}$, $\boldsymbol{b}=\boldsymbol{a}_1\times(\boldsymbol{r}_2-\boldsymbol{r}_1)=\{1,\ 1,\ -4\}$. The direction vector of the common perpendicular $\boldsymbol{a}_1\times\boldsymbol{b}=\{-9,\ 9,\ 0\}$ or, multiplying by $\frac{1}{9}$, $\{-1,\ 1,\ 0\}$. For the initial point we take an arbitrary point $K_1(2+2t;\ 3+2t;\ t)$ of the line (7). We obtain the equation of the common perpendicular

$$\frac{x-(2+2t)}{-1}=\frac{y-(3+2t)}{1}=\frac{z-t}{0} \tag{9}$$

where t is an arbitrary number. To find the point K_2 of intersection of the common perpendicular (9) with the straight line (8), substitute expression (8) into Eq. (9). This yields

$$\frac{3+2(t'-t)}{-1}=\frac{1+2(t'-t)}{1}=\frac{1+(t'-t)}{0}$$

Any one of these equations yields $t'=t-1$; substituting into (8), we get $K_2(3+2t,\ 2+2t,\ t)$, so that

$$d=|K_1K_2|=$$

$$=\sqrt{[(3+2t)-(2+2t)]^2+[(2+2t)-(3+2t)]^2+[t-t]^2}=\sqrt{2}$$

165. The Shortest Distance Between Two Straight Lines

The shortest distance between the straight lines L_1 and L_2 is the length d of their common perpendicular. It can be found by forming the equations of the common perpendicular (Sec. 164, Examples 1 and 2). A simpler way, however, is to find d directly.

(1) If L_1 and L_2 are not parallel (Fig. 180), then

$$d=\frac{|(\boldsymbol{r}_2-\boldsymbol{r}_1)\,\boldsymbol{a}_1\boldsymbol{a}_2|}{|\boldsymbol{a}_1\times\boldsymbol{a}_2|}=\frac{|\boldsymbol{r}_2-\boldsymbol{r}_1)\,\boldsymbol{a}_1\boldsymbol{a}_2|}{\sqrt{(\boldsymbol{a}_1\times\boldsymbol{a}_2)^2}} \tag{1}$$

which is smooth in the $\mathbb{R}^{N_1}$ topology, the two local coordinate charts $(\mathcal{U}_{T(1)}, \pi_{T(1)})$ and $(\mathcal{U}_{T(2)}, \pi_{T(2)})$ have diffeomorphic intersection, and consequently $POL_{g,N_0}(M)$ is a differentiable orbifold locally modelled on $(\mathcal{U}_T, \pi_T) \subset \mathcal{T}^{met}_{g,N_0}(M)/Aut(T)$ as stated.

A direct consequence of Proposition 1.4 is the following

Theorem 1.3 *The space of Polyhedral structures $POL_{g,N_0}(M)$ generated by closed polyhedral surfaces (T_l, M) of genus g with N_0 vertices has*

$$\mathcal{C}ard\ \left\{\mathcal{T}_{g,N_0}(M)\right\}, \tag{1.59}$$

distinct orbifold strata, where $\mathcal{C}ard$ denotes the cardinality of the set of distinct triangulations considered.

Proof Since, according to Proposition 1.4, the strata $\frac{\mathbb{R}^{N_1}_+}{Aut(T)}$ of $POL_{g,N_0}(M)$ are labelled by the finite set of distinct triangulations $[T] \in \mathcal{T}_{g,N_0}(M)$, the theorem immediately follows. ■

In order to explore the basic properties of the space of polyhedral structures $POL_{g,N_0}(M)$ we need to discuss the structure of $\mathcal{T}^{met}_{g,N_0}(M)$ in the neighborhood of a given polyhedral surface (T_l, M). This will provide the appropriate notion of local deformation of polyhedral surfaces. A thorough analysis of the deformation theory of polyhedral surface, (in the general case of Euclidean, Hyperbolic, and Spherical triangulated surfaces), is presented in a series of remarkable papers by Feng Luo [7, 12, 13], who, building on the influential work of Thurston [22], Rivin [19], and Leibon [11], provides a very detailed and illustrative geometrical framework for the theory. Here we take a slightly different point of view, more apt to the physical applications, emphasizing the natural connections with the Witten–Kontsevich theory.

1.8 Cotangent Cones and Circle Bundles $\mathcal{Q}_{(k)}$ Over $\mathcal{T}^{met}_{g,N_0}(M)$

A basic question in discussing the deformation theory of $\mathcal{T}^{met}_{g,N_0}(M)$ is to characterize the space of the infinitesimal deformations of a given polyhedral surface (T_l, M), i.e. a suitable notion of tangent space to $\mathcal{T}^{met}_{g,N_0}(M)$ at (T_l, M). The idea is to formalize the intuitive picture of what a deformation of a neighborhood of a vertex $\sigma^0(k)$ in a polyhedral surface looks like. To this end, we inject the given vertex $\sigma^0(k)$ in the origin O of $(\mathbb{R}^3; O, x, y, z)$, where we identify $\mathbb{R}^3$, endowed with the vector product ×, with the Lie algebra $\mathfrak{so}(3)$ of the rotation group $SO(3)$. Since $\sigma^0(k)$ is a conical point whose generators are edges of Euclidean triangles, we can associate with $\sigma^0(k)$ the polyhedral cone with apex O, whose generators have lengths normalized to 1 and whose directrix is a piecewise–geodesic curve on the surface of a unit sphere $\mathbb{S}^2$ centered at the origin. This curve is a spherical polygon whose side–lengths are provided by the original vertex angles $\{\theta_\alpha\}$ generating the conical geometry around $\sigma^0(k)$. This construction has a natural $SO(3)$ symmetry which, when reduced, generates a set of spherical polygons which parametrizes all possible distinct polyhedral cones in $(\mathbb{R}^3; O, x, y, z)$ having the same intrinsic metric geometry of the local Euclidean structure $\mathscr{E}\left(Star[\sigma^0(k)]\right)$ near $\sigma^0(k)$. This set characterizes the *polyhedral cotangent cone* to $\mathscr{E}\left(Star[\sigma^0(k)]\right)$ at $\sigma^0(k)$. There is a natural bundle associated with this construction which, to some extent, provides a suitable notion of (co)tangent space to $\mathscr{T}^{met}_{g,N_0}(M)$ at (T_l, M).

We begin with a few notational remarks. Recall that if $q(k) \geq 2$ triangles $\sigma^2(h_\alpha, k, h_{\alpha+1})$ are incident on $\sigma^0(k)$, then

$$Star[\sigma^0(k)] \doteq \cup_{\alpha=1}^{q(k)} \sigma^2(h_\alpha, k, h_{\alpha+1}), \quad h_{q(k)+1} \equiv h_1, \tag{1.60}$$

where the index α is taken modulo $q(k)$. We denote by

$$\mathscr{E}\left(Star[\sigma^0(k)]\right) \doteq \left\{(\theta_{\alpha,k,\alpha+1},\ \theta_{k,\alpha+1,\alpha},\ \theta_{\alpha+1,\alpha,k})\right\}, \tag{1.61}$$

the generic conically complete locally Euclidean structure on $Star[\sigma^0(k)]$, and consider the ordered sequence of vertex angles at $\sigma^0(k)$

$$\left\{\theta_{\alpha,k,\alpha+1}\right\}_{\alpha=1}^{\alpha=q(k)}, \quad \theta_{q(k),k,q(k)+1} \equiv \theta_{q(k),k,1}, \tag{1.62}$$

as a point of $[0, \pi]^{q(k)}$, modulo cyclic permutations in $\mathbb{Z}_{q(k)}$. The boundary points 0 and π corresponds to the degeneration of those triangles $\sigma^2(h_\alpha, k, h_{\alpha+1})$ whose corresponding vertex angle $\theta_{\alpha,k,\alpha+1}$ either goes to 0, (a *thinning* triangle), or to π, (a *fattening* triangle). Note that in the former case we have that the edge length $l(h_\alpha, h_{\alpha+1}) \to 0$ with $l(l(k, h_\alpha)$ and $l(k, h_{\alpha+1})$ both > 0; whereas, in the latter case we have $l(h_\alpha, h_{\alpha+1}) = l(k, h_\alpha) + l(k, h_{\alpha+1})$. According to Proposition 1.1 to any $\mathscr{E}\left(Star[\sigma^0(k)]\right)$ we can associate a conical defect

$$\Theta(k) \doteq \sum_{\alpha=1}^{q(k)} \theta_{\alpha,k,\alpha+1}, \tag{1.63}$$

supported at $\sigma^0(k)$, which induces a conical geometry on $Star[\sigma^0(k)]$. Since (1.63) depends only on the $\sigma^0(k)$ angles $\{\theta_{\alpha,k,\alpha+1}\} \in \mathscr{E}\left(Star[\sigma^0(k)]\right)$, it is natural to define the set of *vertex angle structures* at $\sigma^0(k)$ associated with $\mathscr{E}\left(Star[\sigma^0(k)]\right)$ according to

$$\mathscr{V}ert_{q(k)} := \left\{\{\theta_\alpha\}_k \in [0, \pi]^{q(k)}/\mathbb{Z}^{q(k)} \,\middle|\, \exists \mathscr{E}\left(Star[\sigma^0(k)]\right) \ \ s.t. \{\theta_\alpha\}_k = \{\theta_{\alpha,k,\alpha+1}\}\right\}, \tag{1.64}$$

(we shall often drop the index k in $\{\theta_\alpha\}_k$ if it is clear from the geometrical context which vertex we are considering). Similarly, for a given $\Theta(k) \in \mathbb{R}^+$, we define the set of *vertex angle structures* associated with the conical angle $\Theta(k)$ as

$$\mathcal{V}ert_{q(k)}[\Theta(k)] \;:=\; \left\{ \{\theta_\alpha\}_k \in \mathcal{V}ert_{q(k)} \Big| \sum_{\alpha=1}^{q(k)} \theta_\alpha \,=\, \Theta(k) \right\}. \tag{1.65}$$

Remark 1.5 Since the automorphism group $Aut(T)$ of a given a triangulation (T_l, M) in $\mathcal{T}^{met}_{g,N_0}(M)$ fixes every vertex, we can consistently label the vertices of (T_l, M) by the index set $V := (1, \ldots, k, \ldots, N_0)$. This also induces a corresponding labeling on the vertex angles $\{\theta(h, k, j)\}$ of (T_l, M) which is coherent with the vertex star–grouping (1.62). Explicitly, if we define the ordering

$$\ldots \prec \{\theta_\alpha\}_k \prec \{\theta_\beta\}_{k+1} \prec \ldots, \tag{1.66}$$

i.e.,

$$\ldots \prec \{\theta_{\alpha,k,\alpha+1}\}_{\alpha=1}^{\alpha=q(k)} \prec \{\theta_{\beta,k+1,\beta+1}\}_{\beta=1}^{\alpha=q(k+1)} \prec \ldots, \tag{1.67}$$

we can label the vertex angles $\{\theta(h, k, j)\}$ by an index set Φ with cardinality $3N_2$. In particular we can associate to the polyhedral surface (T_l, M) the vertex angles vector

$$\begin{aligned} \mathcal{T}^{met}_{g,N_0}(M) &\longrightarrow (0, \pi)^{3N_2} \,=\, \oplus_{k=1}^{N_0}\; \mathcal{V}ert_{q(k)} \\ (T_l, M) &\longmapsto \overrightarrow{\vartheta}(T_l) := \left(\{\theta_\alpha\}_1, \ldots, \{\theta_\beta\}_{N_0}\right), \end{aligned} \tag{1.68}$$

and the *angle–vertex* incidence matrix

$$A_{T_l} \;:=\; [a_{kJ}]_{k \in V,\, J \in \Phi}\,, \tag{1.69}$$

where $a_{kJ} \equiv 1$ if the vertex angle $\angle_J$ is incident on the vertex $\sigma^0(k)$, $a_{kJ} \equiv 0$ otherwise. Namely, $a_{kJ} \equiv 1$ iff $\angle_J = \theta_{\alpha,k,\alpha+1}$ for some $\alpha \in (1, \ldots, q(k))$. Note in particular that the subset of triangulations $\mathcal{T}^{met}_{g,N_0}(M;\, \{\Theta(k)\})$ with a prescribed set of conical angles $\{\Theta(k)\}$ can be equivalently characterized by the condition

$$\mathcal{T}^{met}_{g,N_0}(M;\, \{\Theta(k)\}) = \left\{ (T_l, M) \in \mathcal{T}^{met}_{g,N_0}(M) \Big|\; A_{T_l}\, \overrightarrow{\vartheta}(T_l)^t = \overrightarrow{\Theta}(T_l)^t \right\}, \tag{1.70}$$

where $A^{T_l}\overrightarrow{\vartheta}(T_l)^t$ denotes the matrix product between A_{T_l} and the transposed (column) vector $\overrightarrow{\vartheta}(T_l)$, and where $\overrightarrow{\Theta}(T_l)$ denotes the given conical angles vector associated with (T_l, M), i.e.

$$\overrightarrow{\Theta}(T_l) := \;(\Theta(1), \ldots, \Theta(k), \ldots, \Theta(N_0))\,. \tag{1.71}$$

□

The general idea behind the introduction of $\mathcal{V}ert_{q(k)}$ and $\mathcal{V}ert_{q(k)}[\Theta(k)]$ is that these sets may serve as coordinate spaces for the conical angles $\{\Theta(k)\}$ associated with polyhedral surfaces. However this fails short of being a significant parametrization since the incidence order $q(k)$ may vary with the vertex $\sigma^0(k)$ and with the polyhedral surface $(T_l, M) \in \mathscr{T}^{met}_{g,N_0}(M)$ considered. To bypass this difficulty, it is convenient to *telescope* [4] the set $\{\theta_\alpha\}_{\alpha=1}^{q(k)}$ in $\mathscr{V}ert_{q(k)}$ as $q(k) \to \infty$, i.e. to inject $\{\theta_\alpha\}_{\alpha=1}^{q(k)}$ not in a particular $\mathscr{V}ert_{q(k)}$ but rather in the inductive limit of $\mathscr{V}ert_{q(k)}$ as $q(k) \to \infty$. This is easily realized by observing that there is a natural sequence of inclusions

$$\left(\theta_1, \dots, \theta_{q(k)}\right) \hookrightarrow \mathscr{V}ert_{q(k)} \hookrightarrow \dots \mathscr{V}ert_{q(k)+h} \hookrightarrow \mathscr{V}ert_{q(k)+h+1} \hookrightarrow \dots, \tag{1.72}$$

defined, (e.g., in the $\mathscr{V}ert_{q(k)} \hookrightarrow \mathscr{V}ert_{q(k)+1}$ case), by the $q(k)+1$ distinct injections

$$\left(\theta_1, \dots, \theta_{q(k)}\right) \xrightarrow{j_\beta^{q,q+1}} \left(\theta_1, \dots, \theta_{\beta-1}, 0, \theta_\beta, \dots, \theta_{q(k)}\right), \tag{1.73}$$

where $\beta = 1, \dots, q(k)+1$. Thus, independently from the particular vertex $\sigma^0(k)$ and triangulation (T_l, M) considered, we introduce the following characterization

Definition 1.17 The inductive limit of the family $\left\{\mathscr{V}ert_q, j_\beta^{q,q+1}\right\}$, as $q \to \infty$, defines the space of *vertex angle structures*

$$\mathscr{V}ert := \lim_{q \to \infty} \left\{\mathscr{V}ert_q \hookrightarrow \mathscr{V}ert_{q+1}, \; j_\beta^{q,q+1}\right\} \simeq [0, \pi]^\infty, \tag{1.74}$$

associated with the set of Euclidean vertex stars $\left\{\mathscr{E}\left(Star[\sigma^0(k)]\right)\right\}$ of polyhedral surfaces in $\mathscr{T}^{met}_{g,N_0}(M)$.

Explicitly, we may think of a sequences $\{\theta_\alpha\}_{\alpha=1}^{q(k)} \in \mathscr{V}ert_{q(k)}$, associated with $\mathscr{E}\left(Star[\sigma^0(k)]\right)$, as the coordinates of the corresponding conical structure in the local chart $\mathscr{V}ert_{q(k)}$ of $\mathscr{V}ert$, i.e.

$$\oplus_{k=1}^{N_0} \; \mathscr{V}ert_{q(k)} \hookrightarrow \mathscr{V}ert. \tag{1.75}$$

We can locally model the geometrical realizations of the local chart $\mathscr{V}ert_{q(k)}$ in terms of spherical polygons (Fig. 1.14). This will characterize a natural polygonal bundle over $\mathscr{V}ert$ which, as described in the introductory remarks, will play the role of the cotangent bundle to $\mathscr{T}^{met}_{g,N_0}(M)$. To carry out such a construction explicitly, let us consider the link of $\sigma^0(k)$ in $Star[\sigma^0(k)] \in (T_l, M) \in \mathscr{T}^{met}_{g,N_0}(M)$,

$$link(k) := link_{(T_l,M)}\left(\sigma^0(k)\right) \simeq \mathbb{S}^1, \tag{1.76}$$

viz. the union of all edges $\sigma^1(h_\alpha, h_{\alpha+1})$ in $Star[\sigma^0(k)]$ satisfying $\sigma^1(h_\alpha, h_{\alpha+1}) \cap \sigma^0(k) = \emptyset$, (see Theorem 1.1). We can naturally map $link(k)$ to a closed rectifiable piecewise–smooth Jordan curve $c_{(k)}$ on the unit sphere

$$\begin{aligned} c_{(k)} \; : \; [0,1] &\longrightarrow link(k) \hookrightarrow \mathbb{S}^2, \\ t \;\; &\longmapsto \;\; x(t) \hookrightarrow c_{(k)}(t), \end{aligned} \tag{1.77}$$

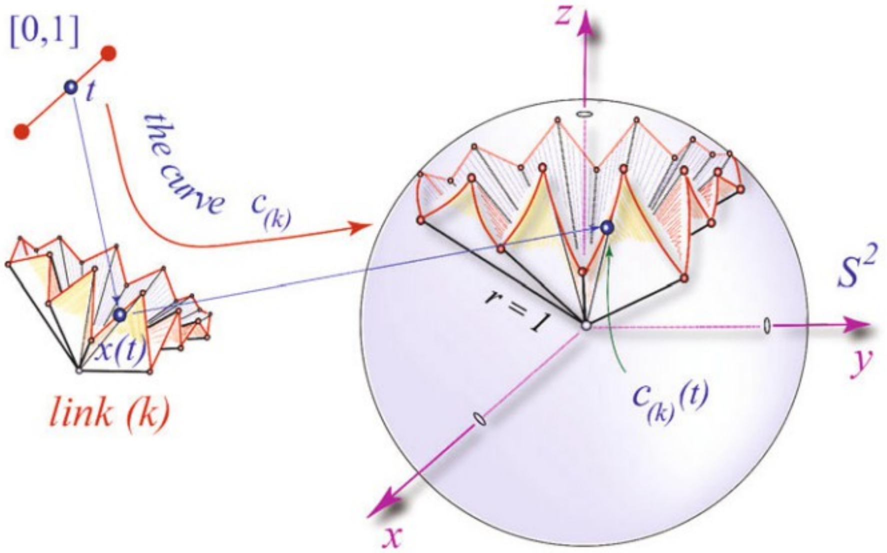

Fig. 1.14 The image of the curve (1.77) is characterized by the intersection, in ($\mathbb{R}^3$; O, x, y, z), of a geometric realization of $\mathcal{E}\left(Star[\sigma^0(k)]\right)$ with a unit sphere $\mathbb{S}^2$ centered in the origin $O \equiv \sigma^0(k)$. This intersection is well-defined up to a natural $SO(3)$ action

where $x(t) \in link(k)$, and where $c_{(k)}(0) = c_{(k)}(1)$. The image $c_{(k)}([0,1])$ of the curve $c_{(k)}$ can be explicitly constructed by intersecting, in $\left((\mathbb{R}^3, \times) \cong \mathfrak{so}(3);\, O, x, y, z\right)$, a geometrical realization of the given Euclidean structure $\mathcal{E}\left(Star[\sigma^0(k)]\right)$ with a unit sphere $\mathbb{S}^2$ centered in the origin O, (see Fig. 1.14).This generates a cone whose intrinsic metric depends only on the length $|c_{(k)}|$ of the curve $c_{(k)}$, (see Fig. 1.15), and we have the characterization, (see also [5])

Lemma 1.1 *The conical angle $\Theta(k)$ at the vertex $\sigma^0(k)$ is the length $|c_{(k)}|$ of the Jordan curve* (1.77). ☐

The mapping (1.77) also induces on the curve $c_{(k)}$ the decoration defined by the $q(k)$ points $\{p_\alpha\}$ images of the vertices $\{\sigma^0(h_\alpha)\} \in link(k)$. In particular the vertex angle $\theta_\alpha(k)$ associated with the triangle $\sigma^2(h_\alpha, k, h_\alpha)$ provides the length

$$\left|c_{(k)}(\alpha, \alpha+1)\right| := \theta_\alpha(k), \tag{1.78}$$

of the arc of geodesic $c_{(k)}(\alpha, \alpha+1)$ between the point p_α and $p_{\alpha+1}$.

Remark 1.6 The $\{c_{(k)}(\alpha, \alpha+1)\}$ are geodesic arcs since they are defined by the intersection between $\mathbb{S}^2$ and planes passing through the center of $\mathbb{S}^2$.

M. Kapovich and J. Millson have studied in depth the properties of the set of spherical polygons and of the associated moduli spaces, (see [9] and references therein). Here we exploit a few elementary aspects of their analysis playing an important role in our framework. We start by recalling the

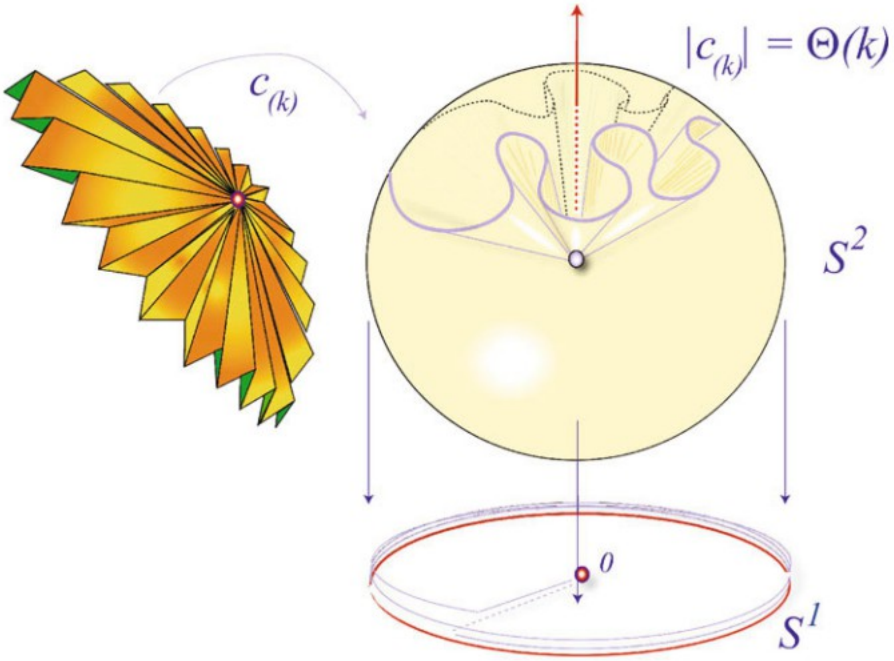

Fig. 1.15 The cone associated with the curve $c_{(k)}$ on the unit sphere S^2. The intrinsic metric of such a cone depends only on the length $|c_{(k)}|$ of the curve $c_{(k)}$, (to emphasize this we have rounded the image of the curve). This length is the conical angle $\Theta(k)$ at the vertex. If the cone generated by $c_{(k)}$ is cut open along a generator and unfolded into the (complex) plane, the curve $c_{(k)}$ covers the circle S^1 and $\Theta(k)$ gives the length (with multiplicity) of the circuitation around S^1

Definition 1.18 (Labeled Spherical Polygons [9]) A $q(k)$–tuple of oriented geodesic arcs $c_{(k)}(\alpha, \alpha+1) \in \mathbb{S}^2$ of lengths

$$0 < \left|c_{(k)}(\alpha, \alpha+1)\right| < \pi, \tag{1.79}$$

such that the end–point of the geodesic segment $c_{(k)}(\alpha, \alpha+1)$ coincides with the initial point of the geodesic segment $c_{(k)}(\alpha+1, \alpha+2)$ defines a closed spherical $q(k)$–gon

$$P_{(k)}(c_{(k)}) := \{c_{(k)}(\alpha, \alpha+1)\}. \tag{1.80}$$

□

Let us remark that the labeling here refers to the fact that the geodesic segments $c_{(k)}(\alpha, \alpha+1)$ defining the edges of the polygon are path–ordered. Moreover, as long as $0 < \left|c_{(k)}(\alpha, \alpha+1)\right| < \pi$, the geodesic arcs $c_{(k)}(\alpha, \alpha+1)$ are equivalently characterized by the ordered sequence of $q(k)$ points $\{p_\alpha\}$, and we can identify $P_{(k)}(c_{(k)}) = \{p_\alpha\}$. The more general case $\left|c_{(k)}(\alpha, \alpha+1)\right| \in [0, \pi]$, which corresponds to spherical polygons associated with degenerating triangles in $\mathscr{E}(Star[\sigma^0(k)])$, can be handled with a detailed analysis of the possible singular polygonal configurations associated with the triangle degenerations. In order to avoid the complications due to these singular configurations, we shall consider uniquely the generic case under the restriction (1.79).

There is a natural $SO(3)$ diagonal action on the spherical polygons $P_{(k)}(c_{(k)})$ defined by [9]

$$g \cdot P_{(k)}(c_{(k)}) := \left(g \cdot \overrightarrow{Op}_1, \ldots, g \cdot \overrightarrow{Op}_{q(k)} \right), \tag{1.81}$$

where $g \in SO(3)$ and where $\overrightarrow{Op}_\alpha$ is the vector in $\mathbb{R}^3$ connecting the center O of $\mathbb{S}^2$ with the point $p_\alpha \in \mathbb{S}^2$. Denote by $\mathscr{P}_{q(k)}(\mathbb{S}^2)$ the space of spherical polygons [9]. Since, according to the above remarks, there is a one–to–one correspondence between $SO(3)$ equivalence classes of spherical polygons and polyhedral cones modelling a neighborhood of the vertex $\sigma^0(k)$ it is natural to introduce the

Definition 1.19 The quotient space of $\mathscr{P}_{q(k)}(\mathbb{S}^2)$ by the $SO(3)$ action described above,

$$\mathscr{Q}_{q(k)}(\mathbb{S}^2) := \mathscr{P}_{q(k)}(\mathbb{S}^2) \,/\, SO(3), \tag{1.82}$$

defines the space of *polyhedral cones* over the vertex $\sigma^0(k) \in (T_l, M)$.

In order to fix the $SO(3)$ gauge freedom in $\mathscr{P}_{q(k)}(\mathbb{S}^2)$ in (1.82) we start by remarking that the configuration space of spherical polygons with given side-lengths $\{\left|c_{(k)}(\alpha, \alpha+1)\right|\}$ can be characterized as the set

$$\mathscr{P}_{(k)}(\mathbb{S}^2; \{\left|c_{(k)}(\alpha, \alpha+1)\right|\}) := \tag{1.83}$$

$$\left\{ \{p_\alpha\} \in \mathbb{S}^{2\,q(k)} \mid \overrightarrow{Op}_\alpha \cdot \overrightarrow{Op}_{\alpha+1} = \cos\, \left|c_{(k)}(\alpha, \alpha+1)\right| \right\},$$

where $\cdot$ denotes the scalar product in $\mathbb{R}^3$. In particular, we can always choose the geodesic arc $c_{(k)}(q(k), 1)$ of the spherical polygon $P_{(k)}(c_{(k)})$ to lie in the (O, x, y)–plane $\subset \mathbb{R}^3$. Let $(\overrightarrow{\varepsilon}_1, \overrightarrow{\varepsilon}_2)$ be orthonormal basis vectors in (O, x, y), and let us denote by p_0 the midpoint of the geodesic arc $c_{(k)}(q(k), 1)$. We take p_0 to be the origin of the piecewise geodesic path $c_{(k)}$. Rotate the polygon $P_{(k)}(c_{(k)})$ around the origin in the (O, x, y)–plane so that $\overrightarrow{Op}_0 \equiv \overrightarrow{\varepsilon}_1$. This fixes the position of the vector $\overrightarrow{Op}_1$ according to (Fig. 1.16)

$$\overrightarrow{Op}_1 = \cos \frac{\left|c_{(k)}(q(k), 1)\right|}{2} \overrightarrow{\varepsilon}_1 + \sin \frac{\left|c_{(k)}(q(k), 1)\right|}{2} \overrightarrow{\varepsilon}_2. \tag{1.84}$$

In such a representation there is a natural map defined by

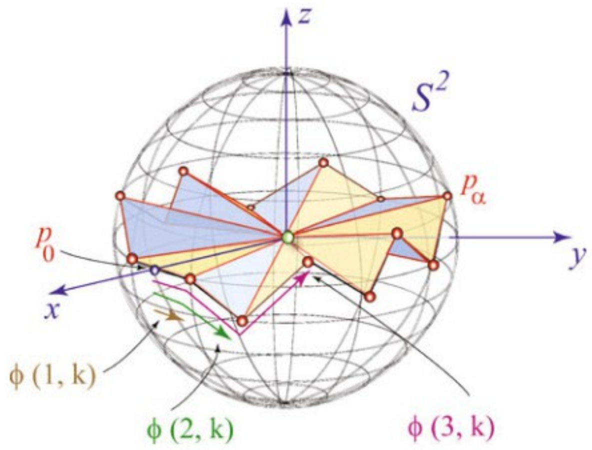

Fig. 1.16 The decoration defined by the $q(k)$ points $\{p_\alpha\}$ images of the vertices $\{\sigma^0(h_\alpha)\} \in link(k)$. The arc–length computed from the origin p_0, defined by choosing the geodesic arc $c_{(k)}(q(k),1)$ of the spherical polygon $P_{(k)}(c_{(k)})$ to lie in the (O, x, y)–plane $\subset \mathbb{R}^3$, characterizes the map $\phi(\alpha,k)$ associated with the point p_α

$$\begin{aligned}\pi_{\phi(k)} \,:\, \mathscr{P}_{q(k)}(\mathbb{S}^2) \;&\longrightarrow\; \left[\mathbb{S}^1/2\pi\right]^{q(k)} \\ \{p_\alpha\} \;&\longmapsto\; \{\phi(\alpha,k)\}_{\alpha=1}^{q(k)} \;:=\; \left\{\frac{\left|c_{(k)}(0,\alpha)\right|}{\Theta(k)}\right\}_{\alpha=1}^{q(k)},\end{aligned} \tag{1.85}$$

where $\left|c_{(k)}(0,\alpha)\right|$ denotes the length of the piecewise geodesic arc of curve $c_{(k)}(0,\alpha)$ between the midpoint $p_0 \in c_{(k)}(q(k),1)$, (the origin of the piecewise geodesic path $c_{(k)}$), and the polygon vertex p_α. Note that the normalization to the total conical angle $\Theta(k) = \sum_{\alpha=1}^{q(k)} \theta_\alpha$ is well–defined since, according to Lemma 1.1,

$$\Theta(k) = \sum_{\alpha=1}^{q(k)} \left|c_{(k)}(\alpha,\alpha+1)\right|. \tag{1.86}$$

Moreover, we have

$$\phi(\alpha+1,k) \;=\; \phi(\alpha,k) \;+\; \frac{\left|c_{(k)}(\alpha,\alpha+1)\right|}{\Theta(k)}\,, \quad \alpha = 1,\ldots,q(k)-1, \tag{1.87}$$

which directly follows from the definition of $\phi(\alpha,k)$, and

$$\phi(1,k) \;=\; \phi(q(k),k) + \frac{\left|c_{(k)}(q(k),1)\right|}{\Theta(k)} \;-\; 1\,, \quad \alpha = q(k), \tag{1.88}$$

which is a consequence of the identity

$$\frac{\left|c_{(k)}(q(k),1)\right|}{\Theta(k)} \;=\; 1 \;-\; \sum_{\alpha=1}^{q(k)-1} \left(\phi(\alpha+1,k) - \phi(\alpha,k)\right). \tag{1.89}$$

Conversely,

$$\left|c_{(k)}(\alpha,\alpha+1)\right| \;=\; \Theta(k)\;[\phi(\alpha+1,k)-\phi(\alpha,k)]\;, \quad \alpha=1,\ldots,q(k)-1, \tag{1.90}$$

and

$$\left|c_{(k)}(q(k),1)\right| \;=\; \Theta(k)\;[\phi(1,k)-\phi(q(k),k)+1]\,. \tag{1.91}$$

It follows that, relative to the framing (1.84), we can uniquely represent any spherical polygon, with given edge lengths $\{\left|c_{(k)}(\alpha,\alpha+1)\right| \;=\; \theta_\alpha(k)\}$, in terms of the set

$$\Xi_{\{\phi(\alpha,k)\}} \;:=\; \left\{\{\phi(\alpha+1,k)-\phi(\alpha,k)\} \mid \{\phi(\alpha,k)\}\in\left[\mathbb{S}^1/2\pi\right]^{q(k)}\right\}. \tag{1.92}$$

The quotient map

$$\mathscr{P}_{(k)}(\mathbb{S}^2;\{\left|c_{(k)}(\alpha,\alpha+1)\right|\}) \longrightarrow \frac{\mathscr{P}_{(k)}(\mathbb{S}^2;\{\left|c_{(k)}(\alpha,\alpha+1)\right|\})}{SO(3)}, \tag{1.93}$$

associating to a polygon $P_{(k)}(c_{(k)})$ its representative in the framing (1.84), shows that (1.90) and (1.91) provide a homeomorphism

$$\Xi_{q(k)}(\{\phi(\alpha,k)\}) \;\longrightarrow\; \frac{\mathscr{P}_{(k)}(\mathbb{S}^2;\{\left|c_{(k)}(\alpha,\alpha+1)\right|\})}{SO(3)}, \tag{1.94}$$

which characterizes $\Xi_{q(k)}(\{\phi(\alpha,k)\})$ as a slice for the $SO(3)$ action on the spaces of spherical polygons with given edge–lengths. It follows that we can represent the space of polyhedral cones over the vertex $\sigma^0(k)$, $\mathscr{Q}_{q(k)}(\mathbb{S}^2)$, according to

$$\mathscr{Q}_{q(k)}(\mathbb{S}^2) \simeq \Xi_{q(k)}(\{\phi(\alpha,k)\}). \tag{1.95}$$

In particular, if $V(T)$ denotes the vertex set of (T_l, M), then the map

$$\begin{aligned} \pi_k \;:\; V(T)\,\times\,\mathscr{V}ert &\longrightarrow \sqcup_{k=1}^{N_0}\mathscr{Q}_{q(k)}(\mathbb{S}^2) \qquad (1.96)\\ (\sigma^0(k),\,\{\theta_\alpha\}_k) &\longmapsto (\{\phi(\alpha,k)\},\,\{\phi(\alpha+1,k)-\phi(\alpha,k)\}=\{\theta_\alpha\}_k)\,, \end{aligned}$$

is a choice of a polyhedral cone (Fig. 1.17) having, near the given vertex $\sigma^0(k)$, the same intrinsic Euclidean structure $\mathscr{E}\left(Star[\sigma^0(k)]\right)$ defined by the vertex angles $\{\theta_\alpha\}_k$. Thus, it is natural to introduce the following

Definition 1.20 The mapping

$$(T_l, M)|_{\sigma^0(k)} \longmapsto \mathscr{Q}_{q(k)}(\mathbb{S}^2), \tag{1.97}$$

defines the polyhedral cotangent cone to (T_l, M) at the vertex $\sigma^0(k)$.

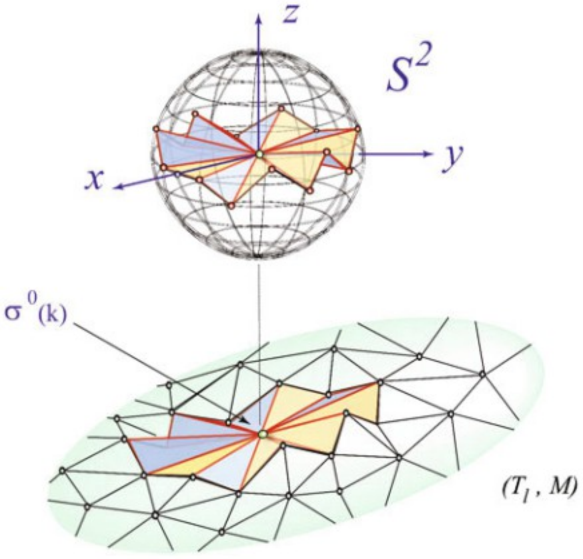

Fig. 1.17 $\mathscr{Q}_{q(k)}(\mathbb{S}^2)$ characterizes the polyhedral cotangent cone to (T_l, M) at the vertex $\sigma^0(k)$

Roughly speaking, the identification of $\mathscr{Q}_{q(k)}(\mathbb{S}^2)$ with the polyhedral cotangent space at $\sigma^0(k)$ is also justified by noticing that the polyhedra in $\mathscr{Q}_{q(k)}(\mathbb{S}^2)$ are side–wise dual to the tangent space [21] over the corresponding open triangle $\breve{\sigma}^2(\alpha, k, \alpha+1)$.

In a well–defined sense, the pair $\left(\sigma^0(k),\ \mathscr{Q}_{q(k)}(\mathbb{S}^2)\right)$ comes decorated with *coordinates*: $(\{\phi(\alpha, k)\})$ associated with the vertex $\sigma^0(k)$, and $(\{\phi(\alpha+1, k) - \phi(\alpha, k)\})$ associated with the choice of a polyhedral cone in $\mathscr{Q}_{q(k)}(\mathbb{S}^2)$ over $\sigma^0(k)$. For later use it is useful to formalize this remark into the

Definition 1.21 The map

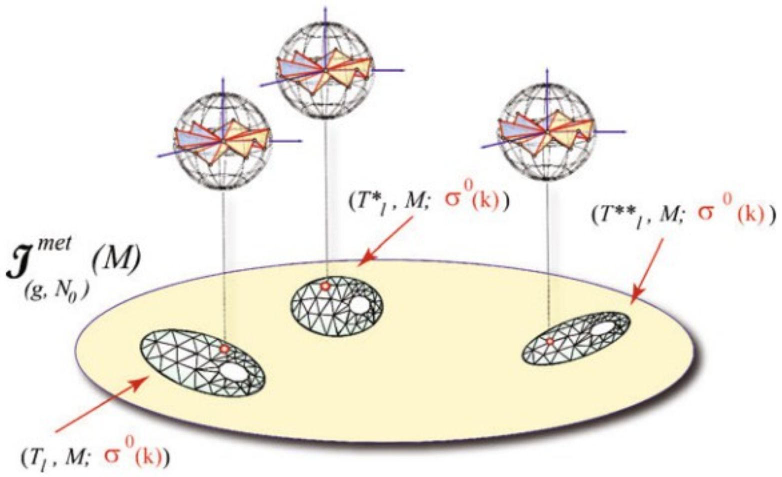
$$(\sigma^0(k),\ \mathscr{Q}_{q(k)}(\mathbb{S}^2)) \longmapsto (\{\phi(\alpha, k)\},\ \{\phi(\alpha+1, k) - \phi(\alpha, k)\}), \tag{1.98}$$

defines the polyhedral cotangent coordinates associated with the vertex $\sigma^0(k) \in (T_l, M)$. In particular the assignment of a 1-form in $(\sigma^0(k),\ \mathscr{Q}_{q(k)}(\mathbb{S}^2))$,

$$\nu_k := \sum_{\alpha=1}^{q(k)} (\phi(\alpha, k) - \phi(\alpha+1, k))\ d\left(\phi(\alpha, k)\right), \tag{1.99}$$

(recall that $\phi(\alpha+1, k) := \phi(1, k)$ for $\alpha = q(k)$), characterizes the choice of a polyhedral cone in $(\sigma^0(k),\ \mathscr{Q}_{q(k)}(\mathbb{S}^2))$.

Note that the 1-form ν_k is intrinsically defined over $\mathscr{Q}_{(k)}(\mathbb{S}^2)$, in the sense that it does not depend on the chosen origin point p_0 used for characterizing the polygonal arc-length map $\phi(\alpha, k)$. The above characterization of the polyhedral cotangent cone to (T_l, M) at the vertex $\sigma^0(k)$ can be extended (Fig. 1.18) to $\mathscr{T}^{met}_{g,N_0}(M)$ according to the



$(T^*_l, M;\ \sigma^0(k))$
$(T^{**}_l, M;\ \sigma^0(k))$
$\mathcal{J}^{met}_{(g,N_0)}(M)$
$(T_l, M;\ \sigma^0(k))$

Fig. 1.18 The polyhedral cotangent cones $\mathcal{Q}_{q(k)}(\mathbb{S}^2)$ to the polyhedral surface (T_l, M) at the vertex $\sigma^0(k)$, characterizes as $(T_l, M; \sigma^0(k))$ varies in $\mathcal{T}^{met}_{g,N_0}(M)$, a (polygonal) circle bundle over $\mathcal{T}^{met}_{g,N_0}(M)$. Since there are N_0 labeled vertices for each (T_l, M), there are N_0 such a bundle over $\mathcal{T}^{met}_{g,N_0}(M)$

Lemma 1.2 *Let* $C_k := (\{\phi(\alpha, k)\}, \{\phi(\alpha + 1, k) - \phi(\alpha, k)\})$ *denote the generic polyhedral cone in* $\mathcal{Q}_{q(k)}(\mathbb{S}^2)$*, then the mapping*

$$\begin{aligned} \mathcal{T}^{met}_{g,N_0}(M) &\longrightarrow \otimes_{k=1}^{N_0} \mathcal{Q}_{q(k)}(\mathbb{S}^2) \\ (T_l, M) &\longmapsto (C_1 \ldots, C_k, \ldots, C_{N_0}) \end{aligned} \tag{1.100}$$

defined by the N_0 *polyhedral cotangent cones at the (labelled vertices of the) the polyhedral surfaces* $(T_l, M) \in \mathcal{T}^{met}_{g,N_0}(M)$*, defines* N_0 *circle bundles* $\mathcal{Q}_{(k)}$ *over* $\mathcal{T}^{met}_{g,N_0}(M)$*.*

Proof The $\mathbb{S}^1$ fiber of $\mathcal{Q}_{(k)}$ is naturally associated with the spherical polygon defining the polyhedral cones in $\mathcal{Q}_{(k)}$. Moreover, the definition of $\phi(k, \alpha)$ easily implies that the bundle projection

$$\begin{aligned} pr_k : \mathcal{Q}_{(k)} &\longrightarrow \mathcal{T}^{met}_{g,N_0}(M) \\ C_k &\longmapsto C_k|_{\sigma^0(k) \in (T_l, M)}\,, \end{aligned} \tag{1.101}$$

is continuous when restricted to open sets of (T_l, M) in $\mathcal{T}^{met}_{g,N_0}(M)$. By considering the inductive limit Ξ_∞ of the family of polyhedral spaces $\left\{\Xi_{\{\phi(\alpha,k)\}}\right\}$ as $q(k) \to \infty$, and by considering the polyhedral cotangent cone $\mathcal{Q}_{(k)}$ as a point in Ξ_∞, it is also easy to see that pr_k is well–defined under the *flip move* (1.51), (we need to use Ξ_∞ because the incidence number $q(k)$ changes under flip moves). ■

at the quantum level that manifests in two states, like the *spin* of an electron which comes as either 'spin up' or 'spin down'[24]. These two quantum states comprise a *qubit,* designated by, [0] and [1], respectively, and may be combined into what is called a *superposition* of states:

$$\psi = c_1[0] + c_2[1]. \tag{27}$$

Here, c_1 and c_2 are *complex* numbers, such that $|c_1|^2$ represents the probability of the electron being in state [0], and $|c_2|^2$ represents the probability of the electron being in state [1]. This is another example of where complex numbers are vital in dealing with problems of the real world.

As we are dealing with probabilities, it is required that: $|c_1|^2 + |c_2|^2 = 1$. Under this proviso, taking all possible complex values c_1 and c_2, we have just created a two-dimensional (complex) Hilbert space. All the vectors, ψ, in this space are represented by the infinitely many different allowable values of c_1 and c_2 in eq. (27).

These vector states can essentially be geometrically represented by what is known as the *Bloch sphere*, as in Fig. 7.5 (left)[25]. When a measurement of the qubit is made, its state will be determined to be either [0] or [1] (due to the collapse of the wave function), and whose value effectively depends on the 'latitude' of the state vector's position on the Bloch sphere.

A quantum computer with 300 qubits can in some sense exist in 2^{300} states *at the same time*. This is more than the number of atoms in the observable Universe[26]. Quantum computers are still in the research and development stage and are suited mainly to particular types of problems (Fig. 7.5 (R)). According to computer scientist Scott Aaronson, the biggest advantages are for "(1) simulating Quantum Physics and Chemistry themselves, which has tremendous potential applications to medicine, materials science, and elsewhere, and (2) breaking the public-key cryptography that's currently used to secure the Internet."

We have just had a peek into the rather mysterious future of computing. Furthermore, quantum computer scientist Seth Lloyd proposed in his book,

---

[24] The notion of spin is derived from the angular momentum of a rotating object, but at the quantum level for a charged particle (like an electron), spin relates to the magnetic field it generates *as if it were* a spinning sphere of charge.

[25] On the Bloch sphere, for θ and ϕ as depicted in Fig. 7.5 (L), there is the geometric representation for the qubit state ψ as:

$$\psi = \sin\frac{\theta}{2}[0] + e^{i\phi}\cos\frac{\theta}{2}[1].$$

The sphere is named after Swiss-American physicist Felix Bloch (1905–1983). Note our familiar friend, the complex exponential $e^{i\phi}$ from Chapter 3.

[26] Note that $2^{300} \approx 10^{90}$, and as mentioned in Chapter 2, the number of atoms in the observable Universe is around 10^{80}.

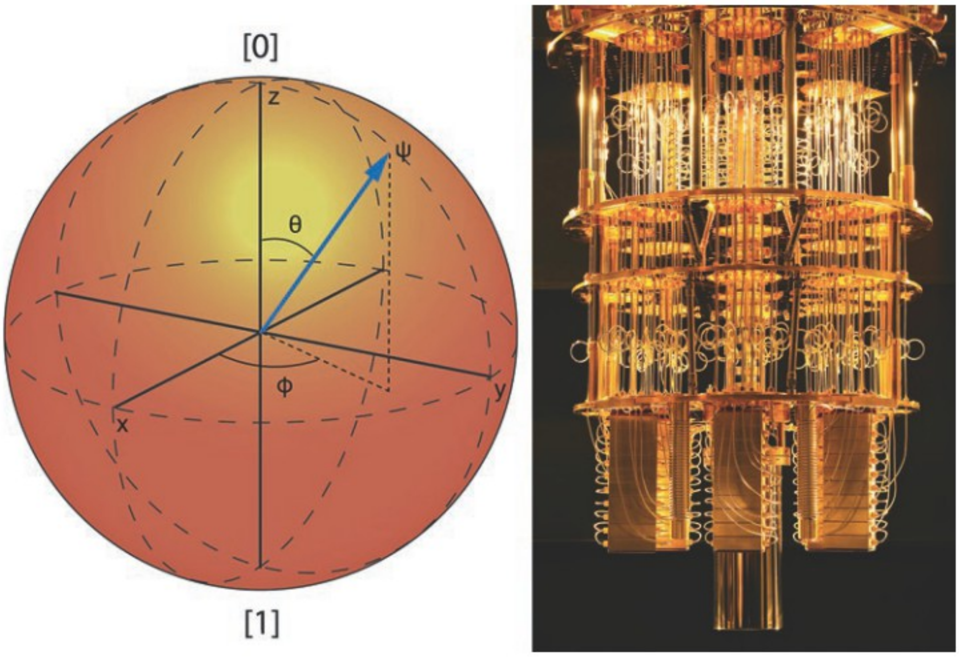

Figure 7.5: (L) The Bloch sphere geometric depiction of a state vector of a qubit. (R) Part of the cooling system and cabling of the rather beautiful IBM Q quantum computer. The chip is located in the canister at the bottom, which must be kept near absolute zero. (Images courtesy of (L) Katy Metcalf, (R) IBM Research *Flickr* CC BY-ND 2.0.)

Programming the Universe, that the entire Universe is a quantum computer that "computes its own behavior." This idea is similar to the digital Physics of Edward Fredkin mentioned in Chapter 5, in the context of the Universe being a cellular automaton.

Related to this latter idea is the notion that in order to simulate behavior in the microscopic quantum world effectively, it will take a quantum computer to do so. In the words of theoretical physicist John Preskill, "…might we already have persuasive evidence that Nature performs tasks going beyond what can be simulated efficiently by classical computers?" This is the quantum computing version of the expression, "It takes a thief to catch a thief."

Preskill proposed the term 'quantum supremacy' in 2012 to denote the point in time when a quantum computer will be able to perform a computing task that would not be possible on a classical computer *in a reasonable period of time*, irrespective of whether or not the computation was in any way useful.

The achievement of this goal of quantum supremacy has been claimed by an AI team at Google, published in an article in *Nature* (October 23, 2019), who used their

53-qubit quantum computer chip called Sycamore. They have performed a calculation in roughly 200 seconds that they argued would have taken the most powerful supercomputer around 10,000 years to perform. It must be added, however, that the problem selected was designed very specifically to favor a quantum computer and is known to be difficult for a classical computer. The authors claimed[27]:

> "Quantum processors based on superconducting qubits can now perform computations in a Hilbert space of dimension $2^{53} \approx 9 \times 10^{15}$, beyond the reach of the fastest classical supercomputers available today. To our knowledge, this experiment marks the first computation that can be performed only on a quantum processor."

On the other hand, in an IBM research blog[28], three of their scientists asserted that the problem Google solved could have been done in 2.5 days on one of its classical supercomputers, which is rather quicker than Google's estimate of 10,000 years. Therefore, "… [Google's assertion] should not be viewed as proof that quantum computers are 'supreme' over classical computers." Needless to say, IBM and Google are fierce rivals in the field of quantum computing.

Part of the problem is the very notion of quantum supremacy and its interpretation. Moreover, whether the computer time is 10,000 years or 2.5 days is not really the point. The IBM authors go on to state that, "quantum computers will never reign 'supreme' over classical computers, but will rather work in concert with them, since each have their unique strengths." Indeed, some problems are more amenable to classical computers and some are more suitable for a quantum computer, though the line between the two types of problems is often a gray area.

What the Google result does demonstrate is control over 53 qubits that are inherently unstable and were held in a quantum superposition state long enough to do a complex calculation. So, achieving this sort of result is an impressive technical achievement and a scientific milestone pointing the way to the future.

For those interested, there are now facilities for anyone from the general public who wishes to learn how to create a program on a quantum computer and to execute it[29]. A comprehensive account of quantum computing, together with much related subject matter, can be found in the fine monograph by Scott Aaronson in the Bibliography.

Since F leaves the horizontal and vertical lines invariant, we see that

$$\begin{aligned} F(a,b) &= F(\{(x,b) : x \in \mathbb{R}\}) \cap F(\{(a,y) : y \in \mathbb{R}\}) \\ &= \{(x,b) : x \in \mathbb{R}\} \cap \{(a,y) : y \in \mathbb{R}\} \\ &= (a,b). \end{aligned}$$

To show that $f = I$, we need to see the effect of the map $f\colon \mathbb{P}^2_{\mathbb{R}} \to \mathbb{P}^2_{\mathbb{R}}$ on the line $\{z = 0\}$.

Let $[x,y,0]$ be a point on the line $\{z = 0\}$. We may consider $[x,y,0]$ as the equivalence class $[\ell]$ of parallel lines ℓ in $\mathbb{A}^2_{\mathbb{R}}$. Each of these lines ℓ in $\mathbb{A}^2_{\mathbb{R}}$ is pointwise fixed by the affine transformation $F\colon \mathbb{A}^2_{\mathbb{R}} \to \mathbb{A}^2_{\mathbb{R}}$. Hence $f([\ell]) = [\ell]$, i.e., $f([x,y,0]) = [x,y,0]$. This completes the proof. ☐

3.8 Principle of Duality

One of the most beautiful properties of the projective planes is the principle of duality, which says that *in a projective plane, every definition remains the same, every theorem remains true when we interchange the words "point" and "line" and consequently interchange "lie on" and "passing through", "join" and "intersection", "collinear" and "concurrent" etc.* If in a statement, we make these changes, the resulting statement is said to be dual to the original one.

To establish this principle, it is enough to show that the axioms imply their own dual. Once we establish this, then given a theorem and its proof, we can dualize the theorem and the proof can be mechanically written down. Now we will prove that the axioms are self-dual.

1. Axiom 1 says that any two distinct points lie on a unique line. The dual statement of this is that *any two lines meet at a unique point.* This statement is nothing but axiom 2. Thus we see that axioms 1 and 2 are dual to each other.

2. Axiom 3 is the existence of four points no three of which are collinear. The dual statement is the existence of a set of four lines no three of which are concurrent. This is equivalent to saying that a projective plane contains a quadrilateral. This was proved in Proposition 3.2.8.

This establishes the principle of duality.

3.9 Classical Theorems in $\mathbb{P}^2_{\mathbb{K}}$

Theorem 3.9.1 (Desargues theorem). *Let* $\triangle(ABC)$ *and* $\triangle(PQR)$ *be two triangles in* $\mathbb{P}^2_{\mathbb{K}}$ *such that the lines* AP, BQ *and* CR *are concurrent. Let* $X = AB \cap PQ$, $Y = BC \cap QR$ *and* $Z = AC \cap PR$. *Then the three points* X, Y *and* Z *are collinear.*

Proof. The proof will utilize a trick which will be employed repeatedly.

Without loss of generality we may assume that the line XY is the line at ∞. Then the rest of the configuration lies in $\mathbb{A}^2_{\mathbb{K}}$, the affine part of $\mathbb{P}^2_{\mathbb{K}}$, i.e., $\mathbb{A}^2_{\mathbb{K}} = \mathbb{P}^2_{\mathbb{K}} \setminus \ell_{XY}$. By assumption the affine lines $AB \setminus \{X\}$ and $PQ \setminus \{X\}$ are parallel in $\mathbb{A}^2_{\mathbb{K}}$; similarly the affine lines $BC \setminus \{Y\}$ and $QR \setminus \{Y\}$ are parallel in $\mathbb{A}^2_{\mathbb{K}}$. Therefore by the affine Desargues theorem, the affine lines $CA \setminus \ell_{XY}$ and $PR \setminus \ell_{XY}$ are parallel. This means that, in $\mathbb{P}^2_{\mathbb{K}}$, the two lines CA and PR meet at a point on the line ℓ_{XY}. Hence the three points X, Y and Z are collinear in $\mathbb{P}^2_{\mathbb{K}}$.

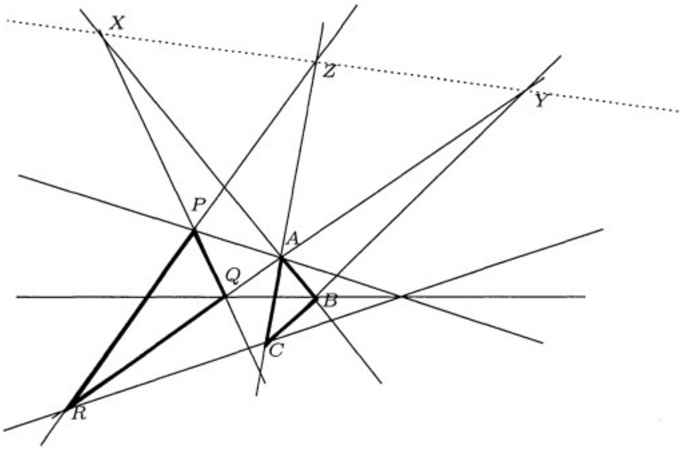

Figure 3.9.1 Desargues Theorem

Second Proof of Desargues theorem. This proof illustrates the use of homogeneous coordinates.

By the fundamental theorem of projective geometry, we may assume that ABC is the standard triangle $\triangle([1,0,0][0,1,0][0,0,1])$. Then the point of concurrence is $[1,1,1]$. The details are left to the reader. (See Figure 3.9.1.)

Since the lines AP, BQ and CR are concurrent at the point $[1,1,1]$, there exist scalars $\lambda_i, \mu_i \in \mathbb{K}^*$ for $1 \le i \le 3$ such that $P = [\lambda_1 + \mu_1, \mu_1, \mu_1]$, $Q = [\mu_2, \lambda_2 + \mu_2, \mu_2]$ and $R = [\mu_3, \mu_3, \lambda_3 + \mu_3]$. Observe that the line $PQ = \{[s(\lambda_1+\mu_1, \mu_1, \mu_1)+t(\mu_2\lambda_2+\mu_2, \mu_2)] : (s,t) \in \mathbb{K}2 \setminus (0,0)\}$ and the line $AB = \{[\alpha, \beta, 0] : (\alpha, \beta) \in \mathbb{K}2 \setminus (0,0)\}$. Since $X = PQ \cap AB$ there exist scalars $s_1, t_1 \in \mathbb{K}$ such that $[s_1(\lambda_1 + \mu_1, \mu_1, \mu_1) + (\mu_2, \lambda_2 + \mu_2, \mu_2)]$ is in AB. Hence $s_1\mu_1 + t_1\mu_2 = 0$ and $X = [s_1\lambda_1, s_2\lambda_2, 0]$. Similarly there exist scalars s_2, t_2, s_3, t_3 such that

- $s_2\mu_2 + t_2\mu_3 = 0$ and $Y = [0, s_2\lambda_2, t_2\lambda_3]$.
- $s_3\mu_3 + t_3\mu_1 = 0$ and $Z = [t_3\lambda_1, 0, s_3\lambda_3]$.

Hence the points X, Y and Z are collinear iff

$$\begin{vmatrix} s_1\lambda_1 & 0 & t_3\lambda_1 \\ t_1\lambda_2 & s_2\lambda_2 & 0 \\ 0 & t_2\lambda_3 & s_3\lambda_3 \end{vmatrix} = (s_1s_2s_3 + t_1t_2t_3)\lambda_1\lambda_2\lambda_3 = 0.$$

Since $\lambda_1\lambda_2\lambda_3 \neq 0$, it is enough to show that $(s_1s_2s_3 + t_1t_2t_3) = 0$. Now the three equations $s_1\mu_1 + t_1\mu_2 = 0$, $s_2\mu_2 + t_2\mu_3 = 0$ and $s_3\mu_1 + t_3\mu_1 = 0$ together imply that $(s_1s_2s_3 + t_1t_2t_3)\mu_1\mu_2\mu_3 = 0$. Again, since $\mu_1\mu_2\mu_3 \neq 0$, it follows that $(s_1s_2s_3 + t_1t_2t_3) = 0$ and the proof of the theorem is complete.

□

We would like to know whether the converse of Desargues theorem is true. We leave this as a set of exercises below.

Exercise 3.9.2.
(i) State the converse of Desargues theorem.
(ii) State the dual of Desargues theorem.
(iii) What is the relation between the converse and the dual of Desargues theorem.
(iv) Can you prove them?

Theorem 3.9.3 (Pappus-Pascal theorem)**.** *Let ABC and PQR be two collinear triples in $\mathbb{P}^2_{\mathbb{K}}$ such that $\ell_{ABC} \neq \ell_{PQR}$. Then the three points $X = AQ \cap BR$, $Y = BP \cap CQ$ and $Z = AP \cap CR$ are collinear.*

Proof. See Figure 3.9.2.

Let ℓ_{XY} be the line joining the points X and Y in $\mathbb{P}^2_{\mathbb{K}}$. To prove the theorem, we need to show that the point Z lies on the line ℓ_{XY}. We

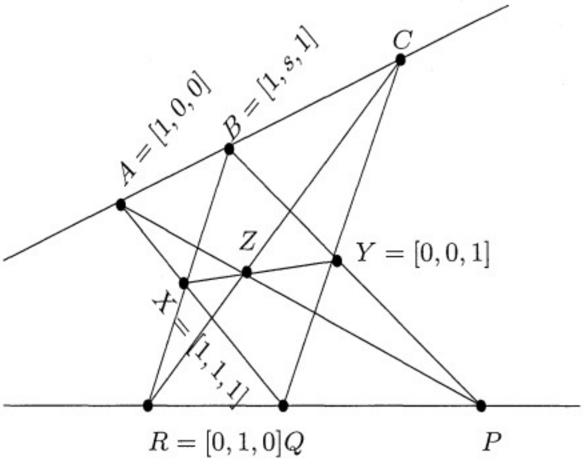

Figure 3.9.2 Pappus-Pascal Theorem

again use the same trick as we did in the proof of Desargues theorem, and take the line ℓ_{XY} as the line at ∞ and look at the configuration in the affine plane $\mathbb{A}^2_{\mathbb{K}} = \mathbb{P}^2_{\mathbb{K}} \setminus \ell_{XY}$. Here we have two lines ℓ_{ABC} and ℓ_{PQR} such that $AQ \parallel BR$ and $BP \parallel CQ$. (Why?) Therefore by the affine form of Pascal's theorem, it follows that $AP \parallel CR$. $\square$

The dual of Pappus-Pascal theorem is known as Pappus-Brianchon theorem. To state the theorem, we introduce some notations.

Definition 3.9.4. Given two lines ℓ_1 and ℓ_2 in a projective plane Π, we denote by $\ell_1\ell_2$, the point of intersection $\ell_1 \cap \ell_2$ of the lines ℓ_1 and ℓ_2.

Given four lines ℓ_1, ℓ_2, ℓ_3 and ℓ_4 in a projective plane Π, the line joining $\ell_1\ell_2$ and $\ell_3\ell_4$ is denoted by $(\ell_1\ell_2)(\ell_3\ell_4)$.

Theorem 3.9.5 (Pappus-Brianchon theorem). *Let ℓ_i, $1 \leq i \leq 6$, be six distinct lines in $\mathbb{P}^2_{\mathbb{K}}$ such that P is the point of concurrence of the lines ℓ_1, ℓ_3 and ℓ_5 and Q the point of concurrence of the lines ℓ_2, ℓ_4 and ℓ_6. Then the lines $(\ell_1\ell_4)(\ell_2\ell_3)$, $(\ell_4\ell_5)(\ell_3\ell_6)$ and $(\ell_5\ell_2)(\ell_4\ell_3)$ are concurrent.*

Proof. The proof is left as an exercise. We just need to use the duality principle. $\square$

Let us recall that a complete quadrangle is a set of four points joined in pairs by six distinct lines; the four points are called the vertices and the lines the edges. Two sides are said to be opposite if they have no common vertex.

Theorem 3.9.6 (Fano's Theorem)**.** *Let $\mathbb{K}$ be a field of characteristic not equal to* 2*. Then the intersections of the three pairs of opposite sides in a quadrangle are never collinear in $\mathbb{P}^2_{\mathbb{K}}$.*

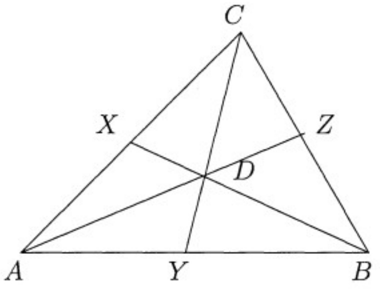

Figure 3.9.3 Fano's Theorem

Proof. Let $ABCD$ be a complete quadrangle. (See Figure 3.9.3 for the configuration). The three pairs of opposite sides are (AC, BD), (AB, CD) and (AD, BC). Let X be the point of intersection of the lines AC and BD, Y the point of intersection of the lines AB and CD and Z the point of intersection of the lines AD and BC. Now our claim is that the three points X, Y and Z are never collinear. We may assume that the line XY is the line at ∞. Let us remove the line XY and look at the remaining configuration in $\mathbb{A}^2_{\mathbb{K}} = \mathbb{P}^2_{\mathbb{K}} \setminus \ell_{XY}$.

In $\mathbb{A}^2_{\mathbb{K}}$, we see that the lines $AC \setminus \{X\}$ and $BD \setminus \{X\}$ are parallel; similarly, the lines $AB \setminus \{Y\}$ and $CD \setminus \{Y\}$ are parallel. This means that the configuration $ABCD$ in $\mathbb{A}^2_{\mathbb{K}}$ is a parallelogram in $\mathbb{A}^2_{\mathbb{K}}$. We know that the diagonals AC and BD of the parallelogram $ABCD$ bisect each other in $\mathbb{A}^2_{\mathbb{K}}$ if the characteristic of $\mathbb{K}$ is not equal to 2 (Theorem 2.9.10). But the lines AC and BD meet at the point Z. Therefore the point $Z = \frac{1}{2}(A+C) = \frac{1}{2}(B+D)$. This shows that the point $Z \in \mathbb{A}^2_{\mathbb{K}} = \mathbb{P}^2_{\mathbb{K}} \setminus \ell_{XY}$, i.e., Z does not lie on the line ℓ_{XY}. Hence the points X, Y and Z are not collinear.

□

The dual of Fano's Theorem is

Theorem 3.9.7. *The diagonals of a complete quadrilateral are never concurrent in* $\mathbb{P}^2_{\mathbb{K}}$*, where* $\text{char}\,\mathbb{K} \neq 2$. □

Remark 3.9.8. If the characteristic of the field $\mathbb{K}$ is 2, then the points X, Y and Z of Fano's configuration are collinear.

Thus, Fano's theorem in $\mathbb{P}^2_{\mathbb{K}}$ is true if and only if the characteristic of the field $\mathbb{K}$ is not equal to 2. (See Theorem 6.11 in [6].) On a general projective plane, Fano's theorem is taken as an axiom. (See [3], p.231)

3.10 Projective Line

Even though our primary concern is plane geometries, we shall define projective spaces of dimension n for each $n \in \mathbb{N}$ over an arbitrary field $\mathbb{K}$ and later specialize to the case $n = 1$.

We fix a field $\mathbb{K}$. The n dimensional *projective space* over $\mathbb{K}$ is defined to be the set of all one dimensional vector subspaces of $\mathbb{K}^{n+1}$. It is denoted by $\mathbb{P}^n(\mathbb{K})$. In particular, we call $\mathbb{P}^1(\mathbb{K})$ as the *projective line* over $\mathbb{K}$.

As in the case of the projective plane, we have a system of homogeneous coordinates in $\mathbb{P}^n(\mathbb{K})$. A point P has homogeneous coordinates $[x_0, x_1, \ldots, x_n]$ if $(x_0, \ldots, x_n)$ is a nonzero vector in the one dimensional vector subspace P. Again as in the projective plane, the group $\mathrm{GL}(n+1, \mathbb{K})$ of nonsingular linear maps over $\mathbb{K}^{n+1}$ acts on $\mathbb{P}^n(\mathbb{K})$ via the map $[x_0, x_1, \ldots, x_n] \mapsto [A(x_0, x_1, \ldots, x_n)]$. We then get the projective linear group $\mathrm{PGL}(n+1, \mathbb{K}) := \mathrm{GL}(n+1, \mathbb{K})/\mathbb{K}^*$, the quotient of $\mathrm{GL}(n+1, \mathbb{K})$ modulo its centre.

Henceforth, we shall concentrate on the projective line over $\mathbb{K}$.

Lemma 3.10.1. *Given three distinct points* P, Q, R *in* $\mathbb{P}^1(\mathbb{K})$*, we can find vectors* $p, q, r \in \mathbb{K}^2$ *such that (i)* $P = \mathbb{K}p$, $Q = \mathbb{K}q$ *and* $R = \mathbb{K}r$ *and (ii)* $p = q + r$.

Proof. Easy. Choose nonzero elements q_1, r_1 in Q, R respectively. Then $\{q_1, r_1\}$ is a basis of $\mathbb{K}^2$. Write $p = aq_1 + br_1$. Note that $a \neq 0$ and $b \neq 0$. (Why?) Let $q = aq_1$ and $r = br_1$. □

The following result should be compared with Theorem 3.7.1.

Theorem 3.10.2. *Given two ordered sets* $(P_1Q_1R_1)$ *and* $(P_2Q_2R_2)$ *of three points in* $\mathbb{P}^1(\mathbb{K})$*, there exists a unique* $A \in PGL(2, \mathbb{K})$ *which takes* P_1 *to* P_2 *etc.*

Proof. By the previous lemma, we can find vectors p_i, q_i, r_i such that $P_i = \mathbb{K}p_i$ etc. Also, we have $p_i = q_i + r_i$. Now $\{q_1, r_1\}$ and $\{q_2, r_2\}$ are bases of $\mathbb{K}^2$ so that there exists a unique linear map $A\colon \mathbb{K}^2 \to \mathbb{K}^2$ such that $Aq_1 = q_2$ etc. Clearly, $Ap_1 = p_2$.

To prove uniqueness, it suffices to show that if $A \in PGL(2, \mathbb{K})$ has two distinct fixed points, then it is the identity. Choose vectors p, q, r as in the lemma. Then $Ap = ap$, $Aq = bq$ and $Ar = cr$. Since

$$a(q + r) = ap = Ap = A(q + r) = Aq + Ar = bq + cr,$$

by linear independence of $\{q, r\}$, it follows that $a = b = c$. As a consequence, $A = aI$. □

Lemma 3.10.3. *Let A, B, C, D be four distinct points of $\mathbb{P}^1(\mathbb{K})$. We can find vectors $a, b, c, d \in \mathbb{K}^2$ such that*

(i) $A = \mathbb{K}a$, $B = \mathbb{K}b$, $C = \mathbb{K}c$ *and* $D = \mathbb{K}d$.
(ii) $c = a + b$.
(iii) $d = \lambda a + b$.

Furthermore, the scalar λ in (iii) is independent of the choices made.

Proof. We have already achieved (ii) in Lemma 3.10.1. Let $0 \neq d' \in D$. Then $d' = \alpha a + \beta b$. Note that $\alpha \neq 0 \neq \beta$ so that

$$0 \neq \frac{d'}{\beta} = \frac{\alpha}{\beta} a + b \in D.$$

Choose $d = d'/\beta$ so that $D = \mathbb{K}d$, $d = \lambda a + b$, where $\lambda = \alpha/\beta$.

To prove the uniqueness of λ: Let a_1, b_1, c_1, d_1 do the job. There exist scalars r, s such that $a_1 = ra$ and $b_1 = sb$. Then $c_1 = a_1 + b_1 = ra + sb$ must be a scalar multiple of $c = a + b$. Hence we conclude that $r = s$. (Why?) If $d_1 = \mu a_1 + b_1$, we have

$$d_1 = \mu ra + rb = r(\mu a + b)$$

is a scalar multiple of

$$d = \lambda a + b$$

iff $\mu = \lambda$. □

Definition 3.10.4. Let (A, B, C, D) be an ordered set of four distinct points in $\mathbb{P}^1(\mathbb{K})$. Then its *cross-ratio* is defined to be the scalar λ of the last theorem.

In the rest of the section, we shall approach this concept from a different direction and arrive at a formula for the cross-ratio.

The action of $\mathrm{GL}(2,\mathbb{K})$ on $\mathbb{K}^2$ induces an action on $\mathbb{P}^1_{\mathbb{K}}$ as follows: Let $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ be an element in $\mathrm{GL}(2,\mathbb{K})$. Then, for $(x,y) \in \mathbb{K}^2$,

$$A(x,y) = (ax+by, cx+dy).$$

Since A is nonsingular, $A(x,y)$ is non-zero if the vector (x,y) is non-zero. Using this observation, we define a map $f_A \colon \mathbb{P}^1_{\mathbb{K}} \to \mathbb{P}^1_{\mathbb{K}}$ by setting

$$f_A[x,y] := [ax+by, cx+dy], \text{ for } [x,y] \in \mathbb{P}^1_{\mathbb{K}}.$$

We need to show that this is well-defined. That is, if $[x'y'] = [x,y]$, then $[A(x',y')] = [A(x,y)]$. This is easy and left to the reader. Note that if $B = \lambda A$ for some non-zero $\lambda \in \mathbb{K}$, then $f_A = f_B$ on $\mathbb{P}^1_{\mathbb{K}}$.

Exercise 3.10.5. Show that if $A, B \in \mathrm{GL}(2,\mathbb{K})$ are such that $f_A = f_B$ on $\mathbb{P}^1_{\mathbb{K}}$, then $B = \lambda A$ for some $\lambda \in \mathbb{K}$. *Hint:* Refer to Lemma 3.6.1.

Given a field $\mathbb{K}$, we add an "ideal point" ∞, not in $\mathbb{K}$, to get $\mathbb{K}_\infty := \mathbb{K} \cup \{\infty\}$.

The proof of the following proposition is left to the reader.

Proposition 3.10.6. *The map* $\Psi \colon \mathbb{P}^1_{\mathbb{K}} \to \mathbb{K}_\infty$ *given by*

$$\Psi([z,w]) = \begin{cases} z/w & \text{if} \quad w \neq 0 \\ \infty & \text{if} \quad w = 0 \end{cases}$$

is a bijection.

The inverse $\Psi^{-1} \colon \mathbb{K}_\infty \to \mathbb{P}^1_{\mathbb{K}}$ *is given by* $z \mapsto [z,1]$ *for* $z \neq \infty$ *and* $\infty \mapsto [1,0]$. ☐

Exercise 3.10.7. Let X and Y be arbitrary sets. If $f \colon X \to X$ is a bijection and if $\varphi \colon X \to Y$ is a bijection, the map $\varphi \circ f \circ \varphi^{-1} \colon Y \to Y$ is a bijection.

We restrict ourselves to the complex number field $\mathbb{C}$.

Any bijection of $\mathbb{P}^1_{\mathbb{C}}$ induces a bijection of $\mathbb{C}_\infty$ by the above exercise. In particular, for $A = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in PGL(2,\mathbb{C})$, the map $f_A \colon \mathbb{P}^1_{\mathbb{C}} \to \mathbb{P}^1_{\mathbb{C}}$ induces a bijection $F_A : \mathbb{C}_\infty \to \mathbb{C}_\infty$. Now we would like to write down the map F_A explicitly.

By Exercise 3.10.7, the map $F_A = \Psi \circ f_A \circ \Psi^{-1}$.

Let $z \neq \infty$. Then $\Psi^{-1}(z) = [z, 1]$. This point $[z, 1]$ is mapped by f_A to $[A(z, 1)] = [az + b, cz + d]$. The map Ψ sends the point $[az + b, cz + d]$ to $(az + b)/(cz + d)$, if $cz + d \neq 0$.

Similarly, one shows that $F_A(\infty) = a/c$ and $F_A(-d/c) = \infty$. To summarize, for $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in GL(2, \mathbb{C})$, the map F_A is given as follows:

$$F_A(z) = \begin{cases} \frac{az+b}{cz+d} & \text{if} \quad z \in \mathbb{C},\, z \neq -\frac{d}{c} \\ \infty & \text{if} \quad z = \frac{-d}{c} \\ a/c & \text{if} \quad z = \infty. \end{cases} \tag{3.10.1}$$

The map $F_A \colon \mathbb{C}_\infty \to \mathbb{C}_\infty$ is called the *fractional linear transformation*, (bilinear transformation, Möbius transformation) associated with A. Note that given complex numbers a, b, c and d such that $ad - bc \neq 0$, we can define a map $\varphi \colon \mathbb{C}_\infty \to \mathbb{C}_\infty$ just by (3.10.1) without introducing $\mathbb{P}^1_{\mathbb{C}}$.

Exercise 3.10.8. For what $A \in$ PGL $(2, \mathbb{C})$, do we have $f_A(\infty) = \infty$?

Remark 3.10.9. All the analysis above goes through if we replace $\mathbb{C}$ by any field $\mathbb{K}$.

Remark 3.10.10. There are three classes of elementary fractional linear transformations: The translation $z \mapsto z + b$, the multiplication by a nonzero scalar $z \mapsto az$ (which is geometrically magnification by $|a|$ and a rotation by $e^{i\theta}$ if $a = |a|e^{i\theta}$) and the inversion $z \mapsto 1/z$. In fact, any fractional linear transformation can be written as a composite of these three. To see this observe that

$$\varphi(z) = \frac{az + b}{cz + d} = \frac{a}{c} + \frac{bc - ad}{c^2} \frac{1}{z + (d/c)}.$$

(Hint: Division of polynomials!) Thus φ is given by

$$\begin{aligned} z &\mapsto w_1 = z + (d/c) \\ w_1 &\mapsto w_2 = \frac{1}{w_1} = \frac{1}{z + (d/c)} \\ w_2 &\mapsto w_3 = \frac{bc - ad}{c^2} w_2 = \frac{bc - ad}{c^2} \frac{1}{z + (d/c)} \\ w_3 &\mapsto w_4 = \frac{a}{c} + w_3 = \frac{a}{c} + \frac{bc - ad}{c^2} \frac{1}{z + (d/c)}. \end{aligned}$$

We claim that given three distinct points x_1, x_2 and x_3 in $\mathbb{A}^1_{\mathbb{K}} \subseteq \mathbb{P}^1_{\mathbb{K}}$, there exists a unique A in $PGL(2, \mathbb{K})$ such that $\Psi_A(x_1) = 0$, $\Psi_A(x_2) = 1$ and $\Psi_A(x_3) = \infty$. If such an A exists, then

1. $\Psi_A(x_1) = 0$ iff $ax_1 + b = 0$ iff $b = -ax_1$.
2. $\Psi_A(x_3) = \infty$ iff $cx_3 + d = 0$ iff $d = -cx_3$.
3. $\Psi_A(x_2) = 1$ iff $ax_2 + b = cx_2 + d$. Now by substituting the values of b and d in terms of x_1 and x_3, we see that $ax_2 + b = cx_2 + d$ iff $a(x_2 - x_1) = c(x_2 - x_3)$. Hence $c = \dfrac{a(x_2 - x_1)}{(x_2 - x_3)}$.

Therefore

$$\begin{aligned}\Psi_A(x) &= \frac{ax+b}{cx+d} \\ &= \frac{ax - ax_1}{\frac{a(x_2-x_1)}{x_2-x_3}x - \frac{a(x_2-x_1)}{x_2-x_3}x_3} \\ &= \frac{(x-x_1)(x_2-x_3)}{(x_2-x_1)(x-x_3)} \\ &= \frac{(x-x_1)(x_2-x_3)}{(x-x_3)(x_2-x_1)}.\end{aligned}$$

This shows that the required matrix A is given by

$$A = \begin{pmatrix} x_2 - x_3 & -(x_2 - x_3)x_1 \\ x_2 - x_1 & -x_3(x_2 - x_1) \end{pmatrix}.$$

As a mnemonic short-cut, we arrive at the above formula as follows. Since x_1 should go to zero, we need a term of the form $(x - x_1)$. Since x_2 should go to 1, this expression is modified as $(x-x_1)/(x_2-x_1)$. Now, x_3 should go to ∞. To achieve this, we need the reciprocal of $x - x_3$. Thus we get an expression of the form

$$\left(\frac{x - x_1}{x_2 - x_1}\right)\left(\frac{1}{x - x_3}\right).$$

Under this $x_1 \mapsto 0$ and $x_3 \mapsto \infty$. To ensure $x_2 \mapsto 1$, we modify this as

$$\left(\frac{x - x_1}{x_2 - x_1}\right)\left(\frac{x_2 - x_3}{x - x_3}\right).$$

Since the points x_1, x_2 and x_3 are all distinct,

$$\det(A) = (x_2 - x_3)(x_2 - x_1)(x_1 - x_3)$$

is non-zero. Hence A is nonsingular. We denote $\Psi_A(x)$ by $[x_1, x_2, x_3; x]$ and call this element in $\mathbb{K}$ as the *cross-ratio* of the point x with respect to (x_1, x_2, x_3).

Theorem 3.10.11. *The two definitions of cross-ratio are equivalent.*

Proof. Let P_i for $1 \leq i \leq 3$ be three distinct points in $\mathbb{P}^1_{\mathbb{K}}$. Let P be an arbitrary point in $\mathbb{P}^1_{\mathbb{K}}$. We want to show that $(P_1, P_2, P_3, P) = [P_1, P_2, P_3; P]$.

Let us first compute the cross-ratio of P with respect to the triple (P_1, P_2, P_3) according to the first definition. Let $P_1 = \mathbb{K}u_1$, $P_2 = \mathbb{K}u_2$ and $P_3 = \mathbb{K}(u_1 + u_2)$. Then, if $P = \mathbb{K}(xu_1 + yu_2)$, according to the first definition, the cross-ratio $(P_1, P_2, P_3; P) = x/y$.

Let us now consider the standard frame $Q_1 = \mathbb{K}e_1$, $Q_2 = \mathbb{K}e_2$ and $Q_3 = \mathbb{K}(e_1 + e_2)$. Let us now compute the cross-ratio $(Q_1, Q_2, Q_3; P_i)$ and $(Q_1, Q_2, Q_3; P)$ according to the first definition.

Let $P_1 = \mathbb{K}(t_1e_1 + e_2) = \mathbb{K}u_1$, $P_2 = \mathbb{K}(t_2e_1 + e_2) = \mathbb{K}u_2$ and $P_3 = \mathbb{K}(t_3e_1 + e_2) = \mathbb{K}(u_1 + u_2)$. Let us also write $P = \mathbb{K}(te_1 + e_2)$.

If we now show that $t = x/y$, then we are through. First notice that

$$u_1 = a(t_1e_1 + e_2) \tag{3.10.2}$$

$$u_2 = b(t_2e_1 + e_2) \tag{3.10.3}$$

for some non-zero scalars a and b in $\mathbb{K}$. Now, since $P = \mathbb{K}(te_1 + e_2) = \mathbb{K}(xu_1 + yu_2)$, we see that

$$\begin{aligned} te_1 + e_2 &= \alpha(xu_1 + yu_2) && (3.10.4)\\ &= \alpha(x(a(t_1e_1 + e_2)) + y(b(t_2e_1 + e_2))) && (3.10.5)\\ &= \alpha(xat_1 + ybt_2)e_1 + \alpha(xa + yb)e_2. && (3.10.6)\end{aligned}$$

Since e_1 and e_2 form a basis of $\mathbb{K}^2$, it follows that

$$\begin{aligned} t &= xat_1 + ybt_2 && (3.10.7)\\ 1 &= xa + yb. && (3.10.8)\end{aligned}$$

Hence, using (3.10.8) we can write (3.10.7) as

$$\begin{aligned} \alpha(xat_1 + ybt_2) &= \alpha t(xa + yb)\\ &= \alpha txa + \alpha tyb. && (3.10.9)\end{aligned}$$

We can re-write (3.10.9) as

$$\frac{x}{y}a(t_1 - t) + b(t_2 - t) = 0. \tag{3.10.10}$$

It can be further simplified to

$$\frac{x}{y} = \frac{b}{a}\frac{t - t_2}{t_1 - t}. \tag{3.10.11}$$

Therefore, if we can compute the ratio b/a in terms of the t_i's and t, then we will have an expression for x/y involving only the t_i's and we hope that it will yield a proof.

Since $t_3e_1 + e_2 \in \mathbb{K}(u_1 + u_2) = P_3$, there exists a non-zero scalar β such that $t_3e_1 + e_2 = \beta(u_1 + u_2)$. Therefore

$$\begin{aligned} t_3e_1 + e_2 &= \beta(u_1 + u_2) \\ &= \beta[a(t_1e_1 + e_2) + b(t_2e_1 + e_2)] \\ &= \beta[(at_1 + bt_2)e_1 + (a + b)e_2]. \end{aligned} \tag{3.10.12}$$

Again using the fact that the vectors e_1 and e_2 form a basis of $\mathbb{K}^2$, we get from (3.10.12) that $\beta(a + b) = 1$ and $\beta(at_1 + bt_2) = t_3$. Now

$$\begin{aligned} \beta\left((at_1 + bt_2) + (a + b)\right) &= t_3 \\ &= t_3\beta(a + b) \quad \text{and} \\ \beta\left(a(t_1 - t_3) + b(t_2 - t_3)\right) &= 0. \end{aligned} \tag{3.10.13}$$

Since $\beta \neq 0$, we get from (3.10.13) that $a(t_1 - t_3) + b(t_2 - t_3) = 0$. Hence

$$\frac{b}{a} = \frac{t_1 - t_3}{t_3 - t_2}. \tag{3.10.14}$$

Substituting this ratio in (3.10.11) we get

$$\frac{x}{y} = \frac{(t - t_2)(t_1 - t_3)}{(t - t_1)(t_2 - t_3)}. \tag{3.10.15}$$

This completes the proof. □

Exercise 3.10.12. Let $A = \mathbb{K}a$, $B = \mathbb{K}b$ and $C = \mathbb{K}c$, where $c = a + b$, be three distinct points in $\mathbb{P}^1_{\mathbb{K}}$. Let D be any other point in $\mathbb{P}^1_{\mathbb{K}}$. Then we know that the cross-ratio $(A, B, C; D) = \lambda$ where $D = \mathbb{K}(\lambda a + b)$. Show that

1. $(B, A, C; D) = 1/\lambda$,
2. $(C, B, A; D) = \lambda/(1 - \lambda)$,
3. $(A, C, B; D) = \lambda - 1$,
4. $(B, C, A; D) = (1 - \lambda)/\lambda$ and
5. $(C, A, B; D) = 1/(\lambda - 1)$.

Lemma 3.10.13. *If* φ *is a fractional linear transformation and if* z_k*,* $1 \leq k \leq 4$ *are distinct points of* $\mathbb{K}_\infty$*, then*

$$(z_1, z_2, z_3; z_4) = (\varphi(z_1), \varphi(z_2), \varphi(z_3); \varphi(z_4)).$$

That is, the cross-ratio is invariant under fractional linear transformations.

Proof. By using Remark 3.10.10, it suffices to show that the cross-ratio is invariant under elementary fractional linear transformations. This is easy to verify and left to the reader. $\square$

3.11 Projective Completion of Conics

Given a conic C in $\mathbb{A}^2_{\mathbb{R}}$, we look at its image in the projective completion $\mathbb{P}^2_{\mathbb{R}}$ of $\mathbb{A}^2_{\mathbb{R}}$. We denote this conic by C^*. The image will again be a conic, which might have some extra points. So first we set up an algebraic correspondence and then understand the geometric meaning of this completion. We show that the extra points in $\mathbb{P}^2_{\mathbb{R}}$ of the completed conic are the limiting directions of the tangent lines at points on the affine part of the conic as we move along the conic towards infinity.

Let us start with an example to illustrate what we are going to do.

Example 3.11.1. Let ℓ be a line through origin in $\mathbb{A}^2_{\mathbb{R}}$. Then the image of this curve has only one extra point in $\mathbb{P}^2_{\mathbb{R}}$; namely the point at ∞, which as we saw in the completion of $\mathbb{A}^2_{\mathbb{R}}$, can be viewed as the direction vector of the line ℓ. This fact is also geometrically obvious as a line ℓ has the same direction at any of its points.

As a concrete case let us look at the x-axis which we denote by ℓ. Its homogeneous equation is $y = 0$. In $\mathbb{P}^2_{\mathbb{R}}$, the projective completion of $\mathbb{A}^2_{\mathbb{R}}$, the image of all the points that lie on the line $\{(x, 0)\}$ will have homogeneous coordinates $[x, 0, 1]$. They lie on the line ℓ^* and the extra point that lies on ℓ^* is given by $\{y = 0\} \cap \{z = 0\}$ in $\mathbb{P}^2_{\mathbb{R}}$. We easily see that $[1, 0, 0]$ is the only extra point.

Definition 3.11.2. A *conic* C in $\mathbb{A}^2_{\mathbb{R}}$ is given by the solution of an equation of the form $\langle Ax, x\rangle + \langle b, x\rangle + c = 0$, where A is a 2×2 symmetric matrix and b is a point in $\mathbb{A}^2_{\mathbb{R}}$ and c is a real number; and $\langle .,. \rangle$ is the usual dot product in $\mathbb{R}^2$.

The projective completion of the conic C in $\mathbb{P}^2_{\mathbb{R}}$ is got by "homogenising" the equation $\langle Ax, x\rangle + \langle b, x\rangle + c = 0$. It is also denoted by C^*. We will explain this further: Let $P = [x, y, z]$ with $z \neq 0$ be a point in $\mathbb{P}^2_{\mathbb{R}}$.

Jason became fascinated with number Pi, irrational number that is

"a fundamental building block of everything around me, a signifier of nature's perfect symmetry".

Struck by Genius

A geometria do pi é tecida no espaço-tempo

Sempre achei que a geometria de Pi descrevia anéis Einstein (também conhecidos como lentes gravitacionais).

the geometry of Pi

A geometria do pi é tecida no espaço-tempo e é impressionantemente bonita e é encontrada às vezes em lugares surpreendentes.

Sempre achei que a geometria de Pi descrevia anéis Einstein (também conhecidos como lentes gravitacionais), mas parece estar relacionado com estes novos objetos também.

The geometry of Pi is woven into spacetime and it is stunningly beautiful and it is found sometimes in surprising places.

I've always thought the geometry of Pi described Einstein rings

(aka gravitational lensing), but it seems to be related to these new objects also.

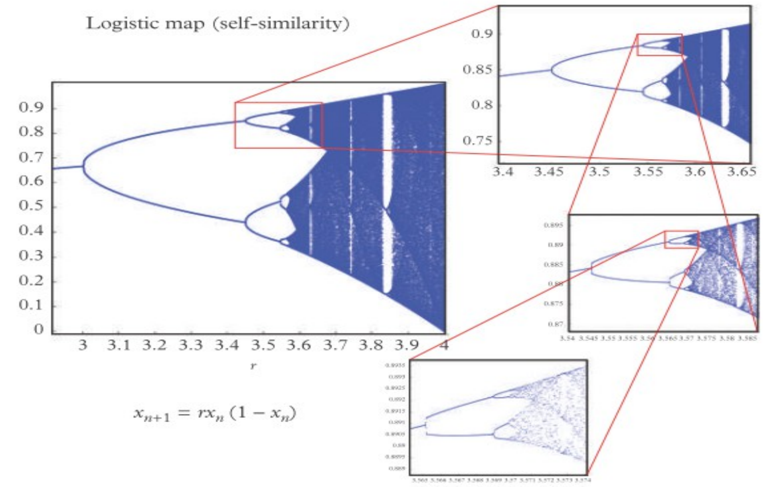

Figure 4.15 *Bifurcation diagram of the logistic map. The sub-areas are self-similar, with the same features appearing as for the larger scale.*

4.4.2 Feigenbaum number and universality

The logistic map is only one of a virtually limitless number of iterated maps. Each different mapping function produces a different graphical solution with different bifurcation cascades. But if every nonlinear system is different, then what type of over-arching principles can be applied to chaos? The answer is that there are common themes among wide classes of nonlinear systems, including quantitative similarities that in some cases become identities. For instance, the logistic map has an inverted quadratic dependence represented by the parabola in Fig. 4.14. One of the discoveries in the field of chaos was the universal behavior of the bifurcation cascade for *every* iterated map that has a lowest-order quadratic dependence (Fig. 4.16). The bifurcation thresholds of r have a fixed ratio in the limit as the bifurcations approach chaos,

$$\delta = \lim_{n\to\infty} \frac{S_{n+2} - S_{n+1}}{S_{n+1} - S_n} = 4.669201609102990671853203 82$$

This Feigenbaum ratio is the same for all quadratic maps (which tend to be the most common). Therefore, in the face of the apparent randomness of chaotic systems, universals do emerge.

4.5 Three-dimensional state space and chaos

The character of nonlinear dynamical systems changes dramatically when going from 2D to 3D state space. Dynamical systems are subject to the no-crossing

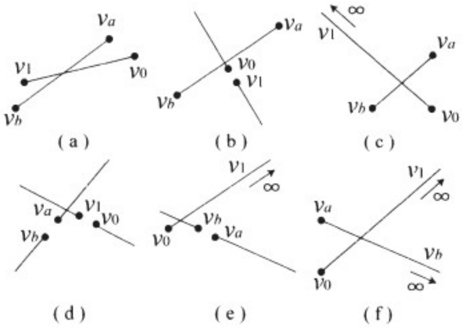

Figure 1.7: Six cases of line segment intersections.

Since a line segment could be transformed into three shapes (Fig. 1.5), and a triangle into five shapes (Fig. 1.6), by a general projective transformation, we have to make $3\times 2=6$ (Fig. 1.7) or $3\times 5=15$ separate routines respectively to cover all the possible cases.

In actual processing, the three types of line segments must each be treated with separate mathematical expressions. For instance, if we denote two endpoint vectors by $\boldsymbol{v}_0$ and $\boldsymbol{v}_1$, we can write as follows:

$$\text{Internal line segment}: \boldsymbol{v} = (1-t)\boldsymbol{v}_0 + t\boldsymbol{v}_1, \qquad (0 \le t \le 1), \quad (1.11)$$

$$\text{Half line}: \boldsymbol{v} = \boldsymbol{v}_0 + \boldsymbol{\alpha}t, \qquad (t \ge 0), \quad (1.12)$$

$$\text{External line segment}: \boldsymbol{v} = \boldsymbol{v}_0 + \boldsymbol{\alpha}t,\ \boldsymbol{v} = \boldsymbol{v}_1 - \boldsymbol{\alpha}t, \quad (t \ge 0). \quad (1.13)$$

In the package, the program, first of all, has to test among all the possible cases which the present case is and pass the control to a corresponding routine. This is not an easy task again. Thus, a seemingly simple problem becomes highly complex by the time a complete program is written.

1.4 Problems of Rational Curves and Surfaces

Because of the high representational capabilities, rational polynomial curves and surfaces are becoming standard descriptions in computer aided geometric design systems.

In dealing with a rational polynomial curve or surface, however, we come across various difficulties.

First, a rational polynomial curve does not allow us to generate an exact point on the curve corresponding to a parameter value because it forces to perform division operations in computing the rational expression itself. Therefore in reality an exact point can not generally be obtained, for example, from a quadratic rational polynomial curve although it is an exact expression of conics.

Second, as mentioned in Section 1.2, the geometric Newton-Raphson method sometimes fails when it is applied to a rational polynomial curve while it does not when applied to an ordinary one.

Third, formulas and algorithms tend to be more complex than those for an ordinary polynomial curve. The projective transformation of the curve is this complex and is not linear with respect to the position vector $\boldsymbol{p}(t)$:

$$\boldsymbol{p}^*(t) = \frac{\boldsymbol{p}(t)\begin{bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{bmatrix} + [t_x\ t_y\ t_z]}{px + qy + rz + s}. \tag{1.14}$$

There are many other formulas and algorithms for rational polynomial curves which take much more complex forms than those for ordinary ones.

Fourth, there is a strict sign restriction on weights w_i, i.e., the signs of w_i must not be mixed in the processing of a rational polynomial curve because various inconveniences, such as non-convex hull property, zero denominator of tangent vectors and so on, may arise if the restriction is not observed. This restriction drastically reduces the high representational capability of rational polynomial curves and surfaces.

Suppose $\boldsymbol{q}_0$, $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ define an ellipse (Fig. 1.8). The negation of the weight of $\boldsymbol{q}_1$ generates its complementary segment. This is a simple way of generating a whole curve. This curve segment is, however, not allowed for processing because the signs of the weights of the control vertices are mixed.

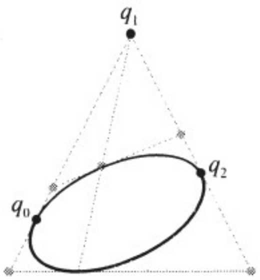

Figure 1.8: Complementary segment.

1.5 Root Cause of All Evil

We have so far pointed out various types of problems inherent in the conventional processing. Let us consider the cause of each problem in the order presented above.

As for the example of non-exactness, it is evident that the cause of non-exactness in the pentagon problem lies in performing the division operations to generate Euclidean coordinates.

In the case of the non-robustness problem of the Newton-Raphson method applied to rational curves and surfaces, it is also self-evident that the cause of the non-robustness lies in the divisional expression of the rational curves and surfaces because this type of non-robustness does not arise when it is applied to ordinary polynomial curves and surfaces.

Figure 1.9: Three types of line segments.

As for the example of non-compactness, the cause may be a little difficult to find out. Let us consider this way; the three types of line segments are the cuts of wedge-shaped planes with the apexes at the origin of three-space O-wXY (Fig. 1.9). Then we understand that the three types of line segments are the results of division operations, and that division operations could cause to increase the number of shape types of a geometric element.

In Section 1.4, we listed up various problems inherent in the processing of rational curves and surfaces. Because these do not appear in the ordinary curves and surfaces, it is evident that the divisional forms of rational curves and surfaces are the causes of these problems.

Considering the discussion above, it does not seem to be difficult for us to conclude that these problems are caused by division operations. Thus we say that *"the division operation is the root cause of all evil."* (This will be borne out by various test results shown in Chapter 25) This observation invites us to consider the data set immediately before division operations, that is, the denominator w and the numerators X, Y, Z as coordinates of a point in place of the coordinates $(x, y, z) = (X/w, Y/w, Z/w)$. While the post-division data set is called *ordinary coordinates* or *Euclidean coordinates*, the pre-division data set (w, X, Y, Z) is called *homogeneous coordinates.*

It is now the time to study homogeneous coordinates.

of $f(x_{i+1})$:

$$f(x_{i+1}) = f(x_i + \delta x) = f(x_i) + \frac{\dot{f}(x_i)}{1!}\delta x + \frac{\ddot{f}(x_i)}{2!}(\delta x)^2 + \dots. \tag{15.2}$$

Setting $f(x_{i+1})=0$ yields:

$$\delta x = -\frac{f(x_i)}{\dot{f}(x_i)}. \tag{15.3}$$

Thus,

$$x_{i+1} = x_i - \frac{f(x_i)}{\dot{f}(x_i)}. \tag{15.4}$$

Determination of the roots of an equation using eq.(15.4) is called the *Newton-Raphson method* (Fig. 15.1). Highly accurate solutions can be obtained efficiently with this method.

The application of the Newton-Raphson method to determination of intersections between geometric elements is often called the *geometric Newton-Raphson method*, which we are dealing with in this chapter.

15.2 Conventional Euclidean Approach

To illustrate the conventional geometric Newton-Raphson method, where processing takes place in Euclidean space, we consider the problem of finding the intersection point between a plane curve and a line segment. We shall consider the cases for ordinary and rational polynomial curves separately.

Ordinary Polynomial Curve Case

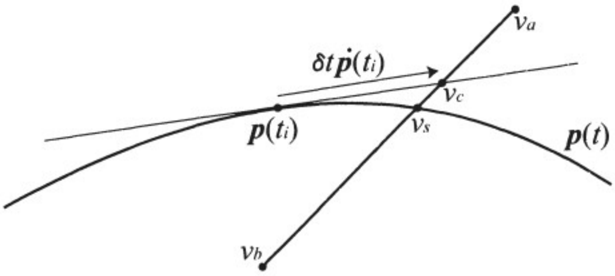

Figure 15.2: Determining intersection point of curve and line segment.

We use the Newton-Raphson method to find the intersection of an ordinary parametric polynomial plane curve (Fig. 15.2):

$$\boldsymbol{p}(t) = [x(t) \;\; y(t)]$$

and a line segment $v_a v_b$, where

$$\boldsymbol{v}_a = [x_a \;\; y_a], \quad \boldsymbol{v}_b = [x_b \;\; y_b].$$

The basic algorithm is as follows:

1. Specify $i = 0$ and an approximate parameter $t = t_0$ to the intersection point.
2. Determine the tangent at $p(t_i)$ on the curve and then find its intersection point with the other geometric element.
3. An increment δt is determined from the intersection point.
4. Increase the parameter t_i by δt, and return to step 2.

The tangent line of the curve at $p(t_i)$ is given by:

$$-\dot{y}(t_i)x + \dot{x}(t_i)y + x(t_i)\dot{y}(t_i) - \dot{x}(t_i)y(t_i) = 0. \tag{15.5}$$

Meanwhile, the line equation for the line segment $v_a v_b$ is given by:

$$(y_a - y_b)x - (x_a - x_b)y + x_a y_b - x_b y_a = 0. \tag{15.6}$$

The intersection point v_c of these two lines is then obtained as:

$$\begin{aligned} x_c &= \frac{\begin{vmatrix} \dot{x}(t_i) & x(t_i)\dot{y}(t_i) - \dot{x}(t_i)y(t_i) \\ x_b - x_a & x_a y_b - x_b y_a \end{vmatrix}}{\begin{vmatrix} \dot{x}(t_i) & \dot{y}(t_i) \\ x_b - x_a & y_b - y_a \end{vmatrix}}, \\ y_c &= \frac{\begin{vmatrix} \dot{y}(t_i) & x(t_i)\dot{y}(t_i) - \dot{x}(t_i)y(t_i) \\ y_b - y_a & x_a y_b - x_b y_a \end{vmatrix}}{\begin{vmatrix} \dot{x}(t_i) & \dot{y}(t_i) \\ x_b - x_a & y_b - y_a \end{vmatrix}}. \end{aligned} \tag{15.7}$$

Now, $\boldsymbol{v}_c$, $\boldsymbol{p}(t_i)$, $\dot{\boldsymbol{p}}(t_i)$ and the parameter increment δt have the following relation:

$$\boldsymbol{v}_c - \boldsymbol{p}(t_i) = \delta t \dot{\boldsymbol{p}}(t_i). \tag{15.8}$$

So we can determine the increment δt from either the expression for x- or y-coordinate above as:

$$\delta t = -\frac{\begin{vmatrix} x(t_i) - x_a & y(t_i) - y_a \\ x_b - x_a & y_b - y_a \end{vmatrix}}{\begin{vmatrix} \dot{x}(t_i) & \dot{y}(t_i) \\ x_b - x_a & y_b - y_a \end{vmatrix}}. \tag{15.9}$$

There is another more general, simpler method to determine δt, which will be useful in later discussions.

First we express the line segment in a parametric form as:

$$\boldsymbol{v}(u) = (1 - u)\boldsymbol{v}_a + u\boldsymbol{v}_b, \quad 0 \le u \le 1. \tag{15.10}$$

If an intersection exists between the curve and line segment, then the following is satisfied at that point:

$$\boldsymbol{p}(t) = \boldsymbol{v}(u).$$

Now, if t_i and u_i are sufficiently close to the intersection point, then there exist δt and δu such that the following equation holds:

$$\boldsymbol{p}(t_i + \delta t) = \boldsymbol{v}(u_i + \delta u). \tag{15.11}$$

Applying the Taylor expansion to both sides and extracting up to the first-order term, we obtain:

$$\begin{aligned} \boldsymbol{p}(t_i) + \delta t \dot{\boldsymbol{p}}(t_i) &\doteqdot \boldsymbol{v}(u_i) + \delta u \dot{\boldsymbol{v}}(u_i) \\ &= (1 - u_i - \delta u)\boldsymbol{v}_a + (u_i + \delta u)\boldsymbol{v}_b. \end{aligned} \tag{15.12}$$

This shows that $\boldsymbol{p}(t_i)+\delta t \dot{\boldsymbol{p}}(t_i)$, $\boldsymbol{v}_a$ and $\boldsymbol{v}_b$ are linearly dependent, so:

$$\begin{vmatrix} 1 & x(t_i) + \delta t \dot{x}(t_i) & y(t_i) + \delta t \dot{y}(t_i) \\ 1 & x_a & y_a \\ 1 & x_b & y_b \end{vmatrix} = 0. \tag{15.13}$$

Solving this for δt yields the same expression as eq.(15.9).

Rational Polynomial Curve Case

Consider now a rational curve given by:

$$\boldsymbol{p}(t) = [x(t) \;\; y(t)] = [\frac{X(t)}{w(t)} \;\; \frac{Y(t)}{w(t)}]. \tag{15.14}$$

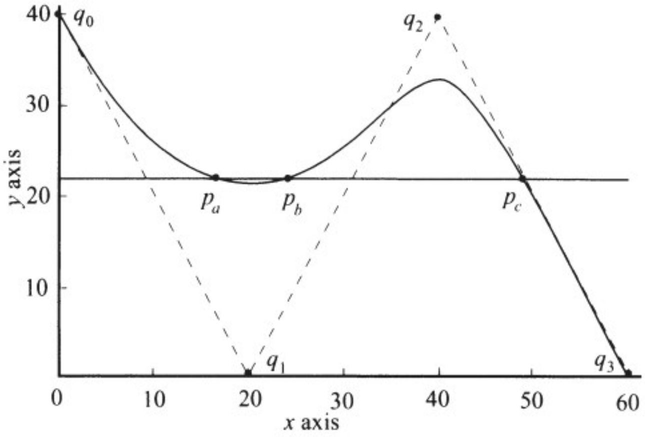
From this, the expression for δt can be obtained in the same manner as for the ordinary polynomial curve above, or:

$$\delta t = -\frac{\begin{vmatrix} \frac{X(t_i)}{w(t_i)} - x_a & \frac{Y(t_i)}{w(t_i)} - y_a \\ x_b - x_a & y_b - y_a \end{vmatrix}}{\begin{vmatrix} \frac{\dot{X}(t_i)w(t_i) - X(t_i)\dot{w}(t_i)}{w(t_i)^2} & \frac{\dot{Y}(t_i)w(t_i) - Y(t_i)\dot{w}(t_i)}{w(t_i)^2} \\ x_b - x_a & y_b - y_a \end{vmatrix}}. \tag{15.15}$$

If we let $w(t_i) = 1$ above, we obtain the same expression as eq.(15.9).

We now rewrite eq.(15.15) using 3×3 determinants as follows:

$$\delta t = -\frac{\begin{vmatrix} 1 & x_a & y_a \\ 0 & \frac{X(t_i)}{w(t_i)} - x_a & \frac{Y(t_i)}{w(t_i)} - y_a \\ 0 & x_b - x_a & y_b - y_a \end{vmatrix}}{\begin{vmatrix} 1 & x_a & y_a \\ 0 & \frac{\dot{X}(t_i)w(t_i) - X(t_i)\dot{w}(t_i)}{w(t_i)^2} & \frac{\dot{Y}(t_i)w(t_i) - Y(t_i)\dot{w}(t_i)}{w(t_i)^2} \\ 0 & x_b - x_a & y_b - y_a \end{vmatrix}}$$



$$\boldsymbol{q}_0 = [0 \;\; 40], \quad \boldsymbol{q}_1 = [20 \;\; 0], \quad \boldsymbol{q}_2 = [40 \;\; 40], \quad \boldsymbol{q}_3 = [60 \;\; 0],$$
$$w_0 = 1, \qquad w_1 = 3, \qquad w_2 = 9, \qquad w_3 = 1.$$

Figure 15.3: Intersection of curve and line segment.

$$= -\frac{\begin{vmatrix} 1 & \frac{X(t_i)}{w(t_i)} & \frac{Y(t_i)}{w(t_i)} \\ w_a & X_a & Y_a \\ w_b & X_b & Y_b \end{vmatrix}}{\begin{vmatrix} 0 & \frac{\dot{X}(t_i)w(t_i) - X(t_i)\dot{w}(t_i)}{w(t_i)^2} & \frac{\dot{Y}(t_i)w(t_i) - Y(t_i)\dot{w}(t_i)}{w(t_i)^2} \\ w_a & X_a & Y_a \\ w_b & X_b & Y_b \end{vmatrix}}. \tag{15.16}$$

15.3 Problems with Euclidean Approach

Problems arise when the conventional method, based on eq.(15.16), is used to process rational polynomial curves. These are now discussed.

A non-robust example was given in Section 1.2 (Fig. 15.3). As Table 15.1 shows for this case, the parameter converges when given the initial value of 0.5, but diverges out to infinity from an initial value of, say, 0.7. That is, the robustness of the algorithm is lost. Convergence to the roots depends on initial values.

Note that this non-robust phenomenon does not arise when the geometric Newton-Raphson method is applied to an ordinary polynomial curve, and that the non-robustness occurs even when the w-values of the control points of the

12.0 General assumption. Throughout this section, $\mathbb{F}$ shall denote one of the Cayley–Dickson division algebras $\mathbb{R}$, $\mathbb{C}$, $\mathbb{H}$, or $\mathbb{O}$.

12.1 The affine plane $\mathscr{A}_2\mathbb{F}$ over $\mathbb{F}$ is constructed as follows. The set of points is $\mathbb{F} \times \mathbb{F}$, and the following subsets of $\mathbb{F} \times \mathbb{F}$ are called lines:

$$\begin{aligned} [s,t] &= \{\,(x, sx+t) \mid x \in \mathbb{F}\,\} \quad \text{for } s,t \in \mathbb{F}\,, \\ [c] &= \{c\} \times \mathbb{F} \quad \text{for } c \in \mathbb{F}\,. \end{aligned}$$

We say that the line $[s,t]$ has *slope* s, and the line $[c]$ has *slope* ∞.

Because $\mathbb{F}$ is a division algebra, it is easily verified that this structure has the following properties:

1) For two points $(x_1, y_1) \neq (x_2, y_2)$ there is a unique line joining them (i.e., containing both of them), namely the line $[s, y_1 - sx_1]$, where s is uniquely determined by the equation

$$s(x_2 - x_1) = y_2 - y_1 \tag{1}$$

if $x_1 \neq x_2$, and the line $[x_1]$ if $x_1 = x_2$.

2) Two lines of different slopes have a unique point of intersection. In fact, we have $[c] \cap [s,t] = \{\,(c, sc+t)\,\}$, and for $s_1 \neq s_2$ we have $[s_1, t_1] \cap [s_2, t_2] = \{\,(x, s_1x + t_1)\,\}$, where x is uniquely determined by the equation

$$(s_1 - s_2)x = t_2 - t_1\,. \tag{2}$$

3) Two different lines are disjoint if they have the same slope, and by property 2) this condition is also necessary. Two lines will be called *parallel* if they have the same slope, i.e., if they are disjoint or equal.

4) The so-called *parallel axiom* holds: For each line L and each point (x, y), there is a unique line which passes through (x, y) and is parallel to L. Depending on whether the slope of L is ∞ or $s \in \mathbb{F}$, this parallel is given by $[x]$ or by $[s, y - sx]$, respectively.

Properties 1) – 4) say that $\mathscr{A}_2\mathbb{F}$ satisfies the axioms of an *affine plane*, see (21.8).

Since $\mathbb{F}$ is biassociative (11.11 and 13), the solutions of equations (1) and (2) may be written down explicitly as

$$s = (y_2 - y_1)(x_2 - x_1)^{-1} \tag{1'}$$

$$x = (s_1 - s_2)^{-1}(t_2 - t_1)\,. \tag{2'}$$

12.2 The projective completion $\overline{\mathscr{A}_2}\mathbb{F}$ of the affine plane $\mathscr{A}_2\mathbb{F}$ is obtained by adjoining 'points at infinity', one for each parallel class. All the lines of the parallel class are thought to intersect in the respective point at infinity. Furthermore, one adds a 'line at infinity' passing through just these points at infinity.

For $s \in \mathbb{F} \cup \{\infty\}$, the point at infinity on the lines of slope s (which form a parallel class) will be denoted by (s), and the line at infinity is

$$[\infty] := \{\, (s) \mid s \in \mathbb{F} \cup \{\infty\} \,\} \ .$$

By this construction, we obtain a geometry in which any two lines $L_1 \neq L_2$ always have a unique point of intersection $L_1 \wedge L_2$. (If L_1, L_2 are lines of the affine plane $\mathscr{A}_2\mathbb{F}$, their intersection point in the projective completion $\overline{\mathscr{A}_2}\mathbb{F}$ is a point at infinity if, and only if, in $\mathscr{A}_2\mathbb{F}$ the lines L_1, L_2 are parallel.) The property that for any two points $p_1 \neq p_2$ there is a unique line $p_1 p_2$ joining them is preserved in this extension process. Thus, the projective completion $\overline{\mathscr{A}_2}\mathbb{F}$ is a *projective* plane in the sense of definition (21.1).

Of course, this construction applies quite generally to any affine plane, see Hughes–Piper [73] Theorem 3.10, p. 83.

For certain points and lines of the projective completion $\overline{\mathscr{A}_2}\mathbb{F}$, we shall systematically use special names as indicated in the diagram of Figure 12a.

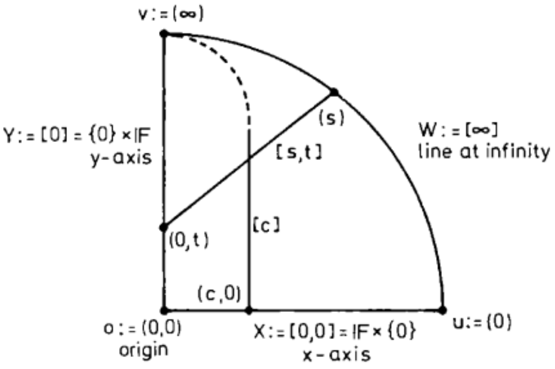

Figure 12a

12.3 Collineations. A *collineation* of an affine or projective plane is a bijection of the set of points onto itself mapping lines onto lines.

As for the latter condition, it suffices to postulate that lines are mapped *into* lines, see (23.2).

A collineation of an affine plane maps every parallel class of lines to a parallel class of lines; one therefore obtains a unique extension to a collineation of the projective completion by permuting the points at infinity accordingly. Conversely, if a collineation of the projective completion leaves the line at infinity invariant, then it arises in this way from an affine collineation. Henceforth, we shall not distinguish between an affine collineation and its projective extension. We remark that, besides these collineations, the projective completion may have collineations which move the line at infinity, cf. (13.5) and (17.6).

It is straightforward that for a collineation φ, for points $p_1 \neq p_2$ and for lines $L_1 \neq L_2$ one has

$$(p_1 p_2)^\varphi = p_1^\varphi p_2^\varphi \quad \text{and} \quad (L_1 \wedge L_2)^\varphi = L_1^\varphi \wedge L_2^\varphi \,.$$

The collineations of a given plane form a group under composition. For a subgroup Δ of this group, for a point p and a line L, the stabilizers Δ_p and Δ_L are the subgroups consisting of all collineations in Δ which fix p or leave L invariant, respectively.

12.4 Axial collineations. We now present a notion which is basic for the study of collineation groups of projective planes, together with some standard results, cf. also (23.7 ff).

(a) Consider a point p and a line L. We say that a collineation φ has *axis* L if φ fixes every point on L; dually, φ has *center* p if φ leaves every line through p invariant. A collineation of a *projective* plane has an axis if, and only if, it has a center (see Hughes–Piper [73] Theorem 4.9, p. 94; in the present chapter, we shall not use this fact). The center may be on the axis or not.

(b) For a group Δ of collineations, $\Delta_{[p,L]}$ denotes the subset of all collineations in Δ with center p and axis L; it is obviously a subgroup. For $\gamma \in \Delta$ one easily verifies the following

Conjugation formula: $\gamma^{-1}\Delta_{[p,L]}\,\gamma = \Delta_{[p^\gamma, L^\gamma]}$,

cf. also (91.1a).

(c) *Uniqueness properties.* A collineation $\delta \in \Delta_{[p,L]}$ having a fixed point q outside $L \cup \{p\}$ must be the identity. Indeed, by joining q to the points of L, one sees that q is a center of δ, too; therefore, every point not on pq is a fixed point, being the intersection of two different lines through the centers p and q, and the same argument applied to such a fixed point instead of q finally shows that $\delta = \mathrm{id}$.

Dually, the only collineation in $\Delta_{[p,L]}$ leaving a line $M \neq L$ with $p \notin M$ invariant is the identity, because then M is an axis as well, its points being the points of intersection of the invariant line M and the invariant lines through the center p.

In particular, if a non-identical collineation has a center and an axis, these are uniquely determined.

We now give concrete descriptions of collineations of $\overline{\mathscr{A}_2\mathbb{F}}$ having a center and an axis. We first deal with such collineations for which center and axis are incident, so-called *elations*. The other case, in which center and axis are not incident, will be taken up later (12.13).

12.5 Proposition: Elations of $\overline{\mathscr{A}_2}\mathbb{F}$.

(a) *The collineations of* $\overline{\mathscr{A}_2}\mathbb{F}$ *having the line at infinity* $W = [\infty]$ *as axis and a center on* W *are precisely the translations*

$$\tau_{a,b} : (x, y) \mapsto (x + a, y + b);\ \ \tau_{a,b}|_W = \mathrm{id}$$

with $a, b \in \mathbb{F}$. *The translation group*

$$\mathsf{T} = \left\{ \tau_{a,b} \;\middle|\; a, b \in \mathbb{F} \right\}$$

is commutative and sharply transitive on the affine point set $\mathbb{F} \times \mathbb{F}$.

(b) *The collineations of* $\overline{\mathscr{A}_2}\mathbb{F}$ *with axis* $Y = [0]$ *and center* $v = (\infty)$ *are precisely the shears*

$$\sigma_a : (x, y) \mapsto (x, y + ax),\ \ (s) \mapsto (s + a),\ \ (\infty) \mapsto (\infty)$$

for $a \in \mathbb{F}$; *they form a commutative group which is sharply transitive on* $W \backslash \{v\}$.

(c) *The collineations of* $\overline{\mathscr{A}_2}\mathbb{F}$ *with axis* $X = [0, 0]$ *and center* $u = (0)$ *are precisely the collineations*

$$\sigma'_a : (x, y) \mapsto (x + ay, y),\ (s) \mapsto ((s^{-1} + a)^{-1}) \quad \textit{for } s \neq 0, -a^{-1},$$
$$(0) \mapsto (0),\ \ (-a^{-1}) \mapsto (\infty),\ \ (\infty) \mapsto (a^{-1})$$

for $a \in \mathbb{F} \setminus \{0\}$ *(together with* $\sigma'_0 = \mathrm{id}$).

Note that (c) is obtained from (b) by conjugation with the following collineation, see the conjugation formula in (12.4b).

12.6. *The reflection*

$$(x, y) \mapsto (y, x),\ (s) \mapsto (s^{-1}) \quad \textit{for } s \neq 0,$$
$$(0) \mapsto (\infty),\ \ (\infty) \mapsto (0)$$

is a collineation of $\overline{\mathscr{A}_2}\mathbb{F}$ *with axis* $[1, 0]$ *and center* (-1).

Proof of (12.5 and 6). 1) We first consider the restrictions of the maps in (12.5a and b) and in (12.6) to the affine plane with point set $\mathbb{F} \times \mathbb{F}$. One may easily verify by direct computation that these restrictions transform affine lines into lines and therefore are collineations of the affine plane $\mathscr{A}_2\mathbb{F}$. For (12.5a and b), this only requires the distributive laws; for (12.6), one also uses biassociativity (11.9). The necessary computations show that lines are mapped as follows:

(1) $$[s, t]^{\tau_{a,b}} = [s, t + b - sa];\quad [c]^{\tau_{a,b}} = [c + a]$$

(2) $$[s, t]^{\sigma_a} = [s + a, t];\quad [c]^{\sigma_a} = [c]\,,$$

and that the reflection of (12.6) interchanges

$$(3)\qquad \begin{array}{lll} [s,t] & \text{with} & [s^{-1}, -s^{-1}t] \quad \text{for } s \neq 0\,, \\ [0,t] & \text{with} & [t]\,. \end{array}$$

The effect of these collineations on the slopes of lines shows that their projective extensions act on the line at infinity W in the specified way.

From (3), one infers that the collineation defined in (12.6) leaves all the lines of slope -1 invariant, so that it has center (-1). It is clear that this collineation has axis $[1,0] = \{\,(x,x) \mid x \in \mathbb{F}\,\}$.

Thus, (12.6) is proved. Concerning (12.5), it now suffices to prove (a) and (b), because (c) then follows from (b), as was noted above.

2) The collineation $\tau_{a,b}$ has axis W. If $a \neq 0$ and if $s \in \mathbb{F}$ is the solution of $sa = b$, then by (1) all the lines $[s,t]$, $t \in \mathbb{F}$, are invariant under $\tau_{a,b}$. Now these are precisely the affine lines through the point (s), so that $\tau_{a,b}$ has center (s). For $a = 0$, the center is (∞), since then all the lines $[c]$ are invariant according to equation (1).

Commutativity of T and transitivity on $\mathbb{F} \times \mathbb{F}$ are obvious. We use a standard transitivity argument in order to show that T contains every collineation with axis W and center p on W. For fixed $p \in W$, the group $\mathsf{A}_{[p,W]}$ of all these collineations contains $\mathsf{T}_{[p,W]}$. Now, for any line $M \neq W$ through p, the latter group is transitive on $M \setminus \{p\}$; indeed, for two different points $q_1, q_2 \in M \setminus \{p\}$, the translation $\tau \in \mathsf{T}$ mapping q_1 to q_2 leaves $M = pq_1 = pq_2$ invariant, so that, by the uniqueness properties (12.4c), the center of τ belongs to M and therefore equals $p = M \wedge W$. Again by the uniqueness properties (12.4c), the group $\mathsf{A}_{[p,W]}$ is now seen to be sharply transitive on $M \setminus \{p\}$, so that $\mathsf{A}_{[p,W]} = \mathsf{T}_{[p,W]}$; see also (23.9). This completes the proof of (12.5a).

3) It is obvious that σ_a has axis $Y = \{0\} \times \mathbb{F}$, and from (2) one sees that all the lines $[c]$ of slope ∞, in other words the lines through $v = (\infty)$, are invariant, so that σ_a has center v. Transitivity of the group $\{\,\sigma_a \mid a \in \mathbb{F}\,\}$ on $W \setminus \{v\}$ is obvious. By the same argument as above, it follows that this group coincides with the group $\mathsf{A}_{[v,Y]}$ of all collineations with axis Y and center v, since the latter group is seen to be sharply transitive on $W \setminus \{v\}$ by virtue of the uniqueness properties (12.4c). Thus, (12.5b) is verified. □

Next, we prove some general statements about collineations having non-collinear fixed points.

12.7 Lemma: Stabilizer of a triangle. *The collineations of* $\overline{\mathcal{A}_2\mathbb{F}}$ *fixing the points* $o = (0,0)$, $u = (0)$, *and* $v = (\infty)$ *are precisely the transformations of the form*

$$(x,y) \mapsto (x^\alpha, y^\beta),\ \ (s) \mapsto (s^\gamma),\ \ (\infty) \mapsto (\infty)$$

with automorphisms α, β, γ *of the additive group of* $\mathbb{F}$ *satisfying*

$$(*) \qquad (sx)^\beta = s^\gamma x^\alpha$$

for all $s, x \in \mathbb{F}$. *In particular, these collineations are completely determined by their actions on the coordinate axes* $\mathbb{F} \times \{0\}$ *and* $\{0\} \times \mathbb{F}$.

Proof. A collineation of this kind leaves the coordinate axes $X = ou$ and $Y = ov$ invariant and maps parallels of X and Y to parallels of X and Y, respectively; this means that in the image of (x, y) the first coordinate is independent of y and the second one is independent of x, so that the collineation is of the stated form with bijections α, β, γ of $\mathbb{F}$ fixing 0. We now find the algebraic conditions for such a transformation to be a collineation. Consider the point $(x, sx+t)$ on the line $[s, t]$ joining $(0, t)$ and (s). The corresponding condition for the image points, requiring that the point $(x^\alpha, (sx+t)^\beta)$ lies on the line joining $(0, t^\beta)$ and (s^γ), that is, on the line $[s^\gamma, t^\beta]$, is expressed algebraically by

$$(1) \qquad (sx+t)^\beta = s^\gamma x^\alpha + t^\beta .$$

The special case $t = 0$, which is just $(*)$, allows us to write (1) as $(sx+t)^\beta = (sx)^\beta + t^\beta$, thus exhibiting the additivity of β, which in turn, once more via $(*)$, implies the additivity of α and γ.

Conversely, if $(*)$ holds and if β is additive, then (1) is valid, and we have a collineation. □

12.8 Corollary: Stabilizer of a quadrangle. *The collineations of* $\overline{\mathscr{A}_2}\mathbb{F}$ *fixing the points* $o = (0, 0)$, $u = (0)$, $v = (\infty)$, *and* $e = (1, 1)$ *are precisely the transformations*

$$(x, y) \mapsto (x^\alpha, y^\alpha), \ (s) \mapsto (s^\alpha), \ (\infty) \mapsto (\infty) \quad \textit{with } \alpha \in \operatorname{Aut}\mathbb{F} .$$

Proof. These collineations are the transformations given in (12.7) which, in addition, satisfy $1^\alpha = 1 = 1^\beta$. From (12.7(∗)) it then follows that also $1^\gamma = 1$, that $\alpha = \beta = \gamma$, and that, consequently, α is an automorphism of $\mathbb{F}$. □

12.9 Remark. *The collineations in* (12.8) *coincide with the affine collineations fixing the points* o, $e_1 = (1, 0)$, *and* $e_2 = (0, 1)$.

Indeed, if we consider them as collineations of the projective completion $\overline{\mathscr{A}_2}\mathbb{F}$, the line at infinity W remains invariant; now $u = (oe_1) \wedge W$, $v = (oe_2) \wedge W$, $e = (e_1 v) \wedge (e_2 u)$, and conversely $e_1 = (ve) \wedge (ou)$, $e_2 = (ue) \wedge (ov)$. □

In the field case $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$, the affine collineation group can now be determined completely.

12.10 Fundamental theorem of affine geometry. *Let* $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$. *The collineations of the affine plane* $\mathscr{A}_2\mathbb{F}$ *are precisely the mappings*

$$(x, y) \mapsto \varphi(x^\alpha, y^\alpha) + (a, b)$$

for $a, b \in \mathbb{F}$, $\alpha \in \operatorname{Aut}\mathbb{F}$, *and* $\varphi \in \mathrm{GL}_2\mathbb{F}$ *(the group of linear transformations of* $\mathbb{F} \times \mathbb{F}$ *considered as a* right $\mathbb{F}$*-vector space). They form the group* $\mathsf{A} = \mathrm{A\Gamma L}_2\mathbb{F}$, *which is the semidirect product* $\mathsf{A} = \mathsf{T} \rtimes \mathsf{A}_o$ *of the translation group* T *described in* (12.5) *by the stabilizer of the origin*

$$\mathsf{A}_o = \Gamma\mathrm{L}_2\mathbb{F} = \operatorname{Aut}\mathbb{F} \ltimes \mathrm{GL}_2\mathbb{F}\,.$$

Remark. This theorem and the proof given below are in fact valid over any (not necessarily commutative) field $\mathbb{F}$, cf. (23.6) and the references given there.

Proof of (12.10). Let A denote the group of all affine collineations. As T is the group of all collineations with axis W and center on W, see (12.5), the conjugation formula (12.4b) implies that T is a normal subgroup of A . By transitivity of T on the affine point set, the Frattini argument (91.2a) shows that $\mathsf{A} = \mathsf{A}_o \cdot \mathsf{T} = \mathsf{T} \cdot \mathsf{A}_o$.

The group $\mathrm{GL}_2\mathbb{F}$ consists of collineations because in the field case the lines are just the one-dimensional affine subspaces of the *right* $\mathbb{F}$-vector space $\mathbb{F} \times \mathbb{F}$, as is immediate from their definition (12.1), so that linear transformations map lines to lines. Now $\mathrm{GL}_2\mathbb{F}$ is sharply transitive on the set of bases of $\mathbb{F} \times \mathbb{F}$, whence $\mathsf{A}_o = \mathsf{A}_{o,(1,0),(0,1)} \cdot \mathrm{GL}_2\mathbb{F}$ by the Frattini argument. Finally, the stabilizer $\mathsf{A}_{o,(1,0),(0,1)}$ is described by $\operatorname{Aut}\mathbb{F}$ according to (12.9 and 8). □

We now determine how these affine collineations act on the line at infinity W. Since $\mathsf{A} = \mathsf{T} \cdot \mathsf{A}_o$, and since the translation group T acts trivially on W, only the collineations fixing o need to be considered.

12.11. *Let* $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$. *The stabilizer* A_o *consists of all the mappings*

$$\gamma_{\alpha,\varphi} : (x, y) \mapsto \varphi(x^\alpha, y^\alpha)$$

for $\alpha \in \operatorname{Aut}\mathbb{F}$ *and* $\varphi \in \mathrm{GL}_2\mathbb{F}$. *If* φ *is described by a matrix as*

$$\varphi : \mathbb{F}^2 \to \mathbb{F}^2 : \begin{pmatrix} x \\ y \end{pmatrix} \mapsto \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix},$$

then the projective extension of the collineation $\gamma_{\alpha,\varphi}$ *acts on the line at infinity as the fractional semilinear transformation*

$$\gamma_{\alpha,\varphi}|_W : W \to W : (s) \mapsto \left((c + d \cdot s^\alpha)(a + b \cdot s^\alpha)^{-1}\right)\,.$$

This should be understood also for $s = 0$ and $s = \infty$, with the usual conventions about the rôle of 0 and ∞ in such expressions, e.g. with $0^{-1} = \infty$, $\infty^{-1} = 0$.

In order to obtain the asserted description of $\gamma_{\alpha,\varphi}|_W$, we decompose the given collineation as $\gamma_{\alpha,\varphi} = \gamma_{\alpha,\mathrm{id}}\,\gamma_{\mathrm{id},\varphi}$. The projective extension of $\gamma_{\alpha,\mathrm{id}}$ is the collineation described in (12.8) mapping (s) to (s^α). The projective extension of $\gamma_{\mathrm{id},\varphi}$ maps (s) to (s'), where s' is the slope of the image of the line $[s,0] = \{\,(x,sx) \mid x \in \mathbb{F}\,\} = (1,s)\mathbb{F}$. The image line is $((a+bs),(c+ds))\mathbb{F} = (1,s')\mathbb{F}$, so that $s' = (c+ds)(a+bs)^{-1}$. The description of $\gamma_{\alpha,\varphi}|_W$ now follows by composition. □

We thus have obtained the following result.

Fundamental theorem for the projective line. *Let* $\mathbb{F} \in \{\mathbb{R},\mathbb{C},\mathbb{H}\}$. *The group* $\mathsf{A}|_W$ *of transformations induced on the line at infinity* W *by the group* A *of collineations of* $\mathscr{A}_2\mathbb{F}$ *(via projective extension) is the product*

$$\mathsf{A}|_W = \operatorname{Aut}\mathbb{F} \cdot \mathrm{PGL}_2\mathbb{F}$$

of the group

$$\mathrm{PGL}_2\mathbb{F} = \left\{\, (s) \mapsto \left((c+ds)(a+bs)^{-1}\right) \;\middle|\; \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \mathrm{GL}_2\mathbb{F} \,\right\}$$

of fractional linear transformations by the group

$$\{\,(s) \mapsto (s^\alpha),\ (\infty) \mapsto (\infty) \mid \alpha \in \operatorname{Aut}\mathbb{F}\,\} \cong \operatorname{Aut}\mathbb{F}\,.$$

Note. In (15.6), we shall present a version of the preceding theorem which is valid for $\mathbb{F} = \mathbb{O}$, as well.

Addenda.

(a) *The last-mentioned group is the stabilizer of* (0), (1), *and* (∞) *in* $\mathsf{A}|_W$.

(b) *The stabilizer of* (0) *and* (∞) *in* $\mathrm{PGL}_2\mathbb{F}$ *consists of the transformations* $(s) \mapsto (dsa^{-1})$ *for* $a,d \in \mathbb{F}^\times$. *These are precisely the maps* $(s) \mapsto (Bs)$ *where* B *belongs to the group* $\mathrm{GO}_n^+\mathbb{R}$ *defined in* (11.21).

(c) *The fractional linear group* $\mathrm{PGL}_2\mathbb{F}$ *is triply transitive on* W. *It is sharply triply transitive if, and only if* $\mathbb{F}$ *is commutative.*

(d) $\operatorname{Aut}\mathbb{F}$ *is trivial for* $\mathbb{F} = \mathbb{R}$. *In the case* $\mathbb{F} = \mathbb{H}$, *the transformation* $(s) \mapsto (s^\alpha)$ *for* $\alpha \in \operatorname{Aut}\mathbb{F}$ *belongs to* $\mathrm{PGL}_2\mathbb{H}$. *Thus,*

$$\mathsf{A}|_W = \mathrm{PGL}_2\mathbb{F} \quad \textit{for } \mathbb{F} = \mathbb{R},\mathbb{H}\,.$$

Proof of Addenda. We begin with assertion (b). The first part of the assertion is immediate from the explicit description of $\mathrm{PGL}_2\mathbb{F}$. The second part has been proved in (11.23).

We now turn to (c). The stabilizer of (∞) in $\mathrm{PGL}_2\mathbb{F}$ contains the transformations $(s) \mapsto (s+c)$ for $c \in \mathbb{F}$ and hence is transitive on $W \setminus (\infty)$. Under $(s) \mapsto (s^{-1})$, the points (0) and (∞) are interchanged. Hence, the group $\mathrm{PGL}_2\mathbb{F}$ is doubly transitive on W, and (b) shows that it is even triply transitive. Also from (b), we infer that the stabilizer Λ of the triple (0), (1), (∞) in $\mathrm{PGL}_2\mathbb{F}$ is induced by the inner automorphisms of $\mathbb{F}$, so that this stabilizer is trivial precisely if $\mathbb{F}$ is commutative. Thus, (c) is proved. At the same time, we have obtained that this stabilizer is contained in the subgroup of $\mathsf{A}|_W$ corresponding to $\operatorname{Aut}\mathbb{F}$, which proves (a). Moreover, the latter subgroup reduces to $\Lambda \subseteq \mathrm{PGL}_2\mathbb{F}$ whenever all automorphisms of $\mathbb{F}$ are inner, so that then $\mathsf{A}|_W = \mathrm{PGL}_2\mathbb{F}$. This is the case for $\mathbb{F} = \mathbb{H}$ by (11.29), whence (d). $\square$

From now on, we include the case $\mathbb{F} = \mathbb{O}$ in our discussion again. Our next topic is a concrete description of collineations with *non*-incident center and axis. Such collineations are called *homologies*.

12.13 Proposition: Homologies of $\overline{\mathscr{A}_2}\mathbb{F}$.

(a) *The collineations of* $\overline{\mathscr{A}_2}\mathbb{F}$ *having the line at infinity* $W = [\infty]$ *as axis and fixing the origin* $o = (0,0)$ *are precisely the mappings*

$$\mu_a : (x, y) \mapsto (xa, ya);\ \ \mu_a|_W = \mathrm{id}$$

$$\text{for } 0 \neq a \in \begin{cases} \mathbb{F} & \text{if } \mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\} \\ \operatorname{Ker}\mathbb{O} = \mathbb{R} & \text{if } \mathbb{F} = \mathbb{O}. \end{cases}$$

They have center o. *These collineations are called* homotheties.

In the field case $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$, *the group of these homotheties is transitive on* $X \setminus \{o, X \wedge W\}$. *For* $\mathbb{F} = \mathbb{O}$, *this is not so.*

(b) *The collineations of* $\overline{\mathscr{A}_2}\mathbb{F}$ *with axis* $X = [0,0]$ *and center* $v = (\infty)$ *are precisely the mappings*

$$(x, y) \mapsto (x, ay),\ \ (s) \mapsto (as)$$

for $0 \neq a \in \mathbb{F}$ *if* $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$, *and for* $0 \neq a \in \mathbb{R}$ *if* $\mathbb{F} = \mathbb{O}$.

(c) *The collineations of* $\overline{\mathscr{A}_2}\mathbb{F}$ *with axis* $Y = [0]$ *and center* $u = (0)$ *are precisely the mappings*

$$(x, y) \mapsto (ax, y),\ \ (s) \mapsto (sa^{-1})$$

for $0 \neq a \in \mathbb{F}$ *if* $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$, *and for* $0 \neq a \in \mathbb{R}$ *if* $\mathbb{F} = \mathbb{O}$.

Remark. The difference between $\mathbb{O}$ and the fields $\mathbb{R}, \mathbb{C}, \mathbb{H}$ exhibited here reflects the non-associativity of $\mathbb{O}$, as will become clear in the proof. Synthetically, this difference is expressed by the fact that Desargues' theorem for non-incident centers and axes, which holds in planes over (not necessarily commutative) fields, is not valid in the octonion plane. The fundamental interrelations between transitivity properties of groups of homologies, the validity of Desargues' theorem, and associativity properties of the coordinate domain are due to Baer [42] Theorem 5.1, p. 146 and Theorem 6.2, p. 151, cf. also (23.22) and the books mentioned there.

Proof of (12.13). (a) The collineations in question are precisely the transformations of the form stated in (12.7) with $\gamma = \mathrm{id}$, i.e., the collineations

$$\delta : (x, y) \mapsto (x^\alpha, y^\beta);\ \ \delta|_W = \mathrm{id}$$

with bijections α, β of $\mathbb{F}$ satisfying

$$(*) \qquad (sx)^\beta = s \cdot x^\alpha$$

for all $s, x \in \mathbb{F}$. With $x = 1$ and $a := 1^\alpha$ this gives $s^\beta = sa$; and putting $s = 1$ we obtain $\beta = \alpha$. Thus, δ is of the form

$$(1) \qquad \delta : (x, y) \mapsto (xa, ya)\ ,$$

and $(*)$ requires that

$$(2) \qquad (sx)a = s(xa)$$

for all $s, x \in \mathbb{F}$.

Now, if $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$, then every element a satisfies (2) because of associativity; if $\mathbb{F} = \mathbb{O}$, then (2) holds precisely for the elements a of the kernel $\operatorname{Ker}\mathbb{O} = \mathbb{R}$, see (11.20). Thus, the first part of assertion (a) is proved.

For $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$, the easy direction of the preceding argument would suffice, namely the verification that the homotheties μ_a are indeed collineations for all $a \in \mathbb{F} \setminus \{0\}$. The proof can then be completed by the following standard transitivity argument. Obviously, in these cases, the set $\{\, \mu_a \mid a \in \mathbb{F} \setminus \{0\}\,\}$ of homotheties is transitive on $X \setminus \{o, X \wedge W\} = \mathbb{F} \times \{0\} \setminus \{(0, 0)\}$; one now observes that, by the uniqueness properties (12.4c), the group $\mathsf{A}_{[o,W]}$ of all homologies with center o and axis W is sharply transitive there and thus consists precisely of the homotheties as stated. See also (23.9).

A further proof for $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$ can be obtained from the fundamental theorem of affine geometry (12.10). The collineations fixing the origin are given in (12.11) together with their actions on W; the collineation $\gamma_{\alpha,\varphi}$ described there has axis W if, and only if $c + d \cdot s^\alpha = s(a + b \cdot s^\alpha)$ for all $s \in \mathbb{F}$. By putting in turn $s = 0, s = 1$, and $s = -1$ one sees that this is equivalent to $c = 0 = b$, $d = a$ and $s^\alpha = a^{-1}sa$ for all $s \in \mathbb{F}$. In this situation, $\gamma_{\alpha,\varphi}$ maps (x, y) to $\varphi(x^\alpha, y^\alpha) = (a \cdot x^\alpha, a \cdot y^\alpha) = (a \cdot (a^{-1}xa), a \cdot (a^{-1}xa)) = (xa, ya)$; this proves our proposition anew. Note that, in the non-commutative case $\mathbb{F} = \mathbb{H}$ at hand, $\gamma_{\alpha,\varphi}$ is not a linear transformation (of the affine point set $\mathbb{H}^2$ considered as a *right* $\mathbb{H}$-vector space)!

(b) may be proved analogously. The collineations with axis X and center v are the mappings

$$(x, y) \mapsto (x, y^{\beta}), \ \ (s) \mapsto (s^{\gamma})$$

with bijections β, γ of $\mathbb{F}$ satisfying $(sx)^{\beta} = s^{\gamma} x$ for all $s, x \in \mathbb{F}$. With $s = 1$ and $c := 1^{\gamma}$, we obtain $x^{\beta} = cx$. Putting $x = 1$, we infer $\gamma = \beta$. Thus, the collineations in question are the transformations $(x, y) \mapsto (x, cy)$, where $c \neq 0$ satisfies

$$(3) \qquad c(sx) = (cs)x \quad \text{for all } s, x \in \mathbb{F} .$$

For $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$, the latter condition is trivially fulfilled because of associativity. For $\mathbb{F} = \mathbb{O}$, by applying conjugation to (3), we obtain the equivalent condition $(\bar{x}\,\bar{s})\bar{c} = \bar{x}(\bar{s}\bar{c})$ for all $s, x \in \mathbb{F}$, which says that $\bar{c}$, and hence c, belongs to the kernel $\mathbb{R}$ of $\mathbb{O}$.

In the field cases $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$, analogous variations of the proof as in (a) are possible, of course.

(c) is obtained from (b) by conjugation; one applies the conjugation formula (12.4b) to the reflection $(x, y) \mapsto (y, x)$, $(s) \mapsto (s^{-1})$ of (12.6), which interchanges the axis X with Y and the center u with v. □

Collineations of $\mathscr{A}_2\mathbb{O}$, Moufang identities, and triality

Finally, we proceed to a more detailed study of the stabilizer ∇ of the triangle $o = (0, 0)$, $u = (0)$, and $v = (\infty)$ in the collineation group of the projective octonion plane $\overline{\mathscr{A}_2\mathbb{O}}$. The group ∇ can also be viewed as the stabilizer of the coordinate axes $X = ou$ and $Y = ov$ in the group of collineations of the affine plane $\mathscr{A}_2\mathbb{O}$. This stabilizer is an easily accessible part of the collineation group. A study of the whole collineation group of the projective plane $\overline{\mathscr{A}_2\mathbb{O}}$ will be the subject of separate sections (17 and 18).

First, we exhibit special collineations which generate ∇ and which are closely related to the Moufang identities (12.15). By an idea of Salzmann [59c], these collineations can be constructed very easily as compositions of elations which are known from (12.5). When translating the geometric fact that these transformations are collineations into algebraic language, one immediately obtains the Moufang identities. They express other facets of the weak associativity properties of $\mathbb{O}$ besides alternativity (11.13). Actually, they are inherent in alternativity, although this is not entirely obvious. Here, this fact may be obtained by inspection of our argument. For purely algebraic proofs, see Pickert [75] 6.1 no. 2, p. 160, Schafer [66] III.1, p. 28, Zhevlakov et al. [82] Lemma 2.7, p. 35.

With the special collineations mentioned above at our disposal, it is then easy to determine ∇. The structure of ∇ is closely related to the triality principle (12.18).

As a special trait of our presentation, triality does not appear as an algebraic fact having geometric applications, but is intertwined with geometric phenomena right from the start.

Our arguments would be valid more generally for any alternative field instead of $\mathbb{O}$. In particular, they work over (not necessarily commutative) fields, as well; but then, the collineations in question may also be obtained directly from the fundamental theorem of affine geometry (12.10), see (12.19), and the Moufang identities are trivially satisfied because of associativity.

12.14 Proposition. *The following mappings are collineations of* $\overline{\mathcal{A}_2\mathbb{O}}$*, for every* $a \in \mathbb{O} \setminus \{0\}$:

$$\begin{aligned} \gamma_a &: (x, y) \mapsto (a^{-1}x, ay), \ (s) \mapsto (asa) \\ \gamma'_a &: (x, y) \mapsto (axa, ya), \ \ (s) \mapsto (sa^{-1}) \\ \gamma''_a &: (x, y) \mapsto (xa, aya), \ \ (s) \mapsto (as)\,. \end{aligned}$$

Proof. We use the elations $\sigma_a : (x, y) \mapsto (x, y + ax)$, $\sigma'_a : (x, y) \mapsto (x + ay, y)$ from (12.5b and c) and check that γ_a is the following product of such elations:

$$(*) \qquad \gamma_a = \sigma'_1\, \sigma_{a-1}\, \sigma'_{-a^{-1}}\, \sigma_{a-a^2}\,.$$

The biassociativity of $\mathbb{O}$ (11.9) will be essential for the necessary calculations. Under the given product of elations, an affine point is mapped as follows:

$$\begin{aligned} (x, y) &\mapsto (x + y, y) \\ &\mapsto (x + y, y + (a - 1)(x + y)) = (x + y, a(x + y) - x) \\ &\mapsto \big(x + y - a^{-1}(a(x + y)) + a^{-1}x, a(x + y) - x\big) = \big(a^{-1}x, a(x + y) - x\big) \\ &\mapsto \big(a^{-1}x, a(x + y) - x + (a - a^2)(a^{-1}x)\big) = \big(a^{-1}x, a(x + y) - x + x - ax\big) \\ &= (a^{-1}x, ay)\,. \end{aligned}$$

The line $[s, 0]$ joining $(0, 0)$ and $(1, s)$ is mapped onto the line joining the image points $(0, 0)$ and (a^{-1}, as); this line is $[asa, 0]$, since $(asa)a^{-1} = as$ by biassociativity, so that indeed $(a^{-1}, as) \in [asa, 0]$. The projective extension thus maps (s) to (asa), and $(*)$ is proved.

According to (12.7), the fact that γ_a is a collineation is expressed algebraically by the identity $a(sx) = (asa)(a^{-1}x)$. Substituting $z = a^{-1}x$, $az = x$ yields the first *Moufang identity*

$$(1) \qquad a(s(az)) = (asa)z\,.$$

Applying conjugation on both sides of (1) and renaming, one obtains the second Moufang identity

$$(2) \qquad ((ba)x)a = b(axa)\,.$$

With $s = ba$, $sa^{-1} = b$ this is transformed into the identity $(sx)a = (sa^{-1})(axa)$, from which in turn, by applying (12.7) backwards, it follows that γ'_a is a collineation. An immediate verification with the help of biassociativity shows that $\gamma''_a = \gamma_a\gamma'_a$, so that this is a collineation as well. By (12.7) once again, the latter fact is equivalent to the third Moufang identity

$$a(sx)a = (as)(xa)\ . \tag{3}$$

We collect these identities as a corollary to the proof.

12.15 The Moufang identities. *For all $a, b, c \in \mathbb{O}$, the following hold*:

$$\begin{aligned} a(b(ac)) &= (aba)c \\ ((ab)c)b &= a(bcb) \\ (ab)(ca) &= a(bc)a\ . \end{aligned}$$

□

12.16 Lemma. *The group of collineations generated by the collineations γ_a and γ'_a of* (12.14) *for $a \in \mathbb{O} \setminus \{0\}$ fixes the vertices of the triangle o, u, v and is transitive on the set $(\mathbb{O}\setminus\{0\}) \times (\mathbb{O}\setminus\{0\})$ of affine points not incident with the sides of this triangle.*

Proof. For $a, b \in \mathbb{O}\setminus\{0\}$, we show that the point $(1, 1)$ may be mapped to the point (a, b) by a product of collineations of the specified kind. Indeed, since ba belongs to a subfield of $\mathbb{O}$ isomorphic to $\mathbb{C}$, see (11.7), there is $c \in \mathbb{O}$ with $ba = c^3$. Now, using alternativity (11.8), one easily verifies that $\gamma_{c^{-1}}\gamma'_c\gamma_b$ maps $(1, 1)$ to (a, b). □

In the following proposition, we use the notation for orthogonal groups introduced in (11.21).

12.17 Proposition: The stabilizer of the coordinate axes.

(a) *The group ∇ of collineations of $\overline{\mathcal{A}_2\mathbb{O}}$ leaving the points o, u, and v fixed consists of the transformations*

$$(A, B \mid C) : (x, y) \mapsto (Ax, By),\ \ (s) \mapsto (Cs)\ ,$$

where A,B,C belong to $\mathrm{GO}_8^+\mathbb{R}$ and satisfy the triality condition

$$B(s \cdot x) = Cs \cdot Ax \quad \textit{for all } s, x \in \mathbb{O}\ . \tag{$*$}$$

(b) *The group ∇ is the direct product of the subgroup consisting of the transformations*

$$\mu_{r,t} : (x, y) \mapsto (rx, ty),\ \ (s) \mapsto (tr^{-1} \cdot s) \quad \textit{for } 0 < r, t \in \mathbb{R}$$

CHAPTER 2

Some Properties of Circles

> **Although the Greeks worked fruitfully, not only in geometry but also in the most varied fields of mathematics, nevertheless we today have gone beyond them everywhere and certainly also in geometry.**
>
> ***F. Klein***

The circle has been held in highest esteem through the ages. Its perfect form has affected philosophers and astronomers alike. Until Kepler derived his laws, the thought that planets might move in anything but circular paths was unthinkable. Nowadays, the words "square", "line", and the like sometimes have derogatory connotations, but the circle—never. Cleared of superstitious nonsense and pseudo-science, it still stands out, as estimable as ever.

Limitations of space make it impossible for us to present more than a few of the most interesting properties developed since Euclid of the circle and its relation to triangles and other polygons.

2.1 The power of a point with respect to a circle

We begin our investigations by recalling two of Euclid's theorems: III.35, about the product of the parts into which two chords of a circle divide each other (that is, in the notation of Figure 2.1A, $PA \times PA' = PB \times PB'$), and III.36, comparing a secant and a tangent drawn from the same point P outside the circle (in Figure 2.1B, $PA \times PA' = PT^2$). If we agree to regard a tangent as the limiting form of a secant, we can combine these results as follows:

THEOREM 2.11. *If two lines through a point* P *meet a circle at points* A, A' *(possibly coincident) and* B, B' *(possibly coincident), respectively, then* $PA \times PA' = PB \times PB'$.

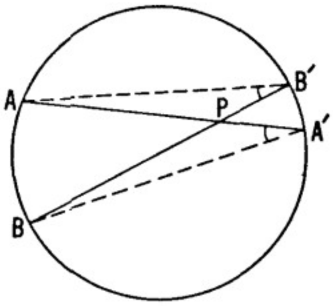

Figure 2.1A

For a proof we merely have to observe that the similar triangles PAB' and PBA' (with a common angle at P) yield

$$\frac{PA}{PB'} = \frac{PB}{PA'}.$$

In Figure 2.1B, we can equally well use the similar triangles PAT and PTA' to obtain

$$\frac{PA}{PT} = \frac{PT}{PA'},$$

and then say $PA \times PA' = PT^2 = PB \times PB'$.

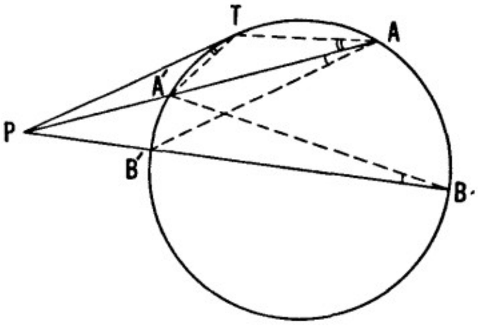

Figure 2.1B

Let R denote the radius of the circle, and d the distance from P to the center. By taking BB' to be the diameter through P (with B farther from P than B'), we see that, if P is inside the circle (as in Figure 2.1A),

$$AP \times PA' = BP \times PB' = (R+d)(R-d) = R^2 - d^2,$$

and if P is outside (as in Figure 2.1B),

$$PA \times PA' = PB \times PB' = (d+R)(d-R) = d^2 - R^2.$$

The equation

$$AP \times PA' = R^2 - d^2$$

provides a quick proof of a formula due to Euler:

THEOREM 2.12. *Let O and I be the circumcenter and incenter, respectively, of a triangle with circumradius R and inradius r; let d be the distance OI. Then*

$$d^2 = R^2 - 2rR. \tag{2.12}$$

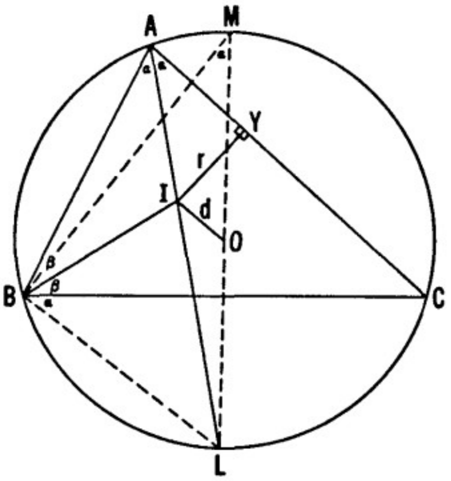

Figure 2.1C

Figure 2.1C shows the internal bisector of $\angle A$ extended to meet the circumcircle at L, the midpoint of the arc BC not containing A. LM is the diameter perpendicular to BC. Writing, for convenience, $\alpha = \frac{1}{2}A$ and $\beta = \frac{1}{2}B$, we notice that

$$\angle BML = \angle BAL = \alpha, \quad \text{and} \quad \angle LBC = \angle LAC = \alpha.$$

Since the exterior angle of $\triangle ABI$ at I is

$$\angle BIL = \alpha + \beta = \angle LBI,$$

$\triangle LBI$ is isosceles: $LI = LB$. Thus

$$\begin{aligned} R^2 - d^2 &= LI \times IA = LB \times IA \\ &= LM \frac{LB/LM}{IY/IA} IY = LM \frac{\sin\alpha}{\sin\alpha} IY \\ &= LM \times IY = 2Rr, \end{aligned}$$

that is, $d^2 = R^2 - 2rR$, as we wished to prove.

For any circle of radius R and any point P distant d from the center, we call

$$d^2 - R^2$$

the *power* of P with respect to the circle. It is clearly positive when P is outside, zero when P lies on the circumference, and negative when P is inside. For the first of these cases we have already obtained the alternative expression

$$PA \times PA',$$

where A and A' are any two points on the circle, collinear with P (as in Theorem 2.11). This expression for the power of a point P remains valid for all positions of P if we agree to adopt Newton's idea of *directed* line segments: a kind of one-dimensional vector algebra in which

$$AP = -PA.$$

The product (or quotient) of two directed segments on one line is regarded as being positive or negative according as the directions agree or disagree. With this convention, the equation

$$d^2 - R^2 = PA \times PA'$$

holds universally. If P is inside the circle,

$$d^2 - R^2 = -(R^2 - d^2) = -AP \times PA' = PA \times PA';$$

and if P is on the circumference, either A or A' coincides with P, so that one of the segments has length zero. In fact, after observing that the product $PA \times PA'$ has the same value for every secant (or chord) through P, we could have used this value as a *definition* for the power of P with respect to the circle.

The word *power* was first used in this sense by Jacob Steiner, whose name has already appeared in Chapter 1.

EXERCISES

1. What is the (algebraically) smallest possible value that the power of a point can have with respect to a circle of given radius R? Which point has this critical power?

2. What is the locus of points of constant power (greater than $-R^2$) with respect to a given circle?

3. If the power of a point has the positive value t^2, interpret the length t geometrically.

4. If PT and PU are tangents from P to two concentric circles, with T

on the smaller, and if the segment PT meets the larger circle at Q, then $PT^2 - PU^2 = QT^2$.

5. The circumradius of a triangle is at least twice the inradius.

6. Express (in terms of r and R) the power of the incenter with respect to the circumcircle.

7. The notation of directed segments enables us to express Stewart's theorem (Exercise 4 of Section 1.2) in the following symmetrical form [5, p. 152]: *If P, A, B, C are four points of which the last three are collinear, then* $PA^2 \times BC + PB^2 \times CA + PC^2 \times AB + BC \times CA \times AB = 0$.

8. A line through the centroid G of ΔABC intersects the sides of the triangle at points X, Y, Z. Using the concept of directed line segments, prove that
$$\frac{1}{GX} + \frac{1}{GY} + \frac{1}{GZ} = 0.$$

9. How far away is the horizon as seen from the top of a mountain one mile high? (Assume the earth to be a sphere of diameter 7920 miles.)

2.2 The radical axis of two circles

The following anecdote was related by E. T. Bell [3, p. 48]. Young Princess Elisabeth, exiled from Bohemia, had successfully attacked a problem in elementary geometry by using coordinates. As Bell states it, "The problem is a fine specimen of the sort that are *not* adapted to the crude brute force of elementary Cartesian geometry." Her teacher was René Descartes (after whom Cartesian coordinates were named†). His reaction was that "he would not undertake to carry out her solution . . . in a month."

The lesson is clear: a solution that is possible in a certain manner may still not be the best or most economical one. At any rate, here is one theorem for which an analytic proof, without being any more difficult than the usual synthetic proof [6, p. 86], has some interesting repercussions:

THEOREM 2.21. *The locus of all points whose powers with respect to two nonconcentric circles are equal is a line perpendicular to the line of centers of the two circles.*

---

† There are some who claim that it was Pierre Fermat (1601–1665) who actually invented analytic geometry. Their contention is that he gave the essential idea to Descartes in a letter.

In terms of rectangular Cartesian coordinates, the square of the distance d between any two points (x, y) and (a, b) is

$$(x - a)^2 + (y - b)^2.$$

Therefore the power of (x, y) with respect to the circle with center (a, b) and radius r is

$$d^2 - r^2 = (x - a)^2 + (y - b)^2 - r^2.$$

In particular, the circle itself, being the locus of points (x, y) of power zero, has the equation

$$(2.22) \qquad (x - a)^2 + (y - b)^2 - r^2 = 0.$$

The same equation, in the form $(x - a)^2 + (y - b)^2 = r^2$, expresses the circle as the locus of points whose distances from (a, b) have the constant value r.

When this circle is expressed in the form

$$(2.23) \qquad x^2 + y^2 - 2ax - 2by + c = 0$$

(where $c = a^2 + b^2 - r^2$), the power of an arbitrary point (x, y) is again expressed by the left side of the equation, namely

$$x^2 + y^2 - 2ax - 2by + c.$$

Another circle having the same center (a, b) but a different radius has an equation of the same form with a different c, and any circle having a different center has an equation of the form

$$(2.24) \qquad x^2 + y^2 - 2a'x - 2b'y + c' = 0,$$

where either $a' \neq a$ or $b' \neq b$ or both. We are thus free to use the equations (2.23) and (2.24) for the two non-concentric circles mentioned in Theorem 2.21. The locus of all points (x, y) whose powers with respect to these two circles are equal is

$$x^2 + y^2 - 2ax - 2by + c = x^2 + y^2 - 2a'x - 2b'y + c'.$$

Since $x^2 + y^2$ cancels, this locus is the *line*

$$(a' - a)x + (b' - b)y = \tfrac{1}{2}(c' - c).$$

By choosing our frame of reference so that the x-axis joins the two centers, we may express the two circles in the simpler form

$$(2.25) \quad x^2 + y^2 - 2ax + c = 0, \qquad x^2 + y^2 - 2a'x + c' = 0,$$

where $a' \neq a$. Then the locus becomes

$$x = \frac{c' - c}{2(a' - a)}.$$

This line, being parallel to the y-axis, is *perpendicular* to the x-axis, which is the join of centers. Since the line can be defined geometrically in terms of the circles (as containing all points of equal power), we could have taken it to be the y-axis itself, as in Figure 2.2A. Thus any two non-concentric circles can be expressed in the still simpler form

$$(2.26) \qquad x^2 + y^2 - 2ax + c = 0, \qquad x^2 + y^2 - 2a'x + c = 0.$$

Now the locus is $x = 0$. Conversely, every point $(0, y)$ on the line $x = 0$ has the *same* power $y^2 + c$ with respect to both circles.

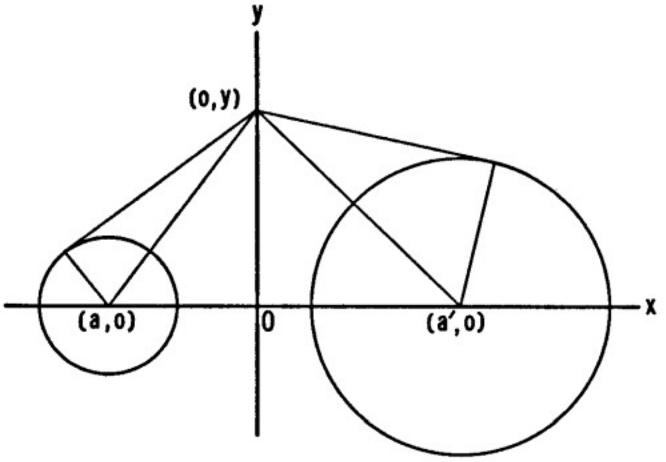

Figure 2.2A

This remark completes the proof. Of course, we could have shortened it by expressing the two circles immediately in the form (2.25); but then we would have missed the beautiful lemma that, for any circle expressed in the standard form (2.23), *the power of the general point* (x, y) *is equal to the expression on the left side of the equation.*

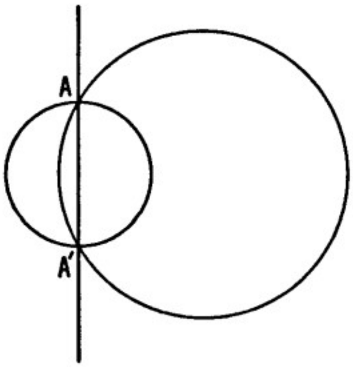

Figure 2.2B

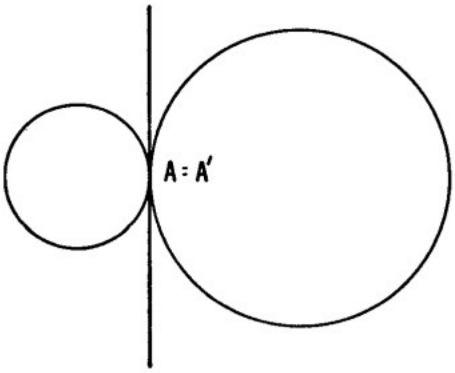

Figure 2.2C

The locus of points of equal power with respect to two non-concentric circles is called their *radical axis*. In the special case when the two circles intersect at two points A and A' (Figure 2.2B), each of these points has zero power for both circles, and therefore the radical axis is simply the line AA'. Similarly, when the two circles touch each other (Figure 2.2C), their radical axis is their common tangent at their point of contact.

EXERCISES

1. What is the locus of all points from which the tangents to two given circles have equal lengths?

2. When the distance between the centers of two circles is greater than the sum of the radii, the circles have four common tangents. The midpoints of these four line segments are collinear.

3. Let PAB, AQB, ABR, $P'BA$, $BQ'A$, BAR' be six *similar* triangles all on the same side of their common side AB. (Three of them are shown in Figure 2.2D; the rest can be derived by reflection† in the perpendicular bisector of the segment AB.) Those vertices of the triangles that do not lie on AB (namely, P, Q, R, P', Q', R') all lie on one circle. *Hint*: Compare the powers of A and B with respect to the circle PQR.

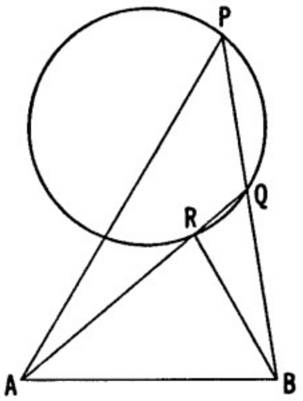

Figure 2.2D

4. Given a and b, for what values of c does the equation 2.23 represent a circle?

5. Describe a construction for the radical axis of two given non-concentric circles: a construction that remains valid when one circle encloses the other.

---

† The operation of reflection is useful in solving many geometric problems. See, for instance, Yaglom [29].

2.3 Coaxal circles

The two circles (2.26) (which may be any two non-concentric circles) are members of an infinite family, represented by the equation

$$x^2 + y^2 - 2ax + c = 0,$$

where c is fixed while a varies over the whole range of real values (except, if c is positive, the values between $\pm\sqrt{c}$). This family is called a *pencil of coaxal circles*, because every two of its members have the same line of centers and the same radical axis. If c is negative, every member of the family meets the y-axis at the same two points $(0, \pm\sqrt{-c})$, and the pencil consists simply of *all the circles through these two points*. Similarly, if $c = 0$, the pencil consists of all the circles that touch the y-axis at the origin. The case when c is positive is illustrated in Figure 2.3A.

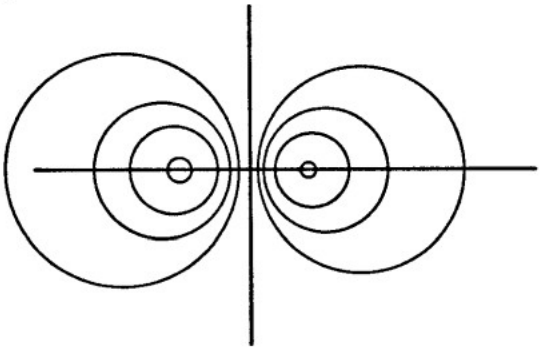

Figure 2.3A

If *three* non-coaxal circles are such that no two are concentric, we can take them in pairs and thus find three radical axes. Any point that has the same power for all three circles must lie on all three of these lines. Conversely, any point of intersection of two of the three radical axes, having the same power for all three circles, must lie on the third line as well. If two of the axes are parallel, then all three must be parallel. In particular:

THEOREM 2.31. *If the centers of three circles form a triangle, there is just one point whose powers with respect to the three circles are all equal.*

This common point of the three radical axes is called the *radical center* of the three circles.

EXERCISES

1. Two circles are in contact internally at a point T. Let the chord AB of

the larger circle be tangent to the smaller circle at a point P. Then the line TP bisects $\angle ATB$.

2. If three non-intersecting circles have radical center O, the points of contact of the six tangents from O to the circles all lie on one circle.

2.4 More on the altitudes and orthocenter of a triangle

The circumcircle of a triangle, already encountered in the previous chapters, deserves further examination. Figure 2.4A shows the circumcircle ABC with center O, diameter AA_0 through A, and radius $OL = R$ perpendicular to BC. We see also the altitude $AD = h_a$. The equal angles at B and A_0 make $\Delta ABD \sim \Delta AA_0C$, so that

$$\frac{h_a}{c} = \frac{b}{AA_0}$$

and

$$h_a = \frac{bc}{2R}. \tag{2.41}$$

Subtracting from $\angle BAC$ the two equal angles

$$\angle A_0AC = \angle BAD = 90° - B,$$

we are left with

$$\begin{aligned}\angle DAA_0 &= A - 2(90° - B) = A + 2B - (A + B + C)\\ &= B - C.\end{aligned}$$

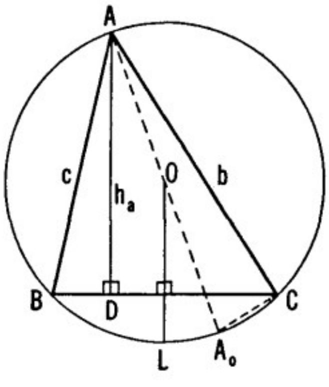

Figure 2.4A

This expression for $\angle DAA_0 = \angle DAO$ has been made with reference to the figure in which $B > C$. If instead we had taken $B < C$, the equal angles A_0AC and BAD would have overlapped, with the result that $\angle DAO = C - B$. We can include both cases by writing

$$\angle DAO = |B - C|. \tag{2.42}$$

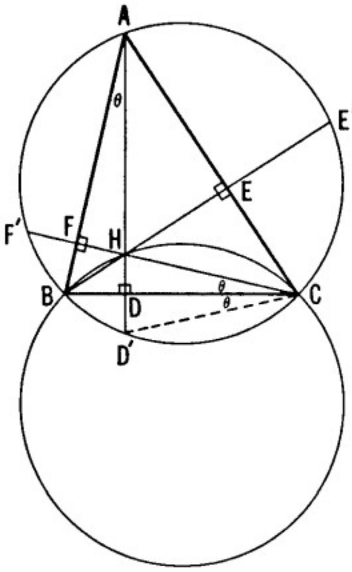

Figure 2.4B

Figure 2.4B shows the three altitudes AD, BE, CF extended to meet the circumcircle at D', E', F'. Of course, H is the orthocenter. Now $\angle DAB = \angle FCB$, both being complements of the angle B. This explains our use of the same symbol θ for both. Also $\angle BCD' = \angle BAD'$, so we have labeled $\angle BCD'$ accordingly. The congruent right-angled triangles CDH and CDD' show us that

$$HD = DD'. \tag{2.43}$$

Similarly, $HE = EE'$ and $HF = FF'$.

Since the circle with diameter AB passes through D and E, Theorem 2.11 tells us that $HA \times HD = HB \times HE$. Similarly $HB \times HE = HC \times HF$. Hence

$$HA \times HD = HB \times HE = HC \times HF. \tag{2.44}$$

If X, Y, Z are any points on the respective sides BC, CA, AB, circles constructed on the cevians AX, BY, CZ as diameters will pass through the feet of the altitudes: D, E, F, respectively. (The second and third circles are shown in Figure 2.4C.) The three expressions equated in (2.44) are the powers of H with respect to these three circles. Hence H is the radical center of the circles, and we have proved two interesting theorems that have appeared at various times as puzzlers:

THEOREM 2.45. *If circles are constructed on two cevians as diameters, their radical axis passes through the orthocenter H of the triangle.*

THEOREM 2.46. *For any three non-coaxal circles having cevians for diameters, H is their radical center.*

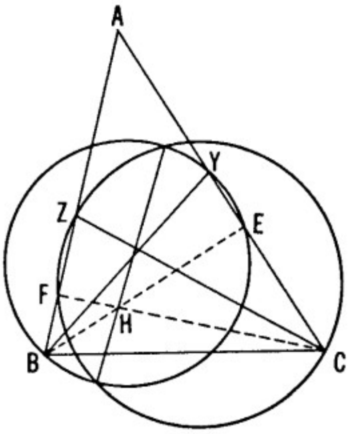

Figure 2.4C

Alternatively, the same results can be obtained by means of the following simple considerations. If AD is the altitude from A, the pencil of coaxal circles·through A and D may be described as the circles having cevians through A as diameters. Two of these cevians are the sides AB and AC. Thus the circles on BC, CA, AB as diameters have the altitudes for their radical axes in pairs, and H for their radical center. (In this manner, the concurrence of the altitudes is seen to be a special case of Theorem 2.31). It follows that H has the same power for *all* circles having cevians for diameters.

Notice the word "non-coaxal" in the statement of Theorem 2.46. This implies that the three cevians are not all drawn from the same vertex of $\triangle ABC$. We shall see in our next theorem that it implies slightly more!

Several amusing problems can be derived from Theorem 2.46 (as applied to cevians AX, BY, CZ) by introducing non-essentials. Although the three cevians need not be concurrent, it makes for greater confusion to let them be concurrent. Thus, we might ask: if circles are constructed on the medians (or altitudes, or angle bisectors) as diameters, prove that their radical center is the orthocenter of the triangle.

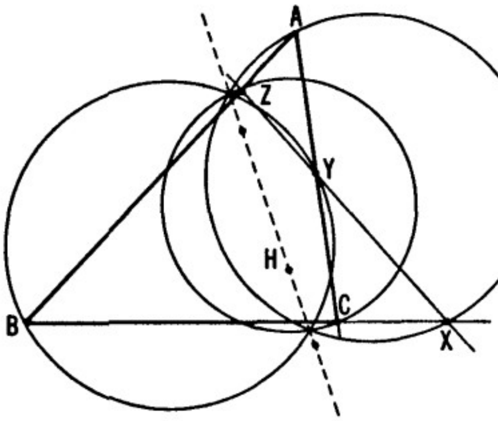

Figure 2.4D

The most interesting case of non-concurrent cevians arises when X, Y, Z are *collinear* points on the lines BC, CA, AB (extended if necessary), as in Figure 2.4D; for then we can equally well say that X, B, C are collinear points on the sides of $\triangle AYZ$, or that Y, C, A are collinear points on the sides of $\triangle BZX$, or that Z, A, B are collinear points on the sides of $\triangle CXY$. Hence the circles on AX, BY, CZ as diameters are so situated that their radical axes pass through H and also (for the same reason) through the orthocenters of the other three triangles. Since these four orthocenters are obviously distinct, the radical axes must coincide, and we have proved

THEOREM 2.47. *If four lines meet one another at six points* A, B, C, X, Y, Z, *so that the sets of collinear points are* XBC, YCA, ZAB, XYZ, *then the circles on* AX, BY, CZ *as diameters are coaxal, and the orthocenters of the four triangles* AYZ, BZX, CXY, ABC *are collinear.*

Another property of a triangle and its altitudes is illustrated in Figure 1.3C. If we inspect the diagram carefully, we reach the conclusion that, just as H is the orthocenter of $\triangle ABC$, A *is the orthocenter of* $\triangle HBC$, and, for the same reason, B is the orthocenter of $\triangle HAC$, and C is the orthocenter of $\triangle HAB$. This configuration $ABCH$ is known as an *orthocentric quadrangle*, and has a number of interesting properties. We merely examine one of them, namely: *If* $ABCH$ *is an orthocentric quadrangle, the circumcircles of the four triangles formed by taking any three of the vertices have equal radii.*

The simplest proof makes use of the equation (2.43) and Figure 2.4B. In this figure, $\triangle HBC$ and $\triangle D'BC$ are congruent, so they must have congruent circumcircles. Hence the circumcircle of $\triangle D'BC$ (or $\triangle ABC$) is congruent to the circumcircle of $\triangle HBC$, and similarly for the other triangles.

EXERCISES

1. The points where the extended altitudes meet the circumcircle form a triangle similar to the orthic triangle.

2. The internal angle bisectors of $\triangle ABC$ are extended to meet the circumcircle at points L, M, N, respectively. Find the angles of $\triangle LMN$ in terms of the angles A, B and C.

2.5 Simson lines

If perpendiculars are dropped onto the sides of a triangle ABC from a point P, the feet of these perpendiculars usually form the vertices of a triangle $A_1B_1C_1$ (the *pedal triangle* discussed in Section 1.9). Let us now examine the exceptional case where the point P lies on the circumcircle, as in Figure 2.5A. To be definite, we have taken P to lie on the arc CA that does not contain B, between A and the point diametrically opposite to B. All other cases can be derived by re-naming A, B, C. Because of the right angles at A_1, B_1 and C_1, P lies also on the circumcircles of triangles A_1BC_1, A_1B_1C and AB_1C_1. Therefore

$$\angle APC = 180° - B = \angle C_1PA_1$$

and, subtracting $\angle APA_1$, we deduce

$$\angle A_1PC = \angle C_1PA.$$

But since points A_1, C, P, B_1 lie on a circle,

$$\angle A_1PC = \angle A_1B_1C,$$

and since points A, B_1, P, C_1 lie on a circle,

$$\angle C_1PA = \angle C_1B_1A.$$

Thus

$$\angle A_1B_1C = \angle C_1B_1A,$$

so that the points A_1, B_1, C_1 are collinear; the pedal triangle is "degenerate.".

Conversely, if a point P is so situated that the pedal triangle of $\triangle ABC$ is degenerate, P must evidently lie in the region of the plane that is inside one angle of $\triangle ABC$ and beyond the opposite side. By re-naming the vertices if necessary, we can assume that this "one angle" is B, and that C_1 lies on the extension of the side BA beyond A, as in Figure 2.5A. We can then reverse the steps in the above discussion of angles and conclude that P lies on the circumcircle. Hence

THEOREM 2.51. *The feet of the perpendiculars from a point to the sides of a triangle are collinear if and only if the point lies on the circumcircle.*

The line containing the feet is known as the *Simson line* (or sometimes just the *simson*) of the point with respect to the triangle. Robert Simson (1687–1768) made several contributions to both geometry and arithmetic. For instance, it was he who discovered that, if f_n is the nth term of the Fibonacci sequence 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, ⋯ , then $f_{n-1}f_{n+1} - f_n^2 = (-1)^n$ [6, pp. 165–168]. The "simson" was attributed to him because it seemed to be typical of his geometrical ideas. However, historians have searched through his works for it in vain. Actually it was discovered in 1797 by William Wallace.

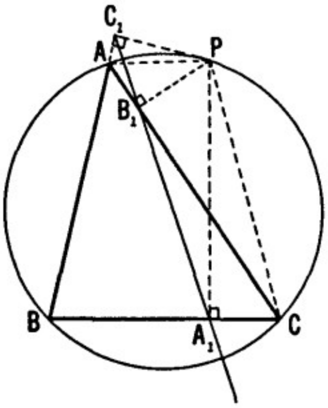

Figure 2.5A

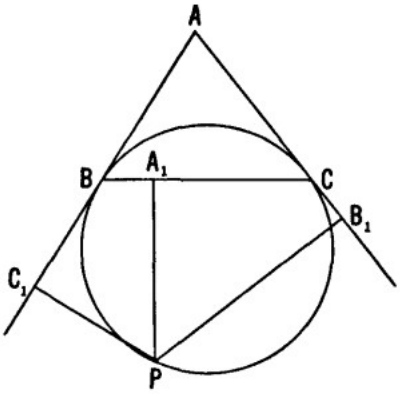

Figure 2.5B

EXERCISES

1. Does our proof of Theorem 2.51 require any modification when $\triangle ABC$ has an obtuse angle?

2. What point on the circle has CA as its Simson line?

3. Are there any points that lie on their own Simson lines? What lines are these?

4. The tangents at two points B and C on a circle meet at A. Let $A_1B_1C_1$ be the pedal triangle of the isosceles triangle ABC for an arbitrary point P on the circle, as in Figure 2.5B. Then

$$PA_1^2 = PB_1 \times PC_1.$$

2.6 Ptolemy's theorem and its extension

The concept of the Simson line can be used to derive a very useful theorem, as follows. Let us examine Figure 2.5A again. Although the "pedal triangle" $A_1B_1C_1$ is degenerate, the lengths of its "sides" are still given by Theorem 1.91:

$$B_1C_1 = \frac{aAP}{2R}, \qquad A_1C_1 = \frac{bBP}{2R}, \qquad A_1B_1 = \frac{cCP}{2R}.$$

Since $A_1B_1 + B_1C_1 = A_1C_1$, we deduce $cCP + aAP = bBP$, that is

$$AB \times CP + BC \times AP = AC \times BP.$$

Since $ABCP$ is a cyclic quadrilateral, we have thus proved Ptolemy's theorem:

THEOREM 2.61. *If a quadrilateral is inscribed in a circle, the sum of the products of the two pairs of opposite sides is equal to the product of the diagonals.*

Ptolemy's theorem has a converse that can be strengthened by observing that, for any location of B_1 other than on the segment A_1C_1, the equation $A_1B_1 + B_1C_1 = A_1C_1$ has to be replaced by the "triangle inequality"

$$A_1B_1 + B_1C_1 > A_1C_1,$$

which yields

$$AB \times CP + BC \times AP > AC \times BP.$$

Hence

THEOREM 2.62. *If ABC is a triangle and P is not on the arc CA of its circumcircle, then*

$$AB \times CP + BC \times AP > AC \times BP.$$

EXERCISES

1. Let P be any point in the plane of an equilateral triangle ABC. Then $PC + PA = PB$ or $PC + PA > PB$ according as P does or does not lie on the arc CA of the circumcircle. [For an interesting application of this result, see **23**, pp. 11–12.]

2. If a point P lies on the arc CD of the circumcircle of a square $ABCD$, then $PA(PA + PC) = PB(PB + PD)$.

3. If a circle cuts two sides and a diagonal of a parallelogram $ABCD$ at points P, R, Q as shown in Figure 2.6A, then

$$AP \times AB + AR \times AD = AQ \times AC.$$

Hint: Apply Theorem 2.61 to the quadrilateral $PQRA$ and then replace the sides of $\triangle PQR$ by the corresponding sides of the similar triangle CBA.

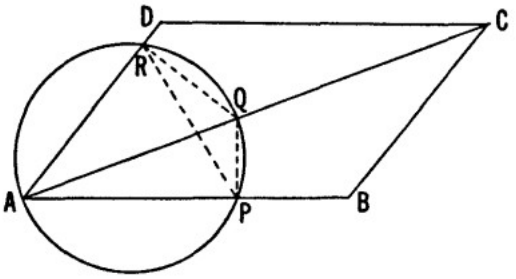

Figure 2.6A

2.7 More on Simson lines

The Simson line has many interesting properties, and it may be worthwhile to investigate some of them. Let us begin by examining Figure 2.7A, which is the same as Figure 2.5A except that the perpendicular PA_1 has been extended to meet the circumcircle at U, and the line AU has been drawn.

The cyclic quadrilaterals $PAUC$ and PB_1A_1C tell us that

$$\angle PUA = \angle PCA = \angle PCB_1 = \angle PA_1B_1.$$

Therefore *the line AU is parallel to the Simson line A_1B_1.*

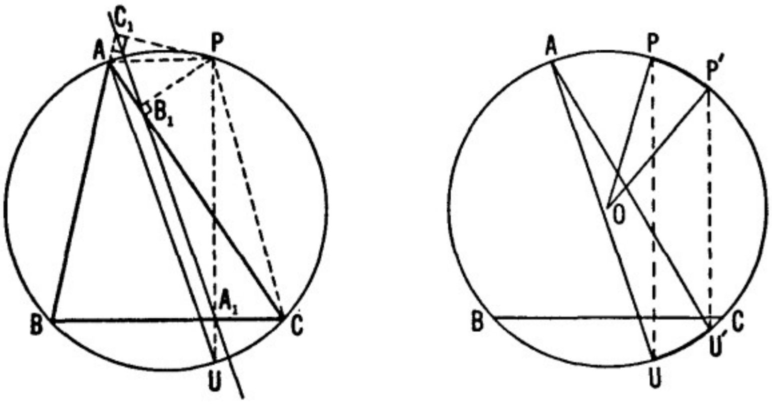

Figure 2.7A Figure 2.7B

Let us now compare the Simson line of P with the Simson line of another point P' (also, of course, on the circumcircle). The angle between these two Simson lines is simply the angle UAU' between the lines AU and AU' which are parallel to them (Figure 2.7B). The two chords PU and $P'U'$, both perpendicular to BC, are parallel to each other, and cut off equal arcs PP' and UU'. Thus

$$\angle UAU' = \tfrac{1}{2}\angle UOU' = \tfrac{1}{2}\angle POP'$$

or, if we distinguish between positive and negative angles,

$$\angle UAU' = \tfrac{1}{2}\angle UOU' = -\tfrac{1}{2}\angle POP'.$$

We have thus proved:

THEOREM 2.71. *The angle between the Simson lines of two points P and P' on the circumcircle is half the angular measure of the arc $P'P$.*

If we imagine P to run steadily round the circumcircle, the line AU will rotate steadily about A at half the angular velocity in the opposite sense, so as to reverse its direction by the time P has described the whole circumference. Meanwhile, the Simson line will turn in a corresponding manner about a continuously changing center of rotation. In fact, the Simson line envelops a beautifully symmetrical curve called a deltoid or "Steiner's hypocycloid" [**20**]. The motion is demonstrated very clearly in the film *Simson Line* by T. J. Fletcher.

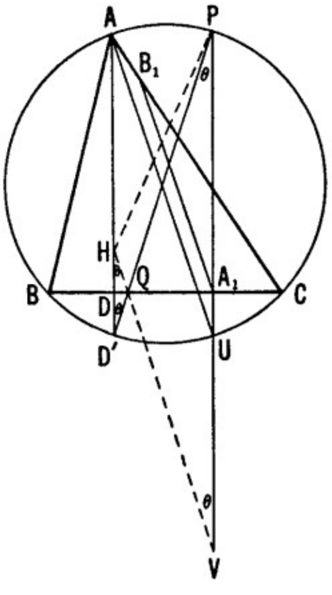

Figure 2.7C

To continue our investigation, let us now examine Figure 2.7C, which is a combination of Figures 2.4B and 2.7A with the extra lines HP, $D'P$ (meeting BC at Q) and HQ (extended to meet PU at V). Since both HD' and PV are perpendicular to BC, equation (2.43) shows that the triangles QHD' and QPV are isosceles. In other words, HV is the image of $D'P$ by reflection in BC. Since

$$\angle D'HV = \angle PVH = \angle D'PU = \angle D'AU,$$

the line HV is parallel to AU, which we have already shown to be parallel to the Simson line of P.

Finally, we observe that, in $\triangle PHV$, the Simson line A_1B_1 is parallel to the side HV and bisects the side PV (at A_1). Hence it must also bisect the remaining side PH:

THEOREM 2.72. *The Simson line of a point (on the circumcircle) bisects the segment joining that point to the orthocenter.*

This has been merely an introduction to the topic of Simson lines. They have many other properties which we must regretfully leave to other sources.

EXERCISES

1. The Simson lines of diametrically opposite points on the circumcircle are perpendicular to each other and meet on the nine-point circle.

2. Let ABC be an equilateral triangle inscribed in a circle with center O, and let P be any point on the circle. Then the Simson line of P bisects the radius OP.

2.8 The Butterfly

The Butterfly theorem has been around for quite a while. We state it as follows (see Figure 2.8A):

THEOREM 2.81. *Through the midpoint M of a chord PQ of a circle, any other chords AB and CD are drawn; chords AD and BC meet PQ at points X and Y. Then M is the midpoint of XY.*

For this theorem numerous proofs have been developed, varying in length and difficulty. Three have been received from Dr. Zoll of Newark State College. He mentioned that one of these was submitted in 1815 by W. G. Horner, discoverer of Horner's Method for approximating the roots of a polynomial equation. (According to E. T. Bell, Horner's Method was anticipated by a Chinese.) For another proof, see R. Johnson [17, p. 78]. The shortest proof employs projective geometry [7, pp. 78, 144]. The one presented here, though not very short, is simple and easy to remember.

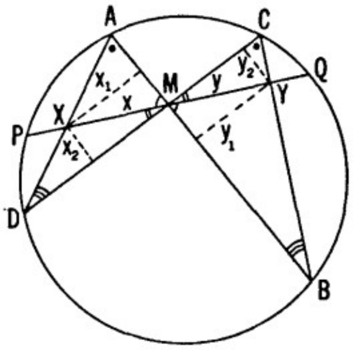

Figure 2.8A

We begin by dropping perpendiculars x_1 and y_1 from X and Y to AB, x_2 and y_2 from X and Y to CD. Writing for convenience $a = PM = MQ$, $x = XM$, $y = MY$, we observe that the pairs of similar triangles Mx_1 and My_1, Mx_2 and My_2, Ax_1 and Cy_2, Dx_2 and By_1 yield

$$\frac{x}{y} = \frac{x_1}{y_1}, \quad \frac{x}{y} = \frac{x_2}{y_2}, \quad \frac{x_1}{y_2} = \frac{AX}{CY}, \quad \frac{x_2}{y_1} = \frac{XD}{YB},$$

whence

$$\frac{x^2}{y^2} = \frac{x_1}{y_1}\frac{x_2}{y_2} = \frac{x_1}{y_2}\frac{x_2}{y_1} = \frac{AX \times XD}{CY \times YB} = \frac{PX \times XQ}{PY \times YQ}$$

$$= \frac{(a-x)(a+x)}{(a+y)(a-y)} = \frac{a^2-x^2}{a^2-y^2} = \frac{a^2}{a^2} = 1,$$

and $x = y$, as we wished to prove.

EXERCISES

1. In Figure 2.8A the lines AC and BD (extended) intersect PQ (extended) at two points which, like X and Y, are equidistant from M.

2. Let PT and PB be two tangents to a circle, AB the diameter through B, and TH the perpendicular from T to AB. Then AP bisects TH.

3. Let the incircle (with center I) of $\triangle ABC$ touch the side BC at X, and let A' be the midpoint of this side. Then the line $A'I$ (extended) bisects AX.

2.9 Morley's theorem

One of the most surprising theorems in elementary geometry was discovered about 1904 by Frank Morley (the father of Christopher Morley, whose novel, *Thunder on the Left*, has a kink in its time sequence that appeals particularly to geometers). He mentioned it to friends in Cambridge, England, and published it twenty years later in Japan. Meanwhile it was rediscovered and presented as a problem in the Educational Times. Two solutions were sent in, one of which, by M. T. Naraniengar,† is as neat as any of the dozens that have been devised since then. The theorem states:

THEOREM 2.91. *The points of intersection of the adjacent trisectors of the angles of any triangle are the vertices of an equilateral triangle.*

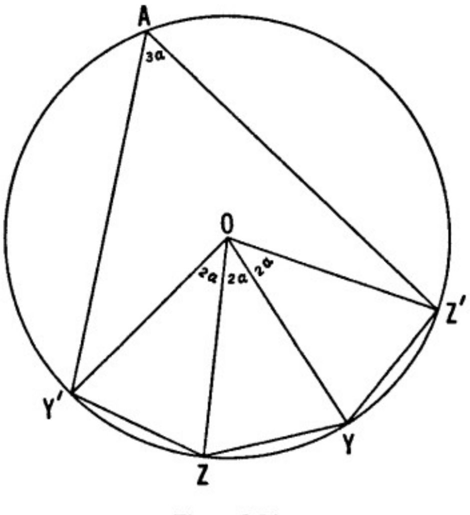

Figure 2.9A

Naraniengar's proof requires a preparatory theorem or lemma (illustrated in Figure 2.9A):

LEMMA. *If four points Y', Z, Y, Z' satisfy the conditions*

---

† Mathematical Questions and Their Solutions from the Educational Times (New Series), 15 (1909), p. 47.

$$Y'Z = ZY = YZ'$$

and

$$\angle YZY' = \angle Z'YZ = 180° - 2\alpha > 60°$$

then they lie on a circle. Moreover, if a point A, *on the side of the line* $Y'Z'$ *away from* Y, *is so situated that* $\angle Y'AZ' = 3\alpha$, *then this fifth point* A *also lies on the same circle.*

To prove the lemma, let the internal bisectors of the equal angles YZY' and $Z'YZ$ meet at O. Then $OY'Z$, OZY, OYZ' are three congruent isosceles triangles having base angles $90° - \alpha$. Their equal sides OY', OZ, OY, OZ' are radii of a circle with center O, and their angles at this common vertex are 2α. In other words, each of the equal chords $Y'Z$, ZY, YZ' subtends an angle 2α at the center O and consequently subtends an angle α at any point on the arc $Y'Z'$ not containing Y. This arc may be described as the locus of points (on the side of the line $Y'Z'$ away from Y) from which the chord $Y'Z'$ subtends an angle 3α. One such point is A; therefore A lies on the circle.

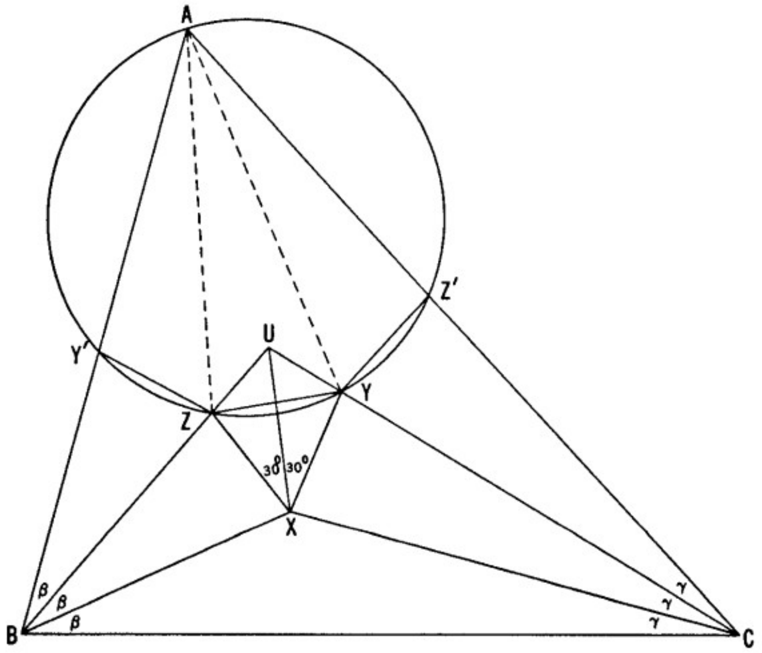

Figure 2.9B

Now we are ready to attack Theorem 2.91 itself. In Figure 2.9B, the trisectors of the angles $B = 3\beta$ and $C = 3\gamma$ meet as shown at the points U and X. In $\triangle BCU$, the angles at B and C are bisected by BX and CX; hence X is the incenter, and the angle at U is bisected by UX. If we construct points Y and Z on the lines CU and BU so that XY and XZ make equal angles 30° with XU on opposite sides, then $\Delta UXY \cong \Delta UXZ$, $XY = XZ$, and since the angle at X is 60° it follows that ΔXYZ is equilateral.

Also ΔUZY is isosceles. Its angle at U is the same as that of ΔUBC, whose other angles are 2β and 2γ; therefore the equal angles of ΔUYZ at Y and Z are each $\beta + \gamma$.

Writing $\alpha = A/3$, we deduce from $A + B + C = 180°$ that

$$\alpha + \beta + \gamma = 60°, \qquad \text{whence} \qquad \beta + \gamma = 60° - \alpha.$$

Thus

$$\angle YZU = 60° - \alpha \qquad \text{and} \qquad \angle XZU = 120° - \alpha.$$

Our next step is to mark off $BY' = BX$ on BA, and $CZ' = CX$ on CA. We now have

$$\Delta BZX \cong \Delta BZY' \qquad \text{and} \qquad \Delta CYX \cong \Delta CYZ',$$

so that

$$Y'Z = ZX = ZY = YX = YZ'.$$

Before we can apply the lemma, we still have to evaluate $\angle YZY'$ and $\angle Z'YZ$. However, this is a simple matter. Since the equal angles BZY' and BZX have equal supplements,

$$\angle UZY' = \angle XZU = 120° - \alpha$$

and

$$\begin{aligned} \angle YZY' &= \angle YZU + \angle UZY' = (60° - \alpha) + (120° - \alpha) \\ &= 180° - 2\alpha. \end{aligned}$$

Similarly, $\angle Z'YZ = 180° - 2\alpha$; and of course $\alpha = \frac{1}{3}A < 60°$.

Applying the lemma, we deduce that the five points Y', Z, Y, Z', A all lie on a circle. Since the equal chords $Y'Z$, ZY, YZ' subtend equal angles α at A, the lines AZ and AY trisect the angle A of ΔABC. In other words, the points X, Y, Z, which were artificially constructed so as to form an equilateral triangle, are in fact the points described in Morley's theorem. The proof is now complete.

EXERCISES

1. Let the angle trisectors AZ and CX (extended) meet at V, BX and AY at W. Then the three lines UX, VY, WZ are concurrent. (That is, in the language of projective geometry, UVW and XYZ are *perspective* triangles. In general, UVW is *not* equilateral.)

2. For what kind of triangle ABC will the pentagon $AY'ZYZ'$ be regular?

3. When $\triangle ABC$ is equilateral, the four points Y', Z, Y, Z' occur among the vertices of a regular enneagon (9-gon) in which A is the vertex opposite to the side ZY.

4. For a triangle with angles 3α, 3β, 3γ and circumradius R, Morley's triangle has sides $8R \sin \alpha \sin \beta \sin \gamma$.

5. If $Z'Y = YZ = ZY'$ on the side $Z'Y'$ of a rectangle $BCZ'Y'$ whose center X forms an equilateral triangle with Y and Z, then BX and BZ trisect the right angle at B.

1.3 Non-linearity and wave phenomena

Non-linearity means that in general wavefronts can interact with each other and with regions of static curvature. This can allow a variety of interesting phenomena, some of which we discuss below. There are probably plenty more such phenomena which will be among the surprises that await the birth of gravitational wave astronomy.

(a) Waves can be scattered by strong background curvature. For example, the gravitational waves emanating from the coalescence of a binary neutron star system, and its subsequent collapse to form a black hole, will be scattered in the intense curvature of the forming black hole (Thorne, 1987, and references therein).

(b) Waves can be focussed by background curvature. On a cosmological scale galaxies can focus gravitational waves from distant sources as they are already observed to do optically with quasars. On a more local scale, the Sun can act as a lens to focus plane gravitational waves to a focal point near to the orbit of Jupiter (about 20 AU from the Sun). There is a catch here, however, and it is probably not worth sending a gravitational wave detector out there. The problem is that the solar lens is not a lot larger than a gravitational wavelength. Thorne (1983) shows that strong focussing only occurs if the gravitational diameter of the Sun, $4GM/c^2$, is large compared to the wavelength; otherwise diffraction spreads the beam sufficiently that the focussed amplitude is not much increased. Thus only waves of frequency $> 10^4$ Hz will be strongly focussed, and, as we shall see later, these are not of great interest.

(c) Waves can be parametrically amplified in regions of time varying curvature. If the curvature is varying dynamically, for example in the early universe after the big bang, gravitational waves can be amplified as they interact with the background. This can increase the amplitude of gravitational waves emanating from fluctuations in the early universe. Similarly, the background curvature may be modulated by one source of waves (which an engineer might call the pump). A second incident wave (the signal) may be amplified and frequency shifted by this interaction exactly as a microwave or optical signal is amplified by a pumped non-linear medium. Thus a coalescing binary with orbital frequency ω_b will upconvert incident radiation to frequency $\omega_b + \omega_i$ while simultaneously generating radiation at twice the binary frequency. Similarly, one can imagine (probably very unlikely) processes whereby a massive black hole focusses intense gravitational waves causing non-linear harmonic generation.

(d) Waves interact with self generated curvature. This is epitomised by the geon, proposed by Wheeler (1962). A geon is a bundle of gravitational waves held together by its own self generated curvature. While most doubt that such objects could exist, one can conjecture about beams or pulses of self focussing gravitational waves, confining themselves in their own self generated valley of background curvature.

(e) Colliding gravitational waves can focus each other so strongly that the wavefront may collapse to form a singularity. If the singularity forms only around one wavefront, a high velocity black hole will fly out from the collision, but if it forms about both wavefronts the resulting black hole will be nearly stationary (Yurtsever, 1988a–c).

These are some of the exotic aspects of the non-linearity. At a more immediately practical level, the problem of the non-linearity of general relativity affects above all the modelling of sources of gravitational waves. Thus the majority of source calculations can only be approximations. Even with the use of powerful numerical codes, the behaviour of matter under conditions of intense gravity and high densities is so uncertain that our confidence in their results cannot be high. (See, for example, Nakamura, 1987.) In spite of this, however, we will see in chapter 2 that good order of magnitude estimates exist for a range of wave generation processes.

1.4 Introduction to gravitational waves

In the case of the analysis for detection of gravitational waves it is a different matter. For even the strongest imaginable gravitational waves from astrophysical sources we need only consider plane, linear waves on an essentially flat space background. This is because the amplitude of waves crossing the solar system, even from relatively nearby strong sources, must always be exceedingly low, despite the fact that the energy flux may be enormous. We will come back to this point in chapter 2. As a result, in spite of non-linearity, we go ahead and make a separation, which is not fully precise. We assume superposition, which is essential to our concept of gravitational waves, which is not strictly rigorous, which is bothersome to some theorists, but which need bother experimentalists not at all. We separate spacetime curvature into a background term and a wave term by assuming that the background curvature varies slowly while the wave varies rapidly. That is

$$R_{\alpha\beta\mu\nu} = R^{\mathrm{B}}_{\alpha\beta\mu\nu} + R^{\mathrm{W}}_{\alpha\beta\mu\nu}. \tag{1.3}$$

It is possible to go on to further simplify things by assuming plane waves on a background of flat Minkowski spacetime, or alternatively to simplify Einstein's equations for weak fields and explicitly solve for a wave solution. We shall only sketch the barest details of the derivation here, as it involves considerable mathematical detail readily found elsewhere, and anyhow is outside the scope of this book.

1. Basic Theory of Curves and Surfaces

1.1 General

1.1.1 Properties of Object Shapes and Their Mathematical Representation

Before a computer can perform processing relating to a shape, a mathematical description of that shape must be provided on the computer's memory. Such a description should preserve as many of the properties of the actual object shape as possible. From the point of view of computer processing the following properties are particularly important.

(1) Spatial Uniqueness

Two objects cannot occupy the same space at the same time. This property is called *spatial uniqueness*. Object shapes are expressed in a computer by data structures using numerical shape data and functions, but spatial uniqueness is very difficult to express. Therefore a program is needed to test for overlap between positions of two bodies.

(2) Boundedness and Continuity

An object shape occupies a bounded space defined by a number of mutually adjacent surfaces of finite extent. In this book, this property is called the *boundedness* of the object shape. In performing computer-aided design it is extremely important for the range over which the shape being designed extends to be conveniently expressed. Let us consider the case of a curve. The curve in Fig. 1.1 is multivalued: it takes on several y-values for some values of x, and also several x-values for some values of y. If this curve is described by

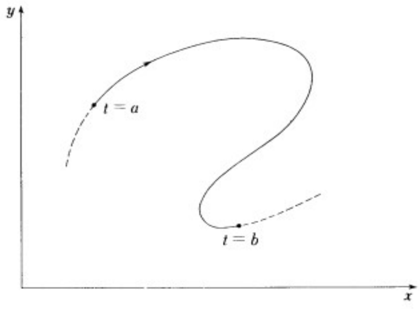

Fig. 1.1. A curve segment for which y is multi-valued with respect to x and x is multi-valued with respect to y

a function $y=F(x)$, trying to describe its range can be very difficult. On the other hand, if it is described by a parametric vector function $\boldsymbol{P}(t)=[x(t)\ y(t)]$, then the range can be described simply as $a \leqq t \leqq b$ where $t=a$ and $t=b$ at the two ends of the curve.

Curved (or plane) object surfaces are in continuous connection, without a break, along curved boundary lines or ridge lines. This property of an object is called *continuity*. Many types of processing on shapes make effective use of this continuity property. Consequently, in expressing an object shape on a computer, it is important to express how the surfaces connect to each other along boundary curves. This description is performed by a *data structure*.

(3) Independence of Coordinate Axes

An object shape is independent of the coordinate system in which it is described. This seems natural enough, but it is an important condition in formulating a mathematical model of the object. As an example, consider the problem of selecting points on a clay model, measuring their coordinates and then fitting them to a mathematical representation of a curve. This is normally done by letting the measured points define the curve and *interpolating* between them. The final curve must be the same regardless of the coordinate system in which the coordinates of the points were measured. This property is called *shape invariance under transformation*. If the method of arriving at a mathematical representation is inappropriate, the condition of shape invariance under transformation will not be satisfied.

For example, consider the following parametric curve.

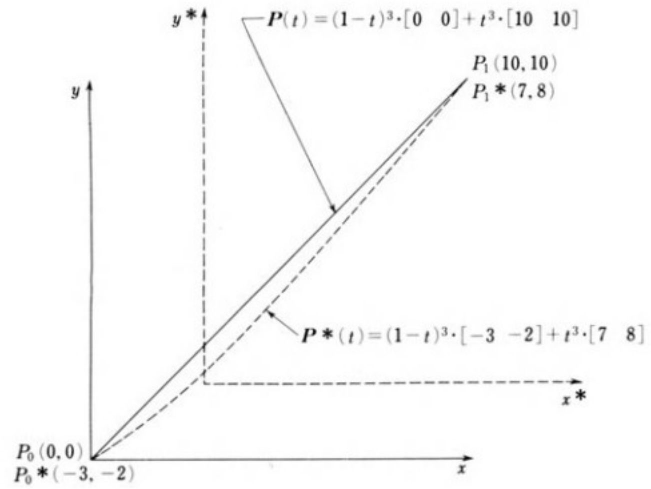
$$\boldsymbol{P}(t)=A_0(t)\,\boldsymbol{P}_0+A_1(t)\,\boldsymbol{P}_1 \quad (0 \leqq t \leqq 1) \tag{1.1}$$

where $A_0(t)=(1-t)^3$ and $A_1(t)=t^3$. In this case, the relations $A_0(0)=1$, $A_0(1)=0$, $A_1(0)=0$, $A_1(1)=1$ hold, so we see that $\boldsymbol{P}(t)$ is a curve which passes through the two points $\boldsymbol{P}_0$ and $\boldsymbol{P}_1$. Taking $\boldsymbol{P}_0=[0\ 0]$ and $\boldsymbol{P}_1=[10\ 10]$, $\boldsymbol{P}(t)$ describes the line segment connecting $\boldsymbol{P}_0$ and $\boldsymbol{P}_1$ (refer to Fig. 1.2). Expressing $\boldsymbol{P}_0$ and $\boldsymbol{P}_1$ in the x^*y^* coordinate system, $\boldsymbol{P}_0^*=[-3\ -2]$ and $\boldsymbol{P}_1^*=[7\ 8]$; then if we let

$$\boldsymbol{P}^*(t)=A_0(t)\,\boldsymbol{P}_0^*+A_1(t)\,\boldsymbol{P}_1^*$$

$\boldsymbol{P}^*(t)$ passes through the same points as $\boldsymbol{P}(t)$ at $t=0$ and $t=1$, but for $0<t<1$ $\boldsymbol{P}^*(t)$ describes a curve different from the straight line of $\boldsymbol{P}(t)$. That is, the straight line representation of Eq. (1.1) is not desirable.

In Eq. (1.1) a curve is described as a vector using the parameter t. There is an alternate way to describe curves, the non-parametric method in the form $y=F(x)$. In the latter representation, at a point at which the curve becomes parallel to the y-axis the slope dy/dx becomes infinite, making it difficult to handle on a computer. In practice it becomes necessary to use another suitable coordinate system in which the slope does not become infinite. However, depending on the shape of the curve being represented, there are



y^*
$P(t)=(1-t)^3\cdot[0\ \ 0]+t^3\cdot[10\ \ 10]$
$P_1\,(10,10)$
y
$P_1{*}\,(7,8)$
$P{*}(t)=(1-t)^3\cdot[-3\ \ -2]+t^3\cdot[7\ \ 8]$
x^*
$P_0\,(0,0)$
$P_0{*}\,(-3,-2)$
x

Fig. 1.2. An example in which a shape does not remain invariant under coordinate transformation

some cases in which the slope will become infinite no matter what coordinate system is chosen. This happens when the curve is closed. On the other hand, with a parametric representation the slope is:

$$\frac{dy}{dx}=\frac{dy}{dt}\bigg/\frac{dx}{dt}=\frac{\dot{y}}{\dot{x}}$$

so the direction parallel to the y-axis can be simply represented by:

$$\dot{x}=0.$$

The shape of an object is independent, unaffected by the coordinate system in which it is described. This property of an object is called *axis independence*. Axis independence must exist in order for a shape to be expressed on a computer.

In the above we have studied a relation between two types of mathematical representation of a curve and the properties of a shape. We have seen that an expression for a curve in the form $y=F(x)$ is inadequate to represent the properties possessed by shapes. A parametric representation overcomes this difficulty.

The advantages which a parametric representation of a curve has over a non-parametric representation can be summarized as follows.

1) Axis independence can be expressed (refer to Sect. 1.1.3).
2) It is easier to specify the regions of a multivalued curve.
3) Since it is an independent expression with respect to x, y and z (x and y in the case of a plane curve), affine transformations and projective

transformations can easily be performed by 4 × 4 matrices (3 × 3 matrices for plane curves).

4) Representation of space curves is easy.

In order to express a space curve by a non-parametric representation, it must be defined as the intersection of two curved surfaces: $y = F(x)$ and $z = G(x)$, or $\varphi_1(x, y, z) = 0$ and $\varphi_2(x, y, z) = 0$. In a parametric representation it can be represented in the form $\boldsymbol{P}(t) = [x(t)\ y(t)\ z(t)]$.

5) Since x, y and z are expressed as explicit functions of the parameter t, a point on the curve can be easily computed.

Since curved surfaces are basically regarded as being represented by groups of curves, the above arguments with respect to curves can be thought of as also applying to curved surfaces.

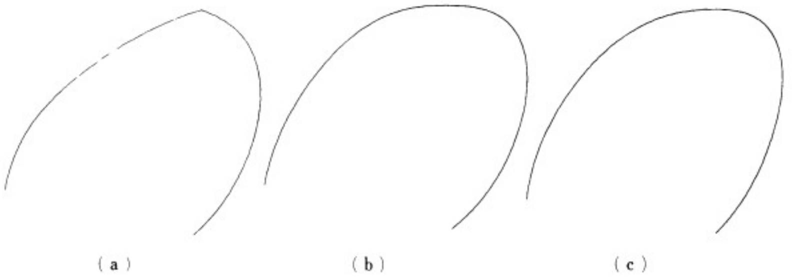
1.1.2 Design and Mathematical Representations

A mathematical representation of a curve or curved surface must not only express the properties possessed by a shape, they must also satisfy certain necessary conditions for design.

(1) Abundant Expression Power Having Generality

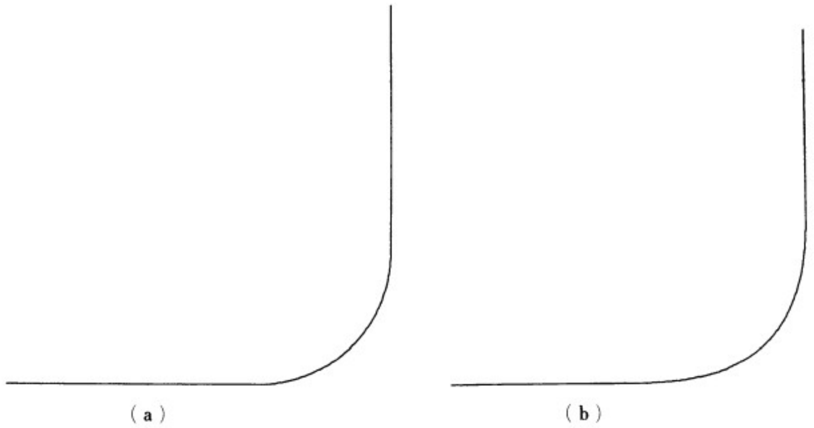
The designer's demands with regard to shapes are not limited; they change frequently, and a mathematical representation of a shape must be able to respond to them flexibly. For a mathematical representation of a curve, in some cases a straight line is appropriate, while in other cases a conic section such as a circle or ellipse might be appropriate. In addition, in some cases it is desirable not to be limited to fixed shapes, but rather for the representation to have the capability to respond flexibly to any arbitrary shape that the designer draws freely with a stylus.

Ordinarily, a curve or curved surface is thought of as consisting of a number of curve segments or surface patches which are connected together. When designing a smooth curve or curved surface, it is necessary to make sure that the curve segments or surface patches are connected smoothly. Mathematically, continuity to a sufficiently high order derivative (usually up to the slope or the curvature) is required. The smoothness of a curve involves not only this kind of local continuity but also the overall large-scale smoothness of the curve. Figure 1.3 shows examples of curves which are connected in such a manner that there is (a) continuity of position only (class C^0), (b) continuous to the slope (class C^1), (c) continuous to the curvature (class C^2). Figure 1.4 shows a corner R of a curve. In (a), the connection is done with straight line segments and a circular arc, so the slope is continuous at the connection point, but the curvature is discontinuous (class C^1). When the discontinuity of curvature reaches a certain level, it becomes noticeable to the naked eye. (b) shows a corner R with the connection performed with a curve in such a manner that the curvature is continuous (class C^2).



(a) (b) (c)

Fig. 1.3. (a) A class C^0 curve connection, (b) a class C^1 curve connection, (c) a class C^2 curve connection



(a) (b)

Fig. 1.4. Expression of a corner R (a) Class C^1, (b) class C^2

In designing a curve or curved surface, it sometimes happens that it is desired to have the slope be discontinuous at a certain point. In fact, the discontinuity of slope is sometimes necessary. A point where the slope is discontinuous is called a *cusp*. Figure 1.3(a) shows a cusp. A line of discontinuity in a curved surface is called a *crease* (refer to Fig. 1.5).

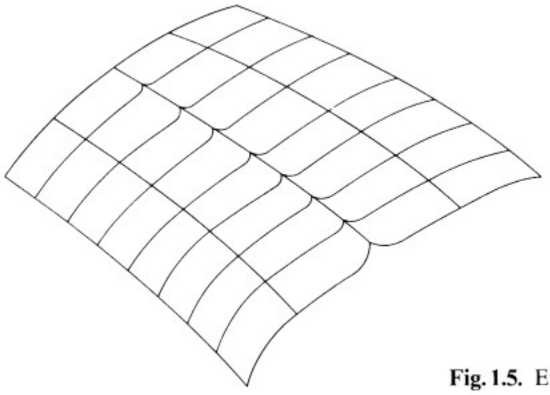


Fig. 1.5. Example of a crease in a curved surface

(2) Ease of Shape Control

Shapes of curves and curved surfaces which appear on the display could ideally be manipulated at will by the designer. At the start of the design work, the designer focuses on the overall shape that is displayed and forms his judgments. Consequently, it is desirable for the designer to be able to exercise *global* shape control (Fig. 1.6). Along the curve there are a number of *control points* which control the shape. Usually the control points are the same points that were used to define the curve. It would be very troublesome if it were necessary to change the parameters of all of the control points in order to change the shape of the curve. Ideally one would be able to change the shape of the entire curve by controlling just one suitable control point. As the design work progresses, the designer's attention shifts from the overall curve to localized sections of it. Then the designer wants to be able to change the shapes of only those sections while leaving the rest of the curve unchanged. Consequently, it is desirable to have the capability for not only global control of the shape of a curve, but also *local* control (Fig. 1.7). A local control capability is a necessary condition for being able to converge the trial-and-error design process.

There are cases in which it is impossible to control the locations of control points in such a way as to obtain the desired shape with only one

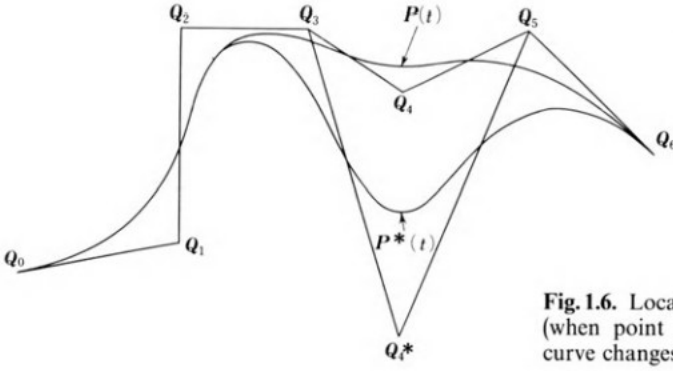

Fig. 1.6. Local control of a curve (when point Q_4 changes to Q_4^*, the curve changes from $P(t)$ to $P^*(t)$)

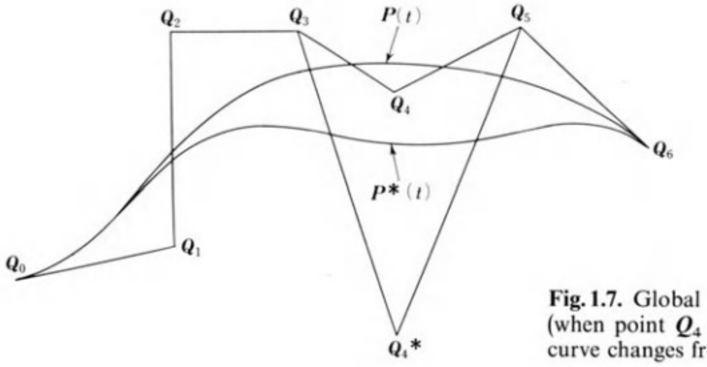

Fig. 1.7. Global control of a curve (when point Q_4 is changed to Q_4^* the curve changes from $P(t)$ to $P^*(t)$)

mathematical expression. In such cases, it is necessary to have some method to improve the capability of the mathematical expression to express a shape. Figures 1.8 and 1.9 show examples of ways in which the ability to express shapes can be increased. In Fig. 1.8 the shape is preserved while one curve segment is split into two segments. In Fig. 1.9 the shape is preserved while the degree of the curve segments is increased by one. What is important here is that the capability to express shapes is increased without changing the shapes themselves.

Some curves have special properties such as the *convex hull property* or the *variation diminishing property*. In such cases shape control is made easier because the changes that a shape will undergo when the control point parameters are varied can be predicted (refer to Chaps. 5 and 6).

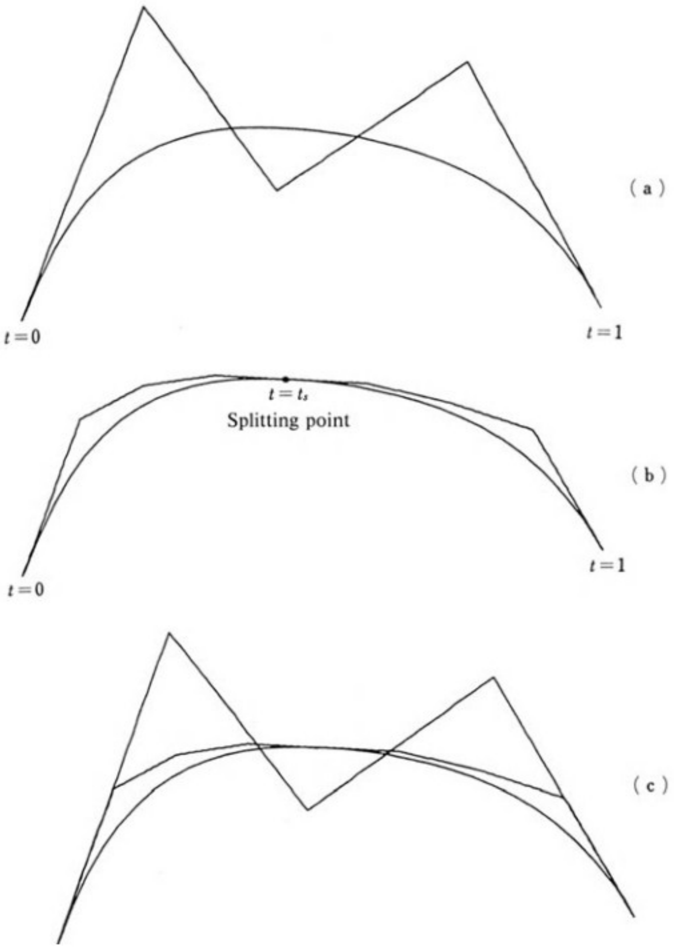

Fig. 1.8. An example of how a curve can be split into two segments while preserving its shape (a Bézier curve) (a) Before splitting, (b) after splitting, (c) after splitting

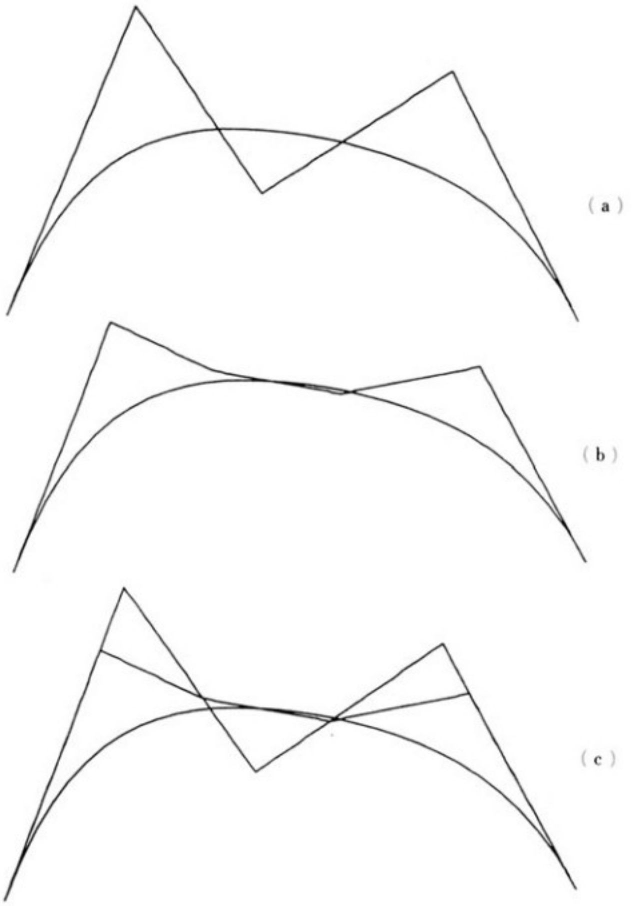

Fig. 1.9. An example in which the shape of the curve is preserved and (in form) the degree of the curve is increased (Bézier curve) (a) Before degree is increased, (b) after degree is increased; (c) before and after degree is increased

1.1.3 Invariance of a Shape Under Coordinate Transformation

In Sect. 1.1.1 we referred to the invariance of a shape under coordinate transformation. Now let us look at the conditions for such invariance to be satisfied.

Let a curve be represented by

$$\begin{aligned} \boldsymbol{P}(t) &= [x(t)\ y(t)\ z(t)] \\ &= [\phi_0(t)\ \phi_1(t) \ldots \phi_n(t)]\ [\boldsymbol{Q}_0\ \boldsymbol{Q}_1 \ldots \boldsymbol{Q}_n]^T. \end{aligned} \tag{1.2}$$

$\phi_0(t)$, $\phi_1(t)$, …, $\phi_n(t)$ are linearly independent polynomial functions of t; $\boldsymbol{Q}_0$, $\boldsymbol{Q}_1$, …, $\boldsymbol{Q}_n$ are the position vectors that define the curve.

Let us separately consider the 3-dimensional rotation matrix $\boldsymbol{T}$ (a 3×3 matrix) and the translation $\boldsymbol{m}=[m_x\ m_y\ m_z]$. In order for the shape to be invariant, it is necessary that the curve expressed in terms of $\boldsymbol{Q}_0^*, \boldsymbol{Q}_1^*, \ldots, \boldsymbol{Q}_n^*$ in the transformed coordinate system transform by the same amount as $\boldsymbol{Q}_0, \boldsymbol{Q}_1, \ldots, \boldsymbol{Q}_n$ do.

For the rotation matrix $\boldsymbol{T}$ we have:

$$\begin{aligned}\boldsymbol{P}^*(t)&=[\phi_0(t)\ \ \phi_1(t)\ \ldots\ \phi_n(t)]\begin{bmatrix}\boldsymbol{Q}_0^*\\ \boldsymbol{Q}_1^*\\ \vdots\\ \boldsymbol{Q}_n^*\end{bmatrix}=[\phi_0(t)\ \ \phi_1(t)\ \ldots\ \phi_n(t)]\begin{bmatrix}\boldsymbol{Q}_0\,\boldsymbol{T}\\ \boldsymbol{Q}_1\,\boldsymbol{T}\\ \vdots\\ \boldsymbol{Q}_n\,\boldsymbol{T}\end{bmatrix}\\ &=[\phi_0(t)\ \ \phi_1(t)\ \ldots\ \phi_n(t)]\begin{bmatrix}\boldsymbol{Q}_0\\ \boldsymbol{Q}_1\\ \vdots\\ \boldsymbol{Q}_n\end{bmatrix}\boldsymbol{T}=\boldsymbol{P}(t)\,\boldsymbol{T}\end{aligned}$$

so that in the case of rotation the condition of invariance is automatically satisfied.

Next let us consider the translation.

$$\begin{aligned}\boldsymbol{P}^*(t)&=[\phi_0(t)\ \ \phi_1(t)\ \ldots\ \phi_n(t)]\begin{bmatrix}\boldsymbol{Q}_0^*\\ \boldsymbol{Q}_1^*\\ \vdots\\ \boldsymbol{Q}_n^*\end{bmatrix}\\ &=[\phi_0(t)\ \ \phi_1(t)\ \ldots\ \phi_n(t)]\begin{bmatrix}\boldsymbol{Q}_0+\boldsymbol{m}\\ \boldsymbol{Q}_1+\boldsymbol{m}\\ \vdots\\ \boldsymbol{Q}_n+\boldsymbol{m}\end{bmatrix}\\ &=[\phi_0(t)\ \ \phi_1(t)\ \ldots\ \phi_n(t)]\begin{bmatrix}\boldsymbol{Q}_0\\ \boldsymbol{Q}_1\\ \vdots\\ \boldsymbol{Q}_n\end{bmatrix}+(\phi_0(t)+\phi_1(t)+\ldots+\phi_n(t))\,\boldsymbol{m}\\ &=\boldsymbol{P}(t)+(\phi_0(t)+\phi_1(t)+\ldots+\phi_n(t))\,\boldsymbol{m}.\end{aligned}\tag{1.3}$$

From Eq. (1.3), in order for the shape to be invariant the relation

$$\phi_0(t)+\phi_1(t)+\ldots+\phi_n(t)\equiv 1\tag{1.4}$$

must be satisfied. Equation (1.4) is sometimes called Cauchy's relation.

1.2 Curve Theory

1.2.1 Parametric Representation of Curves; Tangent Lines and Osculating Planes

Let us express a curve as a vector using the parameter t:

$$\boldsymbol{P}(t) = [x(t) \;\; y(t) \;\; z(t)] .$$

Next consider the derivative vector evaluated at $t = t_0$:[*]

$$\dot{\boldsymbol{P}}(t_0) = [\dot{x}(t_0) \;\; \dot{y}(t_0) \;\; \dot{z}(t_0)] .$$

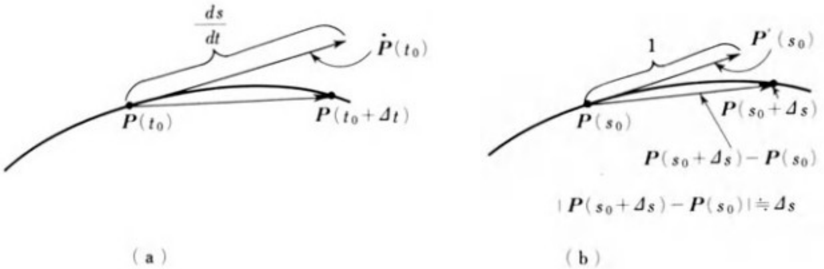
If the condition

$$\dot{\boldsymbol{P}}(t_0) \neq \boldsymbol{0} \tag{1.5}$$

is satisfied, then the curve is said to be *regular* at $t = t_0$. A point at which a curve is regular is called an *ordinary point*, a point at which it is not regular is called a *singular point*. For condition (1.5) for regularity to be satisfied, $\dot{x}(t_0)$, $\dot{y}(t_0)$ and $\dot{z}(t_0)$ must not all be zero at once. This condition is expressed mathematically by the following inequality:

$$\dot{x}(t_0)^2 + \dot{y}(t_0)^2 + \dot{z}(t_0)^2 > 0 . \tag{1.6}$$

If the derivatives of $x(t)$, $y(t)$ and $z(t)$ of a curve $\boldsymbol{P}(t)$ $(a \leqq t \leqq b)$ to order r exist and are continuous, and if the curve is regular throughout the interval, then that curve is said to be of class C^r.



$\frac{ds}{dt}$
$\dot{\boldsymbol{P}}(t_0)$
$\boldsymbol{P}(t_0)$
$\boldsymbol{P}(t_0 + \Delta t)$
1
$\boldsymbol{P}'(s_0)$
$\boldsymbol{P}(s_0)$
$\boldsymbol{P}(s_0 + \Delta s)$

(a)
(b)

Fig. 1.10. Diagrams explaining the tangent vector $\dot{\boldsymbol{P}}(t_0)$ and the unit tangent vector $\boldsymbol{P}'(s_0)$ (a) The tangent vector, (b) the unit tangent vector

---

[*] If t is thought of as time, then the first derivative with respect to t is the velocity vector and the second derivative with respect to t is the acceleration vector

In Fig. 1.10(a), consider the vector $\boldsymbol{P}(t_0+\Delta t)-\boldsymbol{P}(t_0)$, from $\boldsymbol{P}(t_0)$ to $\boldsymbol{P}(t_0+\Delta t)$ on the curve $\boldsymbol{P}(t)$, divided by Δt:

$$\frac{\boldsymbol{P}(t_0+\Delta t)-\boldsymbol{P}(t_0)}{\Delta t}.$$

This vector indicates the direction from $\boldsymbol{P}(t_0)$ to $\boldsymbol{P}(t_0+\Delta t)$. If the curve is regular at $t=t_0$, then this vector converges to the finite magnitude vector $\dot{\boldsymbol{P}}(t_0)$ in the limit as $\Delta t \to 0$. $\dot{\boldsymbol{P}}(t_0)$ is called the tangent vector at the point $t=t_0$.

Let us now use the length s of the curve as a parameter. We will indicate the derivative with respect to s by the prime symbol $'$ to distinguish it from the derivative with respect to t.

Since

$$\frac{d\boldsymbol{P}}{ds} \equiv \boldsymbol{P}' = \frac{d\boldsymbol{P}}{dt}\,\frac{dt}{ds} = \frac{\dot{\boldsymbol{P}}}{\dot{s}} \tag{1.7}$$

$$\frac{ds}{dt} \equiv \dot{s} = \sqrt{\left(\frac{dx}{dt}\right)^2+\left(\frac{dy}{dt}\right)^2+\left(\frac{dz}{dt}\right)^2} = \sqrt{\dot{\boldsymbol{P}}^2} \tag{1.8}$$

then if $\dot{\boldsymbol{P}} \neq \boldsymbol{0}$, we have:

$$\boldsymbol{P}' = \frac{\dot{\boldsymbol{P}}}{\dot{s}} = \frac{\dot{\boldsymbol{P}}}{\sqrt{\dot{\boldsymbol{P}}^2}} \tag{1.9}$$

$$\therefore \ |\boldsymbol{P}'| = 1. \tag{1.10}$$

That is, $\boldsymbol{P}'$ is in the same direction as $\dot{\boldsymbol{P}}$, and its magnitude is 1. $\boldsymbol{P}'$ is called the *unit tangent vector* (refer to Fig. 1.10(b)). It can be seen from Eq. (1.8) that $\dot{s}$ is the magnitude of the tangent vector. In this book, the magnitude of the tangent vector will sometimes be denoted by α, and the unit tangent vector by $\boldsymbol{t}$. Hence we have:

$$\dot{s} \equiv \alpha \tag{1.11}$$

$$\boldsymbol{P}' \equiv \boldsymbol{t}. \tag{1.12}$$

The equation of a tangent line can be expressed in terms of a parameter u as:

$$\boldsymbol{R}(u) = \boldsymbol{P}(t_0) + u\boldsymbol{t}(t_0). \tag{1.13}$$

Here the parameter u is the distance from the tangent point.

At a point where a curve is regular, the tangent line is unique. However, at a singular point there occur various anomalous cases. Examples of singular points are shown in Figs. 1.11 and 1.12. At a cusp, as shown in Fig. 1.11, $\dot{\boldsymbol{P}}$

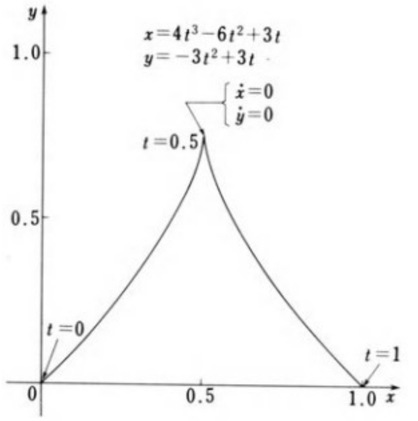

Fig. 1.11. Example of a singular point (1)

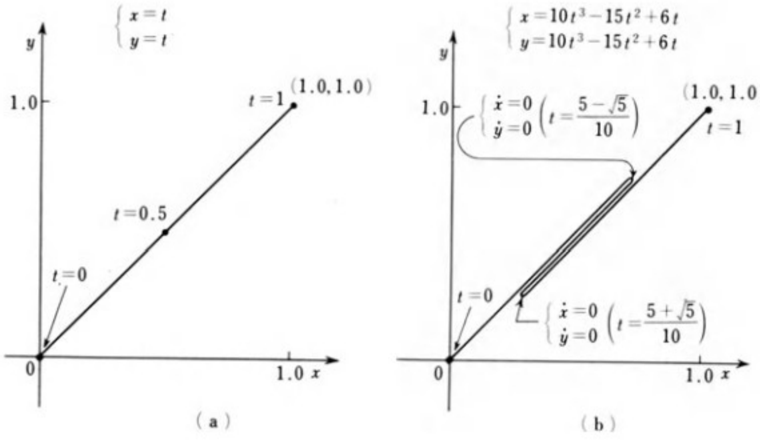

Fig. 1.12. Example of a singular point (2)

can become discontinuous or a **0** vector. Figure 1.12 shows examples in which line segments are expressed parametrically. With the expression used in Fig. 1.12(a), the line segments are regular over the entire interval. In contrast, in Fig. 1.12(b), although the line being expressed is the same two singular points occur within the interval. In this case, as t increases from the starting point $t=0$ to $t=(5-\sqrt{5})/10$, the point on the line progresses steadily toward the end point. At $t=(5-\sqrt{5})/10$ $\dot{x}=\dot{y}=0$, so this point is a singular point. From $t=(5-\sqrt{5})/10$ to $t=(5+\sqrt{5})/10$, as t increases the point on the line progresses back toward the starting point. $t=(5+\sqrt{5})/10$ is another singular point; there the direction reverses again and the point on the line progresses toward the end point $t=1$. The possibilities for such *parameterization,* the assigning of a relation between points on a line and a parameter, are numerous. It is desirable to choose a parameterization such that the curve is normal at as many points as possible.

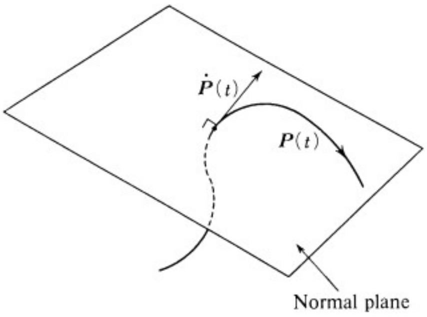

Fig. 1.13. The normal plane

Another type of singular point is one at which the curve *degenerates* to a single point.

A plane which passes through point $\boldsymbol{P}(t_0)$ on a curve and is perpendicular to the tangent line to the curve at that point is called *normal plane* (Fig. 1.13). The equation of a normal plane is:

$$(\boldsymbol{R}-\boldsymbol{P}(t_0))\cdot\dot{\boldsymbol{P}}(t_0)=0. \tag{1.14}$$

Consider a point $\boldsymbol{P}(t_0)$ on a curve and a plane which passes through it and two points very close to it, $\boldsymbol{P}(t_0+\Delta_1 t)$ and $\boldsymbol{P}(t_0+\Delta_2 t)$. The plane that is approached in the limit as $\Delta_1 t$ and $\Delta_2 t$ approach 0 independently is called the *osculating plane* at point $\boldsymbol{P}(t_0)$. The osculating plane is given by the following equation.

$$[\boldsymbol{R}-\boldsymbol{P}(t_0), \dot{\boldsymbol{P}}(t_0), \ddot{\boldsymbol{P}}(t_0)]=0. \tag{1.15}$$

The brackets indicate a triple scalar product; $\dot{\boldsymbol{P}}(t_0)\times\ddot{\boldsymbol{P}}(t_0)\neq 0$. Equation (1.15) is the condition for the three vectors $\boldsymbol{R}-\boldsymbol{P}(t_0)$, $\dot{\boldsymbol{P}}(t_0)$ and $\ddot{\boldsymbol{P}}(t_0)$ to lie in the same plane.

A general plane passing through the point $\boldsymbol{P}(t_0)$ can be written in terms of its unit normal vector $\boldsymbol{a}$ as $\boldsymbol{a}\cdot(\boldsymbol{R}-\boldsymbol{P}(t_0))=0$. The length of the perpendicular distance from the point $\boldsymbol{P}(t_0+\Delta t)$ on the curve $\boldsymbol{P}(t)$ to this plane is:

$$\boldsymbol{a}\cdot(\boldsymbol{P}(t_0+\Delta t)-\boldsymbol{P}(t_0))=\boldsymbol{a}\cdot\left(\dot{\boldsymbol{P}}(t_0)\,\Delta t+\frac{\ddot{\boldsymbol{P}}(t_0)}{2!}\,\Delta t^2+\dots\right)$$

(Fig. 1.14). In the special case when $\boldsymbol{a}\cdot\dot{\boldsymbol{P}}(t_0)=0$, $\boldsymbol{a}\cdot\ddot{\boldsymbol{P}}(t_0)=0$, that is, when the plane is the osculating plane, this length is a 3rd-order infinitesimal with respect to Δt. Consequently, the osculating plane is the plane that best fits the curve at the point $\boldsymbol{P}(t_0)$.

The line that lies in the osculating plane, passes through the point $\boldsymbol{P}(t_0)$ and is perpendicular to the tangent vector $\dot{\boldsymbol{P}}(t_0)$ at that point is called the *principal normal*. The line that passes through point $\boldsymbol{P}(t_0)$ and is perpendicular to the osculating plane is called the *binormal*, and the plane determined by the

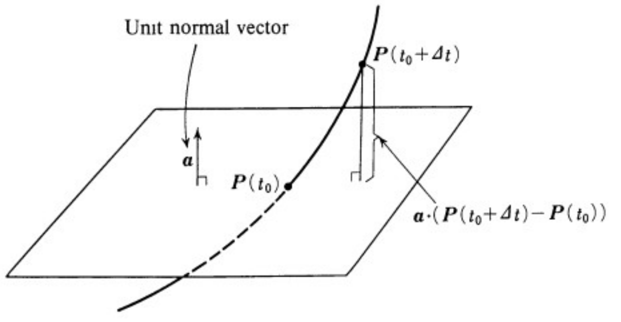

Fig. 1.14. Perpendicular distance from a point on a curve to a plane

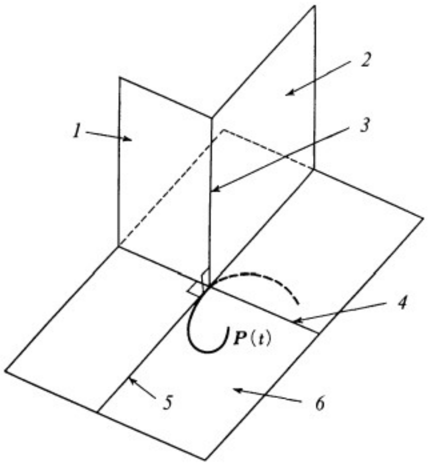

Fig. 1.15. Relation between the normal plane, osculating plane and rectifying plane. *1* normal plane; *2* rectifying plane; *3* binormal; *4* principal normal; *5* tangent line, *6* osculating plane

tangent and the binormal is called the *rectifying plane*. These relations are shown in Fig. 1.15.

1.2.2 Curvature and Torsion

Let us consider the meaning of the second derivative $\boldsymbol{P}''(s) \equiv d^2\boldsymbol{P}/ds^2$. From the definition of a derivative, we have:

$$\boldsymbol{P}''(s_0) = \lim_{\Delta s \to 0} \frac{\boldsymbol{P}'(s_0+\Delta s) - \boldsymbol{P}'(s_0)}{\Delta s}. \tag{1.16}$$

As shown in Fig. 1.16(a) and (b), in the limit as $\Delta s \to 0$ the numerator $\boldsymbol{P}'(s_0+\Delta s) - \boldsymbol{P}'(s_0)$ is perpendicular to the tangent vector at the point $\boldsymbol{P}(s_0)$ and points toward the center of curvature of the curve. It can be seen from

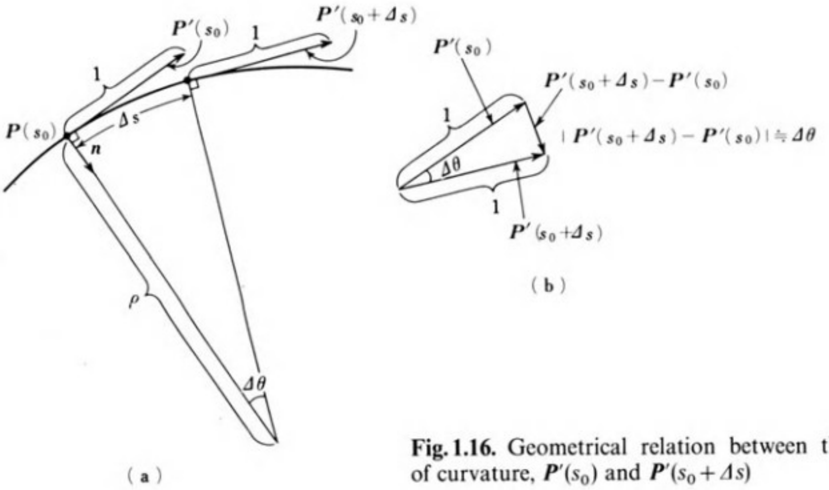

Fig. 1.16. Geometrical relation between the center of curvature, $\boldsymbol{P}'(s_0)$ and $\boldsymbol{P}'(s_0+\Delta s)$

Fig. 1.16(b) that its magnitude is $\Delta\theta$. Consequently, the magnitude of $\boldsymbol{P}''(s_0)$ is:

$$|\boldsymbol{P}''(s_0)| = \lim_{\Delta s\to 0}\frac{\Delta\theta}{\Delta s} = \lim_{\Delta s\to 0}\frac{\frac{1}{\varrho}\Delta s}{\Delta s} = \frac{1}{\varrho} \equiv \kappa .$$

Here ϱ is the radius of curvature and κ is the curvature. $\boldsymbol{P}''$ can be expressed in terms of them as:

$$\boldsymbol{P}'' = \frac{1}{\varrho}\,\boldsymbol{n} \equiv \kappa\boldsymbol{n} . \tag{1.17}$$

Here $\boldsymbol{n}$ is the unit vector pointing toward the center of curvature. Since $\boldsymbol{P}''(s)$ is a vector that has a magnitude equal to the curvature at point s and points toward the center of curvature, it is sometimes called the curvature vector. Curvature is the rate of turning of the unit tangent vector $\boldsymbol{t}$ with respect to the length of the curve s, in other words, a quantity that indicates how rapidly or slowly the curve is turning.

Next, let us find the relationship between the curvature vector $\boldsymbol{P}''(s)$ and the derivative vectors $\dot{\boldsymbol{P}}$ and $\ddot{\boldsymbol{P}}$ with respect to the parameter t. From Eq. (1.9):

$$\boldsymbol{P}'(s) = \frac{\dot{\boldsymbol{P}}}{\sqrt{\dot{\boldsymbol{P}}^2}} .$$

Differentiating the above equation with respect to s gives:

$$\boldsymbol{P}''(s)=\frac{d}{dt}\left(\frac{\dot{\boldsymbol{P}}}{\sqrt{\dot{\boldsymbol{P}}^2}}\right)\frac{dt}{ds}=\frac{\ddot{\boldsymbol{P}}\sqrt{\dot{\boldsymbol{P}}^2}-\dot{\boldsymbol{P}}\left(\dfrac{2\dot{\boldsymbol{P}}}{2\sqrt{\dot{\boldsymbol{P}}^2}}\cdot\ddot{\boldsymbol{P}}\right)}{\dot{\boldsymbol{P}}^2}\;\frac{1}{\sqrt{\dot{\boldsymbol{P}}^2}}$$

$$=\frac{1}{\dot{\boldsymbol{P}}^2}\left[\ddot{\boldsymbol{P}}-\frac{\dot{\boldsymbol{P}}}{\sqrt{\dot{\boldsymbol{P}}^2}}\left(\frac{\dot{\boldsymbol{P}}}{\sqrt{\dot{\boldsymbol{P}}^2}}\cdot\ddot{\boldsymbol{P}}\right)\right]^{4)} \tag{1.18}$$

$$\equiv\frac{\boldsymbol{B}}{\dot{\boldsymbol{P}}^2} \tag{1.19}$$

where:

$$\boldsymbol{B}\equiv\ddot{\boldsymbol{P}}-\frac{\dot{\boldsymbol{P}}}{\sqrt{\dot{\boldsymbol{P}}^2}}\left(\frac{\dot{\boldsymbol{P}}}{\sqrt{\dot{\boldsymbol{P}}^2}}\cdot\ddot{\boldsymbol{P}}\right)\equiv|\boldsymbol{B}|\,\boldsymbol{n}. \tag{1.20}$$

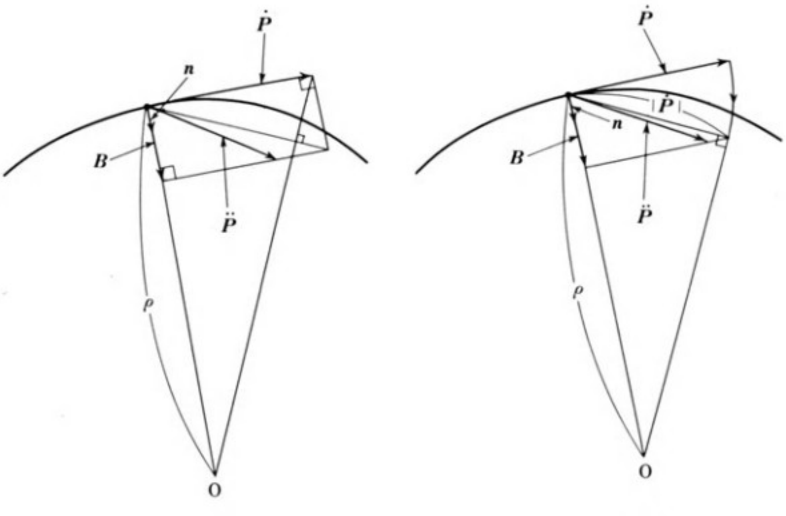
Equation (1.18) gives the relation between the curvature vector and the derivative vectors $\dot{\boldsymbol{P}}(t)$ and $\ddot{\boldsymbol{P}}(t)$ with respect to the parameter t.

Taking the absolute value of Eq. (1.19) gives:

$$|\boldsymbol{P}''(s)|=\frac{1}{\varrho}=\frac{|\boldsymbol{B}|}{|\dot{\boldsymbol{P}}|^2}. \tag{1.21}$$

By using Eqs. (1.18) and (1.21), the center of curvature can be determined graphically as shown in Fig. 1.17.

If we use the relation:



(a) (b)

Fig. 1.17. How to find the center of curvature graphically

$$\dot{s} = \frac{\dot{\boldsymbol{P}}}{\sqrt{\dot{\boldsymbol{P}}^2}} \cdot \ddot{\boldsymbol{P}} \tag{1.22}$$

then Eq. (1.18) becomes:

$$\boldsymbol{P}'' = \frac{1}{\dot{s}^2} (\ddot{\boldsymbol{P}} - \ddot{s}\boldsymbol{t}).$$

Combining this equation with Eq. (1.17) gives:

$$\ddot{\boldsymbol{P}} = \frac{\dot{s}^2}{\varrho} \boldsymbol{n} + \dot{s}\boldsymbol{t}. \tag{1.23}$$

If the parameter t is regarded as time, Eq. (1.23) expresses the well-known dynamical relation that the acceleration $\ddot{\boldsymbol{P}}$ acting on a mass point equals the sum of the tangential acceleration $\ddot{s}\boldsymbol{t}$ and the normal acceleration $(\dot{s}^2/\varrho)\,\boldsymbol{n}$. This relation is shown in Fig. 1.18.

The form of Eq. (1.18) for the curvature vector can be changed as follows:

$$\begin{aligned} \boldsymbol{P}''(s) \equiv \boldsymbol{t}' &= \frac{1}{\dot{\boldsymbol{P}}^4} [\dot{\boldsymbol{P}}^2 \ddot{\boldsymbol{P}} - \dot{\boldsymbol{P}}(\dot{\boldsymbol{P}} \cdot \ddot{\boldsymbol{P}})] \\ &= \frac{(\dot{\boldsymbol{P}} \times \ddot{\boldsymbol{P}}) \times \dot{\boldsymbol{P}}}{\dot{\boldsymbol{P}}^4} && (1.24)^{*)} \\ &= \frac{|\dot{\boldsymbol{P}} \times \ddot{\boldsymbol{P}}|}{|\dot{\boldsymbol{P}}|^3} \boldsymbol{n} && (1.25)^{**)} \\ &\equiv \kappa \boldsymbol{n}. && (1.25') \end{aligned}$$

Consequently, the curvature κ becomes:

$$\kappa = \frac{|\dot{\boldsymbol{P}} \times \ddot{\boldsymbol{P}}|}{|\dot{\boldsymbol{P}}|^3} = \frac{|\dot{\boldsymbol{P}} \times \ddot{\boldsymbol{P}}|}{\dot{s}^3}. \tag{1.26}$$

A point on a curve at which $\kappa = 0$ is called a *point of inflection.*

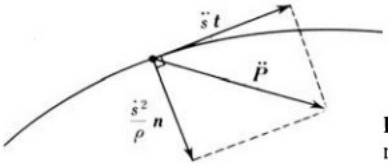


Fig. 1.18. $\ddot{\boldsymbol{P}}$ is the sum of the tangent acceleration and normal acceleration

---

*) Using the identity $\boldsymbol{A} \times (\boldsymbol{B} \times \boldsymbol{C}) = (\boldsymbol{A} \cdot \boldsymbol{C})\boldsymbol{B} - (\boldsymbol{A} \cdot \boldsymbol{B})\boldsymbol{C}$ for the triple vector product

**) $(\boldsymbol{P} \times \boldsymbol{P})$ is perpendicular to $\boldsymbol{P}$, this vector product is itself a vector which points toward the center of curvature.

The vector $\boldsymbol{b}=\boldsymbol{t}\times\boldsymbol{n}$ is called the *unit binormal vector*. The unit binormal vector can be expressed as follows:

$$
\begin{aligned}
\boldsymbol{b} &= \boldsymbol{t}\times\boldsymbol{n}\\
&= \frac{\dot{\boldsymbol{P}}}{|\dot{\boldsymbol{P}}|}\times\left[\frac{1}{\kappa}\,\frac{(\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}})\times\dot{\boldsymbol{P}}}{|\dot{\boldsymbol{P}}|^4}\right]=\frac{1}{\kappa}\,\frac{1}{|\dot{\boldsymbol{P}}|^5}\,[\dot{\boldsymbol{P}}\times((\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}})\times\dot{\boldsymbol{P}})]\\
&= \frac{1}{\kappa}\,\frac{1}{|\dot{\boldsymbol{P}}|^5}\,[|\dot{\boldsymbol{P}}|^2\,(\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}})-(\dot{\boldsymbol{P}}\cdot(\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}}))\,\dot{\boldsymbol{P}}]
\end{aligned}
$$

(using the identity for the triple vector product)

$$
=\frac{1}{\kappa}\,\frac{\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}}}{|\dot{\boldsymbol{P}}|^3}\quad(\because\ \dot{\boldsymbol{P}}\cdot(\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}})=0) \tag{1.27}
$$

$$
=\frac{\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}}}{|\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}}|}. \tag{1.28}
$$

Figure 1.19 shows the relation between the unit tangent vector $\boldsymbol{t}$, the unit principal normal vector $\boldsymbol{n}$ and the unit binormal vector $\boldsymbol{b}$.

Letting $\Delta\phi$ be the angle between the osculating planes at two slightly separated points $\boldsymbol{P}(s_0)$ and $\boldsymbol{P}(s_0+\Delta s)$, the *torsion* of the curve at point $\boldsymbol{P}(s_0)$ is defined as:

$$
\tau=\lim_{\Delta s\to 0}\frac{\Delta\phi}{\Delta s}. \tag{1.29}
$$

Torsion is a measure of the amount of rotation of the osculating plane with respect to the length of the curve s. In other words, torsion is a quantity that indicates whether the curve is twisting rapidly or slowly. Torsion can be expressed mathematically in terms of the derivatives $\dot{\boldsymbol{P}}$, $\ddot{\boldsymbol{P}}$ and $\dddot{\boldsymbol{P}}$ with respect to the parameter t as follows:

$$
\tau=\frac{(\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}})\cdot\dddot{\boldsymbol{P}}}{(\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}})^2}=\frac{[\dot{\boldsymbol{P}},\ddot{\boldsymbol{P}},\dddot{\boldsymbol{P}}]}{(\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}})^2}=\frac{[\dot{\boldsymbol{P}},\ddot{\boldsymbol{P}},\dddot{\boldsymbol{P}}]}{\dot{s}^6\,\kappa^2}. \tag{1.30}
$$

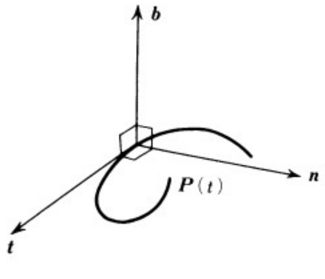

Fig. 1.19. Relation between the unit tangent vector, unit principal normal vector, and unit binormal vector $\boldsymbol{b}$, unit binormal vector; $\boldsymbol{n}$, unit principal normal vector; $\boldsymbol{t}$, unit tangent vector

The condition for a curve to be a plane curve, in other words a curve with zero torsion, is:

$$(\dot{\boldsymbol{P}} \times \ddot{\boldsymbol{P}}) \cdot \dddot{\boldsymbol{P}} = \begin{vmatrix} \dot{x} & \dot{y} & \dot{z} \\ \ddot{x} & \ddot{y} & \ddot{z} \\ x & y & z \end{vmatrix} = 0. \tag{1.31}$$

1.2.3 Frenet Frames and the Frenet-Serret Equations

If we take the directions of the unit tangent vector $\boldsymbol{t}$, the unit principal normal vector $\boldsymbol{n}$ and the unit binormal vector $\boldsymbol{b}$ to be the positive directions along the tangent, the principal normal and the binormal, respectively, then the coordinate system formed by the tangent, the principal normal and the binormal is a right-handed system. These coordinate axes move as the parameter t varies (refer to Fig. 1.19). The set $(\boldsymbol{P}; \boldsymbol{t}, \boldsymbol{n}, \boldsymbol{b})$ is called a *moving frame* or a *Frenet frame*. When properties of a space curve are investigated in the vicinity of various points on it, the Frenet frame of each point is used.

Let us now look at the changes in the Frenet frame as the curve parameter is varied. First from the relation for the unit tangent vector, we have:

$$\frac{d\boldsymbol{P}}{ds} \equiv \boldsymbol{P}' \equiv \boldsymbol{t}.$$

Then, from another of the relations which we derived (refer to Eq. (1.17)):

$$\frac{d\boldsymbol{t}}{ds} \equiv \boldsymbol{t}' = \kappa \boldsymbol{n}.$$

Next, let us find $d\boldsymbol{n}/ds \equiv \boldsymbol{n}'$. Since $\boldsymbol{n}$ is a unit vector,

$$\boldsymbol{n}^2 = 1.$$

Differentiating both sides of this equation with respect to s gives:

$$\boldsymbol{n} \cdot \frac{d\boldsymbol{n}}{ds} = 0.$$

We see from this that $d\boldsymbol{n}/ds$ is perpendicular to $\boldsymbol{n}$. Therefore $d\boldsymbol{n}/ds$ can be written in the following form:

$$\frac{d\boldsymbol{n}}{ds} = a_1 \boldsymbol{t} + a_2 \boldsymbol{b}. \tag{1.32}$$

Taking the scalar product of both sides of this equation with $\boldsymbol{t}$ gives:

$$\boldsymbol{t} \cdot \frac{d\boldsymbol{n}}{ds} = a_1. \tag{1.33}$$

Since we also have the relation:

$$\boldsymbol{t} \cdot \boldsymbol{n} = 0$$

differentiating by s gives:

$$\frac{d\boldsymbol{t}}{ds} \cdot \boldsymbol{n} + \boldsymbol{t} \cdot \frac{d\boldsymbol{n}}{ds} = 0.$$

Consequently we have:

$$\boldsymbol{t} \cdot \frac{d\boldsymbol{n}}{ds} = -\kappa. \tag{1.34}$$

Comparing Eqs. (1.33) and (1.34), we see that $a_1 = -\kappa$. Next, take the scalar product of $\boldsymbol{b}$ with both sides of Eq. (1.32):

$$\boldsymbol{b} \cdot \frac{d\boldsymbol{n}}{ds} = a_2. \tag{1.35}$$

Since we also have the relation:

$$\boldsymbol{b} \cdot \boldsymbol{n} = 0$$

differentiating by s gives:

$$\frac{d\boldsymbol{b}}{ds} \cdot \boldsymbol{n} + \boldsymbol{b} \cdot \frac{d\boldsymbol{n}}{ds} = 0. \tag{1.36}$$

The unit binormal vector $\boldsymbol{b}$ is perpendicular to the osculating plane. Since the torsion is the rate of rotation of the osculating plane with respect to s,

$$\left| \frac{d\boldsymbol{b}}{ds} \right| = \tau. \tag{1.37}$$

Differentiating the relation

$$\boldsymbol{b} \cdot \boldsymbol{t} = 0$$

by s gives:

$$\frac{d\boldsymbol{b}}{ds} \cdot \boldsymbol{t} + \boldsymbol{b} \cdot \frac{d\boldsymbol{t}}{ds} = 0.$$

The second term on the left-hand side of this equation is:

$$\boldsymbol{b} \cdot \frac{d\boldsymbol{t}}{ds} = \boldsymbol{b} \cdot \kappa \boldsymbol{n} = 0,$$

so that:

$$\frac{d\boldsymbol{b}}{ds} \cdot \boldsymbol{t} = 0.$$

From this relation, we see that $d\boldsymbol{b}/ds$ is a vector that is perpendicular to both $\boldsymbol{b}$ and $\boldsymbol{t}$, that is, a vector that is directed along the principal normal. Its magnitude is given by Eq. (1.37) as τ. If we adopt the convention:

$$\frac{d\boldsymbol{b}}{ds} = -\tau \boldsymbol{n}$$

then Eq. (1.36) becomes:

$$-\tau + \boldsymbol{b} \cdot \frac{d\boldsymbol{n}}{ds} = 0.$$

Comparing this equation with Eq. (1.35) we see that $a_2 = \tau$, so that Eq. (1.32) becomes:

$$\frac{d\boldsymbol{n}}{ds} \equiv \boldsymbol{n}' = -\kappa \boldsymbol{t} + \tau \boldsymbol{b}. \tag{1.38}$$

The above results can be summarized as follows:

$$\boldsymbol{P}' = \boldsymbol{t} \tag{1.39}$$

$$\boldsymbol{t}' = \kappa \boldsymbol{n} \tag{1.40}$$

$$\boldsymbol{n}' = -\kappa \boldsymbol{t} + \tau \boldsymbol{b} \tag{1.41}$$

$$\boldsymbol{b}' = -\tau \boldsymbol{n}. \tag{1.42}$$

These equations are called the *Frenet-Serret* equations. The differential geometric properties of space curves are all derived from these equations.

1.2.4 Calculation of a Point on a Curve[6)]

Consider a curve that is expressed as a polynomial in the parameter t, such as the following cubic expression:

$$\boldsymbol{P}(t) = \boldsymbol{A}t^3 + \boldsymbol{B}t^2 + \boldsymbol{C}t + \boldsymbol{D} \quad (0 \leqq t \leqq 1). \tag{1.43}$$

A point on the curve can be calculated by dividing the t-interval up into n segments as follows:

$$\left.\begin{aligned} t &= 0,\ \delta,\ 2\delta, \ldots, n\delta \\ \delta &= 1/n \end{aligned}\right\} \tag{1.44}$$

and substituting into Eq. (1.43) n sequence. In this case it is convenient to change Eq. (1.43) into the following form:

$$\boldsymbol{P}(t) = ((\boldsymbol{A}t + \boldsymbol{B})t + \boldsymbol{C})t + \boldsymbol{D}. \tag{1.45}$$

Equation (1.43) requires 6 multiplications per coordinate per point, but Eq. (1.45) requires only 3, so computations can be performed more rapidly.

Next, let us consider a method of calculating points on a curve at high speed using no multiplications at all, by using finite difference formulas.

$$\begin{aligned}
\boldsymbol{P}(t) &= \boldsymbol{A}t^3 + \boldsymbol{B}t^2 + \boldsymbol{C}t + \boldsymbol{D} \\
\Delta \boldsymbol{P}(t) &= \boldsymbol{P}(t+\delta) - \boldsymbol{P}(t) \\
&= \boldsymbol{A}(t+\delta)^3 + \boldsymbol{B}(t+\delta)^2 + \boldsymbol{C}(t+\delta) + \boldsymbol{D} - \boldsymbol{A}t^3 - \boldsymbol{B}t^2 - \boldsymbol{C}t - \boldsymbol{D} \\
&= 3\boldsymbol{A}\delta t^2 + (3\boldsymbol{A}\delta^2 + 2\boldsymbol{B}\delta)t + \boldsymbol{A}\delta^3 + \boldsymbol{B}\delta^2 + \boldsymbol{C}\delta \\
\Delta^2 \boldsymbol{P}(t) &= \Delta \boldsymbol{P}(t+\delta) - \Delta \boldsymbol{P}(t) \\
&= 3\boldsymbol{A}\delta(t+\delta)^2 + (3\boldsymbol{A}\delta^2 + 2\boldsymbol{B}\delta)\,(t+\delta) + \boldsymbol{A}\delta^3 + \boldsymbol{B}\delta^2 + \boldsymbol{C}\delta \\
&\quad - 3\boldsymbol{A}\delta t^2 - (3\boldsymbol{A}\delta^2 + 2\boldsymbol{B}\delta)t - \boldsymbol{A}\delta^3 - \boldsymbol{B}\delta^2 - \boldsymbol{C}\delta \\
&= 6\boldsymbol{A}\delta^2 t + 6\boldsymbol{A}\delta^3 + 2\boldsymbol{B}\delta^2 \\
\Delta^3 \boldsymbol{P}(t) &= \Delta^2 \boldsymbol{P}(t+\delta) - \Delta^2 \boldsymbol{P}(t) \\
&= 6\boldsymbol{A}\delta^2(t+\delta) + 6\boldsymbol{A}\delta^3 + 2\boldsymbol{B}\delta^2 - 6\boldsymbol{A}\delta^2 t - 6\boldsymbol{A}\delta^3 - 2\boldsymbol{B}\delta^2 \\
&= 6\boldsymbol{A}\delta^3.
\end{aligned}$$

The 3rd-order finite difference is a constant vector that is independent of the parameter. In general, for an nth-order polynomial espression, the nth-order finite difference is a constant vector.

Let us use the notation $\boldsymbol{P}_0$, $\Delta\boldsymbol{P}_0$, $\Delta^2\boldsymbol{P}_0$, $\Delta^3\boldsymbol{P}_0$ and $\boldsymbol{P}_i$, $\Delta\boldsymbol{P}_i$, $\Delta^2\boldsymbol{P}_i$, $\Delta^3\boldsymbol{P}_i$ to denote the various order finite differences at $t=0$ and $t=i\delta$ respectively. Then we have the relations:

$$\left.\begin{aligned}
\boldsymbol{P}_1 &= \boldsymbol{P}_0 + \Delta \boldsymbol{P}_0 \\
\Delta \boldsymbol{P}_1 &= \Delta \boldsymbol{P}_0 + \Delta^2 \boldsymbol{P}_0 \\
\Delta^2 \boldsymbol{P}_1 &= \Delta^2 \boldsymbol{P}_0 + \Delta^3 \boldsymbol{P}_0 \\
\Delta^3 \boldsymbol{P}_1 &= \Delta^3 \boldsymbol{P}_0
\end{aligned}\right\} \tag{1.46}$$

so that if the various order finite differences at $t=0$, that is, $\boldsymbol{P}_0$, $\Delta\boldsymbol{P}_0$, $\Delta^2\boldsymbol{P}_0$, $\Delta^3\boldsymbol{P}_0$ are known, then the points on the curve at $t=\delta$, 2δ, ..., $i\delta$, ... can be found in sequence solely by repeated additions. However, if, for example,

$\delta = 1/2^5$, finite differences such as $\varDelta^3 \boldsymbol{P}_0$ become vectors with very small magnitudes, so that in some cases the length of a computer word is not adequate to maintain sufficient accuracy. In such cases this problem can be solved by storing $\varDelta \boldsymbol{P}_0$, $\varDelta^2 \boldsymbol{P}_0$, $\varDelta^3 \boldsymbol{P}_0$ as $1/\delta$ precision, $1/\delta^2$ precision, $1/\delta^3$ precision numbers, respectively, and applying Eqs. (1.46) in the form:

$$\left.\begin{aligned}
\boldsymbol{P}_1 &= \boldsymbol{P}_0 + \delta\left(\frac{1}{\delta}\,\varDelta \boldsymbol{P}_0\right)\\
\frac{1}{\delta}\,\varDelta \boldsymbol{P}_1 &= \frac{1}{\delta}\,\varDelta \boldsymbol{P}_0 + \delta\left(\frac{1}{\delta^2}\,\varDelta^2 \boldsymbol{P}_0\right)\\
\frac{1}{\delta^2}\,\varDelta^2 \boldsymbol{P}_1 &= \frac{1}{\delta^2}\,\varDelta^2 \boldsymbol{P}_0 + \delta\left(\frac{1}{\delta^3}\,\varDelta^3 \boldsymbol{P}_0\right)\\
\frac{1}{\delta^3}\,\varDelta^3 \boldsymbol{P}_1 &= \frac{1}{\delta^3}\,\varDelta^3 \boldsymbol{P}_0
\end{aligned}\right\} \tag{1.47}$$

If we take $\delta = 1/2^m$ (where m is a positive integer) in the above equations, then the necessary computations can be performed at high speed using exclusively shift operations and additions, without time-consuming multiplications.

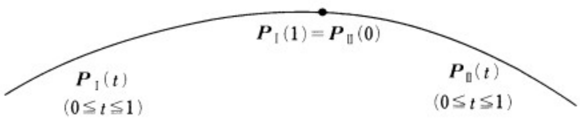
In calculations with Eqs. (1.47) it is convenient to express the various order finite differences at $t=0$ as a 4×3 matrix:

$$\begin{bmatrix} \boldsymbol{P}_0 \\ \dfrac{1}{\delta}\,\varDelta \boldsymbol{P}_0 \\ \dfrac{1}{\delta^2}\,\varDelta^2 \boldsymbol{P}_0 \\ \dfrac{1}{\delta^3}\,\varDelta^3 \boldsymbol{P}_0 \end{bmatrix} = \begin{bmatrix} \boldsymbol{D} \\ \boldsymbol{A}\delta^2 + \boldsymbol{B}\delta + \boldsymbol{C} \\ 6\boldsymbol{A}\delta + 2\boldsymbol{B} \\ 6\boldsymbol{A} \end{bmatrix} \tag{1.48}$$

In this book, the matrix in Eq. (1.48) will be referred to as the finite difference matrix.

1.2.5 Connection of Curve Segments

Let us now consider the problem of connecting a curve segment $\boldsymbol{P}_{\text{II}}(t)$ $(0 \leqq t \leqq 1)$ to the curve segment $\boldsymbol{P}_{\text{I}}(t)$ $(0 \leqq t \leqq 1)$ (Fig. 1.20).



$\boldsymbol{P}_{\text{I}}(1)=\boldsymbol{P}_{\text{II}}(0)$
$\boldsymbol{P}_{\text{I}}(t)$
$(0\leq t\leq 1)$
$\boldsymbol{P}_{\text{II}}(t)$
$(0\leq t\leq 1)$

Fig. 1.20. Continuity conditions for curves Conditions for continuity up to curvature
① $\boldsymbol{P}_{\text{II}}(0)=\boldsymbol{P}_{\text{I}}(1)$; ② $\dot{\boldsymbol{P}}_{\text{II}}(0)=\dfrac{\alpha_2}{\alpha_1}\,\dot{\boldsymbol{P}}_{\text{I}}(1)$, ③ $\ddot{\boldsymbol{P}}_{\text{II}}(0)=\left(\dfrac{\alpha_2}{\alpha_1}\right)^2\ddot{\boldsymbol{P}}_{\text{I}}(1)+\beta\,\dot{\boldsymbol{P}}_{\text{I}}(1)$

First, we have the condition of continuity of position:

$$\boldsymbol{P}_{\mathrm{II}}(0)=\boldsymbol{P}_{\mathrm{I}}(1). \tag{1.49}$$

If the magnitudes of the tangent vectors of $\boldsymbol{P}_{\mathrm{I}}(t)$ and $\boldsymbol{P}_{\mathrm{II}}(t)$ at the connection point are α_1 and α_2 respectively, then the condition for the slope to be continuous is:

$$\frac{1}{\alpha_2}\dot{\boldsymbol{P}}_{\mathrm{II}}(0)=\frac{1}{\alpha_1}\dot{\boldsymbol{P}}_{\mathrm{I}}(1)=\boldsymbol{t} \tag{1.50}$$

or:

$$\dot{\boldsymbol{P}}_{\mathrm{II}}(0)=\frac{\alpha_2}{\alpha_1}\dot{\boldsymbol{P}}_{\mathrm{I}}(1)=\lambda\dot{\boldsymbol{P}}_{\mathrm{I}}(1)\quad\left(\lambda=\frac{\alpha_2}{\alpha_1}\right). \tag{1.51}$$

Next, let us find the condition for the centers of curvature of the two curve segments at the connection point to vary continuously. Equation (1.17) for the curvature is:

$$\boldsymbol{P}''=\kappa\boldsymbol{n}.$$

In this equation κ is the magnitude of the curvature and $\boldsymbol{n}$ is the unit principal normal vector, pointing toward the center of curvature. From the above equation, for the center of curvature of the curve to vary smoothly at the connection point, it is necessary for both κ and $\boldsymbol{n}$ to be continuous.

If the binormal $\boldsymbol{b}=\boldsymbol{t}\times\boldsymbol{n}$ and $\boldsymbol{t}$ are continuous then $\boldsymbol{n}$ is also continuous. Consequently, to find the condition κ and $\boldsymbol{n}$ to be continuous, we require a condition for both κ and $\boldsymbol{b}$ to be continuous. From Eq. (1.27):

$$\kappa\boldsymbol{b}=\frac{\dot{\boldsymbol{P}}\times\ddot{\boldsymbol{P}}}{|\dot{\boldsymbol{P}}|^3}.$$

Consequently, in order for the center of curvature of a curve to vary continuously at a connection point, we must have:

$$\frac{\dot{\boldsymbol{P}}_{\mathrm{II}}(0)\times\ddot{\boldsymbol{P}}_{\mathrm{II}}(0)}{|\dot{\boldsymbol{P}}_{\mathrm{II}}(0)|^3}=\frac{\dot{\boldsymbol{P}}_{\mathrm{I}}(1)\times\ddot{\boldsymbol{P}}_{\mathrm{I}}(1)}{|\dot{\boldsymbol{P}}_{\mathrm{I}}(1)|^3}.$$

Substituting the relation in Eq. (1.51) into this equation and rearranging gives:

$$\dot{\boldsymbol{P}}_{\mathrm{I}}(1)\times\left[\ddot{\boldsymbol{P}}_{\mathrm{II}}(0)-\left(\frac{\alpha_2}{\alpha_1}\right)^2\ddot{\boldsymbol{P}}_{\mathrm{I}}(1)\right]=\boldsymbol{0}.$$

From this equation, the following equation is obtained, with β an arbitrary scalar[7].

$$\begin{aligned}\ddot{\boldsymbol{P}}_{\mathrm{II}}(0)&=\left(\frac{\alpha_2}{\alpha_1}\right)^2\ddot{\boldsymbol{P}}_{\mathrm{I}}(1)+\beta\dot{\boldsymbol{P}}_{\mathrm{I}}(1)\\&=\lambda^2\ddot{\boldsymbol{P}}_{\mathrm{I}}(1)+\beta\dot{\boldsymbol{P}}_{\mathrm{I}}(1)\quad\left(\lambda=\frac{\alpha_2}{\alpha_1}\right).\end{aligned}\tag{1.52}$$

1.2.6 Parameter Transformation

Normally, a curve segment $\boldsymbol{P}(t)$ is normalized so that $t=0$ at one end and $t=1$ at the other end. If we are to use only one part of this curve, from $t=t_0$ to $t=t_1$, or perform some processing on this part, it is convenient to normalize the parameter over this part of the curve (refer to Fig. 1.21). In order to keep the degree of the curve unchanged when performing this transformation, the following linear relation must hold between the old parameter t and the parameter after transformation t^*.

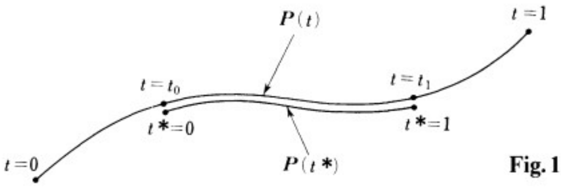


Fig. 1.21. Curve parameter transformation

$$t=(1-t^*)\,t_0+t^*t_1=t_0+(t_1-t_0)\,t^*.\tag{1.53}$$

Substituting this relation for t into the original equation of the curve gives the normalized curve equation in terms of t^*, with t^* varying from 0 to 1 over the interval of interest. For example, in the case of the cubic curve:

$$\boldsymbol{P}(t)=[t^3\ \ t^2\ \ t\ \ 1]\ [\boldsymbol{A}\ \ \boldsymbol{B}\ \ \boldsymbol{C}\ \ \boldsymbol{D}]^T\tag{1.54}$$

the normalized curve equation over the interval $t_0\leqq t\leqq t_1$ is:

$$\begin{aligned}\boldsymbol{P}(t^*)&=[\{t_0+(t_1-t_0)\,t^*\}^3\quad\{t_0+(t_1-t_0)\,t^*\}^2\quad\{t_0+(t_1-t_0)\,t^*\}\quad 1]\begin{bmatrix}\boldsymbol{A}\\\boldsymbol{B}\\\boldsymbol{C}\\\boldsymbol{D}\end{bmatrix}\\&=\begin{matrix}[(t_1-t_0)^3t^{*3}+3\,(t_1-t_0)^2\,t_0\,t^{*2}+3\,(t_1-t_0)\,t_0^2\,t^*+t_0^3\\(t_1-t_0)^2\,t^{*2}+2\,(t_1-t_0)\,t_0\,t^*+t_0^2\quad(t_1-t_0)\,t^*+t_0\quad 1]\end{matrix}\begin{bmatrix}\boldsymbol{A}\\\boldsymbol{B}\\\boldsymbol{C}\\\boldsymbol{D}\end{bmatrix}=\end{aligned}$$

$$= [t^{*3}\ t^{*2}\ t^*\ 1] \begin{bmatrix} (t_1-t_0)^3 & 0 & 0 & 0 \\ 3(t_1-t_0)^2 t_0 & (t_1-t_0)^2 & 0 & 0 \\ 3(t_1-t_0)t_0^2 & 2(t_1-t_0)t_0 & t_1-t_0 & 0 \\ t_0^3 & t_0^2 & t_0 & 1 \end{bmatrix} \begin{bmatrix} \boldsymbol{A} \\ \boldsymbol{B} \\ \boldsymbol{C} \\ \boldsymbol{D} \end{bmatrix} \tag{1.55}$$

$$= [t^{*3}\ t^{*2}\ t^*\ 1] \begin{bmatrix} (t_1-t_0)^3 \boldsymbol{A} \\ 3(t_1-t_0)^2 t_0 \boldsymbol{A} + (t_1-t_0)^2 \boldsymbol{B} \\ 3(t_1-t_0)t_0^2 \boldsymbol{A} + 2(t_1-t_0)t_0 \boldsymbol{B} + (t_1-t_0)\boldsymbol{C} \\ t_0^3 \boldsymbol{A} + t_0^2 \boldsymbol{B} + t_0 \boldsymbol{C} + \boldsymbol{D} \end{bmatrix} \tag{1.56}$$

$$\equiv [t^{*3}\ t^{*2}\ t^*\ 1] \begin{bmatrix} \boldsymbol{A}^* \\ \boldsymbol{B}^* \\ \boldsymbol{C}^* \\ \boldsymbol{D}^* \end{bmatrix}.$$

Let us now see how the tangent vector of the curve changes under the parameter transformation of Eq. (1.53). The tangent vector after transformation becomes:

$$\frac{d\boldsymbol{P}}{dt^*} = \frac{d\boldsymbol{P}}{dt}\frac{dt}{dt^*} = (t_1-t_0)\frac{d\boldsymbol{P}}{dt}. \tag{1.57}$$

That is, the magnitude of the tangent vector is reduced in proportion to the reduction of the range through which the original parameter varies ($0 \leqq t_1 - t_0 \leqq 1$). For the second derivative vector we have:

$$\frac{d^2\boldsymbol{P}}{dt^{*2}} = (t_1-t_0)^2 \frac{d^2\boldsymbol{P}}{dt^2} \tag{1.58}$$

so that it is reduced in proportion to the square of the reduction of the parameter range.

Let us now consider a more general parameter transformation, the rational transformation given by the following equation:

$$t = \frac{at^* + b}{ct^* + 1}.$$

This transformation is sometimes called *bilinear transformation* or a *homographic transformation.* With $t^*=0$ and $t^*=1$ at $t=t_0$ and $t=t_1$, respectively, this transformation takes the following form, with η an arbitrary scalar:

$$t = \frac{(\eta t_1 - t_0)t^* + t_0}{(\eta - 1)t^* + 1}. \tag{1.59}$$

The shape within the old parameter range $t_0 \leqq t \leqq t_1$ is now expressed without shape change in terms of the new parameter which varies in the domain $0 \leqq t^* \leqq 1$. Compared to the transformation of Eq. (1.53), the transformation of Eq. (1.59) has an increased degree of freedom because η can be chosen freely. When $\eta = 1$, the transformation of Eq. (1.59) reduces to the transformation of Eq. (1.53). As η varies, what changes is the relation between a point on the curve and the parameter value; the shape does not change.

In the special case $t_0 = 0$, $t_1 = 1$ we have:

$$t = \frac{\eta t^*}{(\eta - 1)t^* + 1}. \tag{1.60}$$

Equation (1.59) is frequently used in rational polynomial parameter transformations, because only the parameter range changes, while the shape and the degree of the equation remain unchanged. Equation (1.60) is used when one wishes to change only the relation between points on the curve and parameter values, without changing the parameter range.

When the following curve:

$$\left.\begin{aligned} x(t) &= \frac{a_{11}t^2 + a_{21}t + a_{31}}{a_{13}t^2 + a_{23}t + a_{33}} \\ y(t) &= \frac{a_{12}t^2 + a_{22}t + a_{32}}{a_{13}t^2 + a_{23}t + a_{33}} \end{aligned}\right\} \tag{1.61}$$

expressed in terms of rational polynomials in which both the numerator and denominators are quadratic expressions is transformed using Eq. (1.60), the result is similar in which both the numerators and denominators are quadratic expressions. Let us demonstrate this.

The homogeneous vector representation $\boldsymbol{P}(t) = [x(t)\ y(t)\ 1]$ for the rational polynomial curve expressed by Eqs. (1.61) is*):

$$w(t)\boldsymbol{P}(t) = [t^2\ \ t\ \ 1] \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}. \tag{1.62}$$

Substituting the parameter relation of Eq. (1.60) into this equation gives:

$$w(t^*)\boldsymbol{P}(t^*) = \left[\left\{\frac{\eta t^*}{(\eta-1)t^*+1}\right\}^2 \ \ \frac{\eta t^*}{(\eta-1)t^*+1} \ \ 1\right] \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \doteq$$

---

*) As for homogeneous coordinates, refer to Newman & Sproull Principles of Interactive Computer Graphics, Second edition, McGraw-Hill

$$\doteq [\eta^2 t^{*2} \quad \eta t^* \{(\eta-1)t^*+1\} \quad \{(\eta-1)t^*+1\}^2] \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}^{**)}$$

$$= [t^{*2} \; t^* \; 1] \begin{bmatrix} \eta^2 & \eta(\eta-1) & (\eta-1)^2 \\ 0 & \eta & 2(\eta-1) \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}. \tag{1.63}$$

Consequently, in terms of ordinary coordinates we have:

$$x(t^*) = \frac{\{\eta^2 a_{11} + \eta(\eta-1)a_{21} + (\eta-1)^2 a_{31}\} t^{*2} + \{\eta a_{21} + 2(\eta-1)a_{31}\} t^* + a_{31}}{\{\eta^2 a_{13} + \eta(\eta-1)a_{23} + (\eta-1)^2 a_{33}\} t^{*2} + \{\eta a_{23} + 2(\eta-1)a_{33}\} t^* + a_{33}}$$

$$y(t^*) = \frac{\{\eta^2 a_{12} + \eta(\eta-1)a_{22} + (\eta-1)^2 a_{32}\} t^{*2} + \{\eta a_{22} + 2(\eta-1)a_{32}\} t^* + a_{32}}{\{\eta^2 a_{13} + \eta(\eta-1)a_{23} + (\eta-1)^2 a_{33}\} t^{*2} + \{\eta a_{23} + 2(\eta-1)a_{33}\} t^* + a_{33}}.$$

Next, let us look at the change in the tangent vector under this parameter transformation. The tangent vector after the transformation is:

$$\frac{d\boldsymbol{P}}{dt^*} = \frac{d\boldsymbol{P}}{dt}\frac{dt}{dt^*}.$$

From Eq. (1.60), we have:

$$\frac{dt}{dt^*} = \frac{\eta}{\{(\eta-1)t^*+1\}^2}$$

$$\therefore \frac{d\boldsymbol{P}}{dt^*} = \frac{\eta}{\{(\eta-1)t^*+1\}^2}\frac{d\boldsymbol{P}}{dt}. \tag{1.64}$$

Therefore, the tangent vectors at points $t^*=0$ and $t^*=1$ are, respectively:

$$\left.\frac{d\boldsymbol{P}}{dt^*}\right|_{t^*=0} = \eta \left.\frac{d\boldsymbol{P}}{dt}\right|_{t=0}, \qquad \left.\frac{d\boldsymbol{P}}{dt^*}\right|_{t^*=1} = \frac{1}{\eta}\left.\frac{d\boldsymbol{P}}{dt}\right|_{t=1}. \tag{1.65}$$

As a result of using transformation (1.60), the shape is unchanged, the range within which the parameter varies remains the same, and the variation of a point on the curve for a given change in the parameter is changed. As a result, the magnitudes of the tangent vectors at both ends are changed, but the product of the magnitudes of the two tangent vectors remains the same. That is:

**) Multiplying a homogeneous vector by a nonzero scalar constant does not alter its ordinary coordinate vector We shall define the equality in ordinary coordinate vector with the symbol =

$$\left.\frac{d\boldsymbol{P}}{dt^*}\right|_{t^*=0}\cdot\left.\frac{d\boldsymbol{P}}{dt^*}\right|_{t^*=1}=\left.\frac{d\boldsymbol{P}}{dt}\right|_{t=0}\cdot\left.\frac{d\boldsymbol{P}}{dt}\right|_{t=1}. \tag{1.66}$$

1.2.7 Partitioning of a Curve Segment

Let us consider a case in which a curve $\boldsymbol{P}(t)$ is split into two curves $\boldsymbol{P}_1(u)$ $(0 \leqq u \leqq 1)$ and $\boldsymbol{P}_2(u)$ $(0 \leqq u \leqq 1)$ at a point corresponding to $t=t_s$. We will demonstrate this using the cubic curve (1.43) (Fig. 1.22).

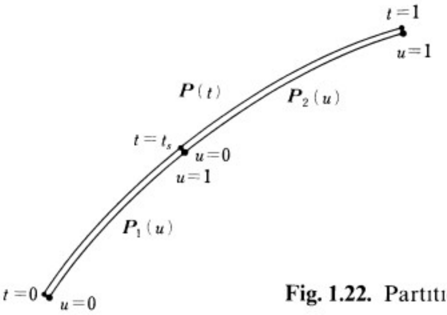

Fig. 1.22. Partitioning of a curve segment

The first curve $\boldsymbol{P}_1(u)$ is obtained by setting $t_0=0$, $t_1=t_s$ and $t^*=u$ in Eq. (1.56). This gives the following expression:

$$\boldsymbol{P}_1(u)=[u^3\ u^2\ u\ 1]\begin{bmatrix} t_s^3\boldsymbol{A} \\ t_s^2\boldsymbol{B} \\ t_s\boldsymbol{C} \\ \boldsymbol{D}\end{bmatrix}. \tag{1.67}$$

The second curve $\boldsymbol{P}_2(u)$ is obtained by setting $t_0=t_s$, $t_1=1$ and $t^*=u$ in Eq. (1.56) to give the expression:

$$\boldsymbol{P}_2(u)=[u^3\ u^2\ u\ 1]\begin{bmatrix} (1-t_s)^3\boldsymbol{A} \\ 3(1-t_s)^2t_s\boldsymbol{A}+(1-t_s)^2\boldsymbol{B} \\ 3(1-t_s)t_s^2\boldsymbol{A}+2(1-t_s)t_s\boldsymbol{B}+(1-t_s)\boldsymbol{C} \\ t_s^3\boldsymbol{A}+t_s^2\boldsymbol{B}+t_s\boldsymbol{C}+\boldsymbol{D}\end{bmatrix}. \tag{1.68}$$

Partitioning the curve in this way makes it possible to apply local control to its shape.

1.2.8 Parametric Cubic Curves

The parametric cubic curve segment (1.43) is completely determined by setting the parameter equal to 0, the position vector to $\boldsymbol{Q}_0$ and the tangent vector to $\dot{\boldsymbol{Q}}_0$ at one end, and the parameter to 1, the position vector to $\boldsymbol{Q}_1$ and the tangent vector to $\dot{\boldsymbol{Q}}_1$ at the other end (for further details refer to Sect. 3.2.1). This gives:

$$\begin{aligned}
&\boldsymbol{A}=2(\boldsymbol{Q}_0-\boldsymbol{Q}_1)+\dot{\boldsymbol{Q}}_0+\dot{\boldsymbol{Q}}_1\\
&\boldsymbol{B}=3(\boldsymbol{Q}_1-\boldsymbol{Q}_0)-2\,\dot{\boldsymbol{Q}}_0-\dot{\boldsymbol{Q}}_1\\
&\boldsymbol{C}=\dot{\boldsymbol{Q}}_0\\
&\boldsymbol{D}=\boldsymbol{Q}_0\,.
\end{aligned}$$

If we have two curve segments such that the two end points of one curve and the directions of the tangent vectors are the same as those of the other,

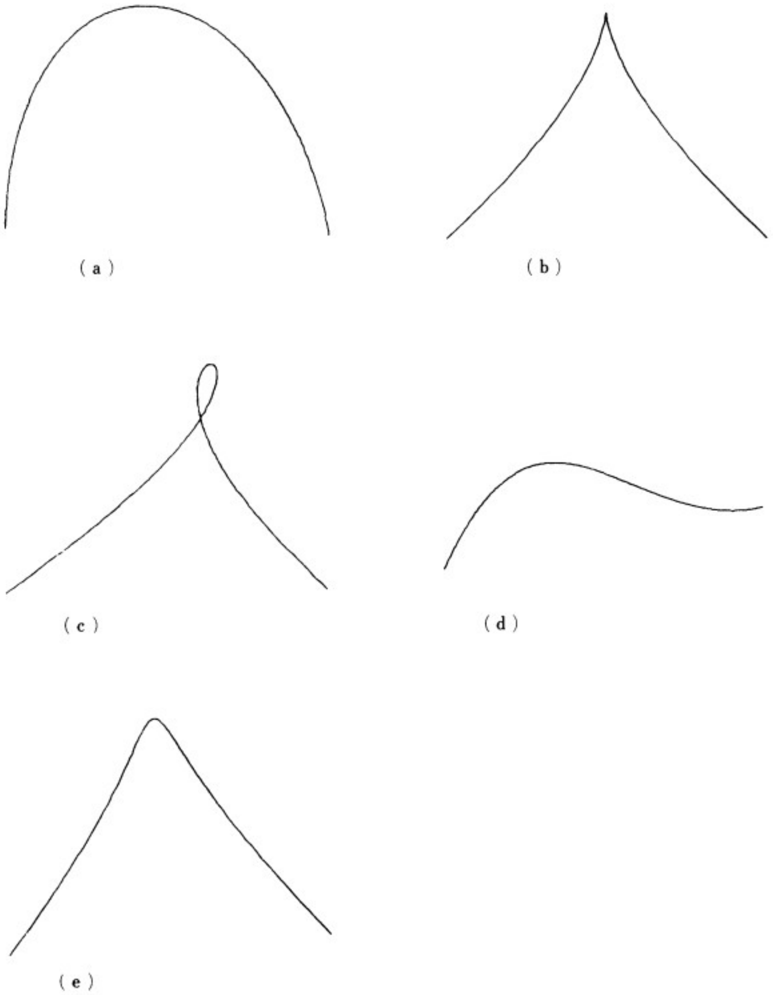

Fig. 1.23. Shapes of parametric cubic curves. (a) case with no abnormalities, (b) cusp; (c) loop, (d) one inflection point; (e) two inflection points

then, if the magnitudes of the tangent vectors at these end points are different, the shapes will be different. The magnitudes as well as directions of the tangent vectors affect the shapes of the curves.

Let us focus attention on a point of inflection of a curve segment. From Eq. (1.26), a point of inflection is a point at which:

$$\dot{\boldsymbol{P}} \times \ddot{\boldsymbol{P}} = \boldsymbol{0}.$$

If we exclude points at which $\dot{\boldsymbol{P}} = \boldsymbol{0}$, then a point of inflection is a point at which:

$$\ddot{\boldsymbol{P}} = g\,\dot{\boldsymbol{P}} \tag{1.69}$$

where g is a scalar. Since this is a second-degree equation with respect to t, we see that as the parameter varies from 0 to 1, a parametric cubic curve can have a maximum of 2 inflection points. A typical shape of a parametric cubic curve is shown in Fig. 1.23.

Next, let us look at the torsion of a parametric cubic curve.

$$\left.\begin{aligned} \dot{\boldsymbol{P}}(t) &= [\dot{x}\ \dot{y}\ \dot{z}] = 3\boldsymbol{A}t^2 + 2\boldsymbol{B}t + \boldsymbol{C} \\ \ddot{\boldsymbol{P}}(t) &= [\ddot{x}\ \ddot{y}\ \ddot{z}] = 6\boldsymbol{A}t + 2\boldsymbol{B} \\ \dddot{\boldsymbol{P}}(t) &= [x\ \ y\ \ z] = 6\boldsymbol{A} \end{aligned}\right\} . \tag{1.70}$$

Substituting these relations into Eq. (1.31), we obtain:

$$\begin{vmatrix} \dot{x} & \dot{y} & \dot{z} \\ \ddot{x} & \ddot{y} & \ddot{z} \\ x & y & z \end{vmatrix} = \begin{vmatrix} 3A_x t^2 + 2B_x t + C_x & 3A_y t^2 + 2B_y t + C_y & 3A_z t^2 + 2B_z t + C_z \\ 6A_x t + 2B_x & 6A_y t + 2B_y & 6A_z t + 2B_z \\ 6A_x & 6A_y & 6A_z \end{vmatrix}$$

$$= -12 \begin{vmatrix} A_x & A_y & A_z \\ B_x & B_y & B_z \\ C_x & C_y & C_z \end{vmatrix}$$

Therefore, the condition for a parametric cubic curve to be a plane curve is:

$$\begin{vmatrix} A_x & A_y & A_z \\ B_x & B_y & B_z \\ C_x & C_y & C_z \end{vmatrix} = 0. \tag{1.71}$$

From this equation a curve for which $A_x = A_y = A_z = 0$, that is a quadratic parametric curve, has zero torsion and is a plane curve. Therefore, we see that the minimum degree that a polynomial curve must have in order to be a space curve is 3. In addition, even for a cubic curve, if the 2nd-degree coefficients (B_x, B_y, B_z) or the 1st-degree coefficients (C_x, C_y, C_z) are 0, the curve is a plane curve.

1.2.9 Length and Area of a Curve

A very small segment of a curve has approximately the same length as the chord which subtends that segment. The chord vector obtained by varying the parameter by Δt is approximately $\dot{\boldsymbol{P}}(t)\Delta t$, so the length l of the curve from the parameter value t_0 to t_1 can be calculated as:

$$l=\int_{t_0}^{t_1} |\dot{\boldsymbol{P}}(t)|\, dt. \tag{1.72}$$

If we assume that the curve is a plane curve that can be represented by Eq. (1.43), then:

$$\begin{aligned} l&=\int_{t_0}^{t_1} \sqrt{A_4t^4+A_3t^3+A_2t^2+A_1t+A_0}\, dt\\ &\equiv\int_{t_0}^{t_1} f(t)\, dt. \end{aligned} \tag{1.73}$$

Here:

$$\begin{aligned} &f(t)=\sqrt{A_4t^4+A_3t^3+A_2t^2+A_1t+A_0}\\ &A_4=9(A_x^2+A_y^2)\\ &A_3=12(A_xB_x+A_yB_y)\\ &A_2=6(A_xC_x+A_yC_y)+4(B_x^2+B_y^2)\\ &A_1=4(B_xC_x+B_yC_y)\\ &A_0=C_x^2+C_y^2. \end{aligned}$$

We apply the following parameter transformation:

$$t=t_0+(t_1-t_0)u$$

in order to be able to use the Gauss quadrature method. The transformation is applied to Eq. (1.73) to give:

$$\begin{aligned} l&=\int_{t_0}^{t_1} f(t)\, dt=(t_1-t_0)\int_0^1 f(t_0+(t_1-t_0)u)\, du=(t_1-t_0)\int_0^1 g(u)\, du\\ &\fallingdotseq(t_1-t_0)\sum_{i=1}^{m} w_i g(u_i). \end{aligned} \tag{1.74}$$

In this equation, m is the number of knots in Gauss' formula, the u_i are the knots and the w_i are weight factors.

Next, in the case of a plane curve, let us find the area of the "pie slice" formed by the origin and a curve segment (Fig. 1.24). The pie slice defined by

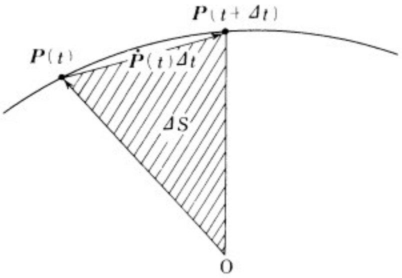

Fig. 1.24. Area enclosed by a curve

the origin and the two points on the curve $\boldsymbol{P}(t)$ and $\boldsymbol{P}(t+\Delta t)$ is approximated by the triangle $O-\boldsymbol{P}(t)-\boldsymbol{P}(t+\Delta t)$. Since this area ΔS is $1/2\,|\boldsymbol{P}(t)\times\dot{\boldsymbol{P}}(t)|\,\Delta t$, the area S swept out by the curve as the parameter varies from t_0 to t_1 is:

$$S=\frac{1}{2}\int_{t_0}^{t_1}|\boldsymbol{P}(t)\times\dot{\boldsymbol{P}}(t)|\,dt. \tag{1.75}$$

1.2.10 Intersection of a Curve with a Plane

A plane is represented by the equation:

$$ax+by+cz+d=0.$$

Since the curve $\boldsymbol{P}(t)=[x(t)\ \ y(t)\ \ z(t)]$ satisfies this equation, we have:

$$ax(t)+by(t)+cz(t)+d=0. \tag{1.76}$$

The roots of this equation can be found by the Newton-Raphson method. If the curve $\boldsymbol{P}(t)$ has been normalized in the range $0\leqq t\leqq 1$, the roots will be confined to this interval. The calculation can be made very efficient by pointing at the intersection points on the display with a stylus to obtain the first iterations.

1.2.11 Intersection of Two Curves

For simplicity let us restrict ourselves to the problem of finding intersections of two plane curves

$$\boldsymbol{P}_1(t)=[x_1(t)\ y_1(t)\ z_1(t)] \quad \text{and} \quad \boldsymbol{P}_2(u)=[x_2(u)\ y_2(u)\ z_2(u)].$$

In this case, we have:

$$\left.\begin{aligned} x_1(t)&=x_2(u)\\ y_1(t)&=y_2(u)\end{aligned}\right\}\qquad (0\leqq t\leqq 1,\ 0\leqq u\leqq 1). \tag{1.77}$$

Let us seek solutions of the simultaneous equations for the two unknowns t and u ($0 \leqq t \leqq 1$, $0 \leqq u \leqq 1$) by the Newton-Raphson method. The calculation can be made very efficient by pointing at the intersection points on the display with a stylus to obtain the first iterations.

If both curves are given by cubic polynomials of the form (1.43), then Eq. (1.77) becomes the following:

$$\left.\begin{aligned} A_{1x}t^3+B_{1x}t^2+C_{1x}t+D_{1x}-(A_{2x}u^3+B_{2x}u^2+C_{2x}u+D_{2x})=0 \\ A_{1y}t^3+B_{1y}t^2+C_{1y}t+D_{1y}-(A_{2y}u^3+B_{2y}u^2+C_{2y}u+D_{2y})=0 \end{aligned}\right\}. \tag{1.78}$$

1.3 Theory of Surfaces

1.3.1 Parametric Representation of Surfaces

Suppose that a curved surface is described by a polynomial in terms of the two parameters u and w which vary on its surface:

$$\boldsymbol{P}(u, w)=[x(u, w) \;\; y(u, w) \;\; z(u, w)]. \tag{1.79}$$

If a curved surface satisfies the conditions that the three Jacobians:

$$J_x \equiv \frac{\partial(y, z)}{\partial(u, w)}{}^{*)}, \qquad J_y \equiv \frac{\partial(z, x)}{\partial(u, w)}, \qquad J_z \equiv \frac{\partial(x, y)}{\partial(u, w)}$$

are not all zero at the same time, in other words, that:

$$J_x^2+J_y^2+J_z^2 \neq 0 \tag{1.80}$$

that the curved surface $\boldsymbol{P}(u, w)$ has all derivatives with respect to x, y and z up to r-th order, and, moreover, that all such derivatives are continuous, then the curved surface defined by Eq. (1.79) is said to be of class C^r.

Condition (1.80) is the condition for the curved surface to not degenerate to a point or a curve, and to not contain any singular points such as spikes. This condition requires constraints on both the curve itself and the parameters. Even for the same curve, it is possible that for one parameter expression condition (1.80) will be satisfied, and for another parameter expression it will not.**)

---

*) This notation is defined by

$$\frac{\partial(y, z)}{\partial(u, w)}=\begin{vmatrix} \dfrac{\partial y}{\partial u} & \dfrac{\partial z}{\partial u} \\[2ex] \dfrac{\partial y}{\partial w} & \dfrac{\partial z}{\partial w} \end{vmatrix}$$

**) For example, if the xy plane is expressed as $x=u$, $y=w$, $z=0$ then $J_z=1$, but if the same plane is expressed as $x=u^3$, $y=w^3$, $z=0$ then at the origin $J_x=J_y=J_z=0$

In the discussion that follows, unless otherwise stated it is assumed that condition (1.80) holds.

If $w = w_0$ (fixed), the curved surface representation describes a curve $\boldsymbol{P}(u, w_0)$ on the curved surface. This curve is called the u-curve. Similarly, the curve $\boldsymbol{P}(u_0, w)$ on the curved surface corresponding to $u = u_0$ (fixed) is called the w-curve.

At a point $\boldsymbol{P}(u_0, w_0)$ on the curved surface, the tangent vector in the direction of the u-curve is:

$$\boldsymbol{P}_u = \left[\frac{\partial x(u, w_0)}{\partial u} \quad \frac{\partial y(u, w_0)}{\partial u} \quad \frac{\partial z(u, w_0)}{\partial u}\right]_{u=u_0}.$$

Similarly, the tangent vector in the direction of the w-curve is:

$$\boldsymbol{P}_w = \left[\frac{\partial x(u_0, w)}{\partial w} \quad \frac{\partial y(u_0, w)}{\partial w} \quad \frac{\partial z(u_0, w)}{\partial w}\right]_{w=w_0}.$$

If these two vectors are drawn starting from the point $\boldsymbol{P}(u_0, w_0)$, if condition (1.80) is satisfied the angle between them is non-zero (Fig. 1.25). That is, condition (1.80) is equivalent to saying that the vectors $\boldsymbol{P}_u$ and $\boldsymbol{P}_w$ are linearly independent at each point on the curved surface. Condition (1.80) is also equivalent to $\boldsymbol{P}_u \times \boldsymbol{P}_w \neq \boldsymbol{0}$ *).

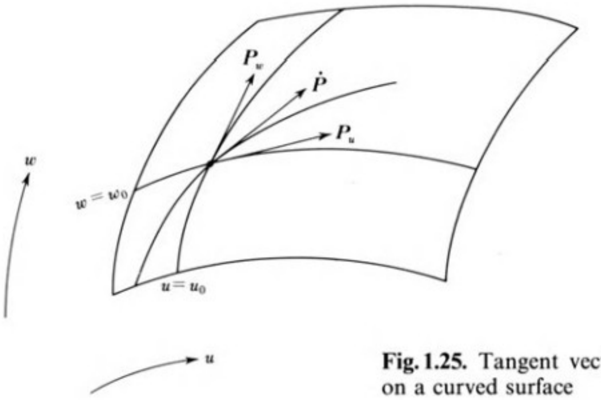

Fig. 1.25. Tangent vectors in two parameter directions on a curved surface

A curve in an arbitrary direction on a curved surface can be expressed in terms of a parameter t as $\boldsymbol{P}(u(t), w(t))$ $(a \leqq t \leqq b)$. Therefore, at point $\boldsymbol{P}(u_0, w_0)$, the tangent vector in the direction of that curve becomes:

$$\left.\frac{d\boldsymbol{P}}{dt}\right|_{t=t_0} = \boldsymbol{P}_u \left.\frac{du}{dt}\right|_{t=t_0} + \boldsymbol{P}_w \left.\frac{dw}{dt}\right|_{t=t_0}. \tag{1.81}$$

---

*) Note that $(\boldsymbol{P}_u \times \boldsymbol{P}_w)^2 = J_x^2 + J_y^2 + J_z^2$

Note that $u_0 = u(t_0)$ and $w_0 = w(t_0)$. The above formula expresses the fact that a tangent vector in an arbitrary direction on the curved surface lies on the plane formed by $\boldsymbol{P}_u$ and $\boldsymbol{P}_w$. This plane is called the tangent plane at the point $\boldsymbol{P}(u_0, w_0)$. Letting $\boldsymbol{R}$ be a position vector on the tangent plane, the tangent plane is given by the following equation.

$$[\boldsymbol{R} - \boldsymbol{P}(u_0, w_0),\ \boldsymbol{P}_u,\ \boldsymbol{P}_w] = 0. \tag{1.82}$$

The straight line that passes through point $\boldsymbol{P}(u_0, w_0)$ and is perpendicular to the tangent plane at that point is called the normal line. The normal vector $\boldsymbol{e}$ can be expressed in terms of $\boldsymbol{P}_u$ and $\boldsymbol{P}_w$ in a right-hand systems as follows:

$$\boldsymbol{e} = \frac{\boldsymbol{P}_u \times \boldsymbol{P}_w}{\sqrt{(\boldsymbol{P}_u \times \boldsymbol{P}_w)^2}} = \frac{\boldsymbol{P}_u \times \boldsymbol{P}_w}{\sqrt{J_x^2 + J_y^2 + J_z^2}}. \tag{1.83}$$

$\boldsymbol{e}$ is called the unit normal vector.

1.3.2 The First Fundamental Matrix of a Surface

As was stated in the preceding section, a curve on the curved surface $\boldsymbol{P}(u, w)$ can be given by $u = u(t)$, $w = w(t)$, $(a \leqq t \leqq b)$. The following notation is used for this.

$$\boldsymbol{u}(t) = [u(t)\ w(t)]. \tag{1.84}$$

From Eq. (1.81), the tangent vector to this curve is given by:

$$\begin{aligned}\dot{\boldsymbol{P}} &= \boldsymbol{P}_u \dot{u} + \boldsymbol{P}_w \dot{w} = [\dot{u}\ \ \dot{w}] \begin{bmatrix} \boldsymbol{P}_u \\ \boldsymbol{P}_w \end{bmatrix} \\ &\equiv \dot{\boldsymbol{u}} \boldsymbol{A}. \end{aligned} \tag{1.85}$$

Here $\boldsymbol{A}$ is defined by:

$$\boldsymbol{A} = \begin{bmatrix} \boldsymbol{P}_u \\ \boldsymbol{P}_w \end{bmatrix}. \tag{1.86}$$

The square of the magnitude $\dot{s}$ of the tangent vector is given by:

$$\begin{aligned} \dot{s}^2 &= \dot{\boldsymbol{P}}(t)^2 = \dot{\boldsymbol{P}}(t) \cdot \dot{\boldsymbol{P}}(t)^T \\ &= [\dot{u}\ \ \dot{w}] \begin{bmatrix} \boldsymbol{P}_u \\ \boldsymbol{P}_w \end{bmatrix} [\boldsymbol{P}_u\ \ \boldsymbol{P}_w] \begin{bmatrix} \dot{u} \\ \dot{w} \end{bmatrix} = [\dot{u}\ \ \dot{w}] \begin{bmatrix} \boldsymbol{P}_u^2 & \boldsymbol{P}_u \cdot \boldsymbol{P}_w \\ \boldsymbol{P}_u \cdot \boldsymbol{P}_w & \boldsymbol{P}_w^2 \end{bmatrix} \begin{bmatrix} \dot{u} \\ \dot{w} \end{bmatrix} \\ &\equiv \dot{\boldsymbol{u}} \boldsymbol{F} \dot{\boldsymbol{u}}^T. \end{aligned} \tag{1.87}$$

Here $\boldsymbol{F}$ is the matrix defined by:

$$\boldsymbol{F}=\begin{bmatrix} \boldsymbol{P}_u^2 & \boldsymbol{P}_u\cdot\boldsymbol{P}_w \\ \boldsymbol{P}_u\cdot\boldsymbol{P}_w & \boldsymbol{P}_w^2 \end{bmatrix}. \tag{1.88}$$

This matrix $\boldsymbol{F}$ is called the first fundamental matrix of the curved surface.

Using the first fundamental matrix, the unit tangent vector $\boldsymbol{t}$ of a curve on a curved surface is:

$$\boldsymbol{t}=\frac{\dot{\boldsymbol{P}}(t)}{|\dot{\boldsymbol{P}}(t)|}=\frac{\dot{\boldsymbol{u}}\boldsymbol{A}}{(\dot{\boldsymbol{u}}\boldsymbol{F}\dot{\boldsymbol{u}}^T)^{\frac{1}{2}}}. \tag{1.89}$$

Therefore, the cosine of the angle θ between the two curves $\boldsymbol{u}_1=\boldsymbol{u}_1(t)$ and $\boldsymbol{u}_2=\boldsymbol{u}_2(t)$ on the curved surface is, using (1.89):

$$\cos\theta=\boldsymbol{t}_1\cdot\boldsymbol{t}_2=\frac{\dot{\boldsymbol{u}}_1\boldsymbol{A}\cdot\boldsymbol{A}^T\dot{\boldsymbol{u}}_2^T}{(\dot{\boldsymbol{u}}_1\boldsymbol{F}\dot{\boldsymbol{u}}_1^T)^{\frac{1}{2}}(\dot{\boldsymbol{u}}_2\boldsymbol{F}\dot{\boldsymbol{u}}_2^T)^{\frac{1}{2}}}=\frac{\dot{\boldsymbol{u}}_1\boldsymbol{F}\dot{\boldsymbol{u}}_2^T}{(\dot{\boldsymbol{u}}_1\boldsymbol{F}\dot{\boldsymbol{u}}_1^T)^{\frac{1}{2}}(\dot{\boldsymbol{u}}_2\boldsymbol{F}\dot{\boldsymbol{u}}_2^T)^{\frac{1}{2}}}. \tag{1.90}$$

The length of a curve on the curved surface is given by:

$$l=\int_{t_0}^{t_1}\dot{s}\,dt=\int_{t_0}^{t_1}(\dot{\boldsymbol{u}}\boldsymbol{F}\dot{\boldsymbol{u}}^T)^{\frac{1}{2}}\,dt. \tag{1.91}$$

Next, let us consider a small area of a curved surface surrounded by the parametric curves $u=u_0$, $u=u_0+\Delta u$, $w=w_0$, $w=w_0+\Delta w$. Referring to Fig. 1.26, we see that the area ΔS of this small segment of surface is:

$$\Delta S \fallingdotseq |\boldsymbol{P}_u\times\boldsymbol{P}_w|\,\Delta u\,\Delta w.$$

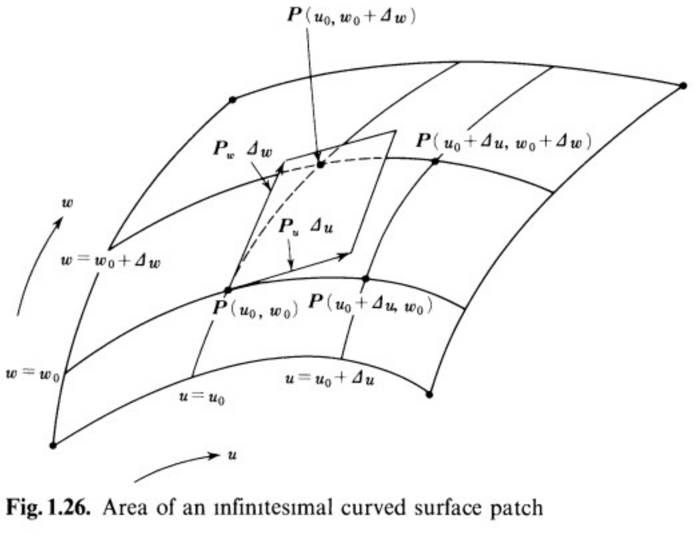

Fig. 1.26. Area of an infinitesimal curved surface patch

We also have:

$$|\boldsymbol{P}_u \times \boldsymbol{P}_w|^2 = \boldsymbol{P}_u^2 \boldsymbol{P}_w^2 - (\boldsymbol{P}_u \cdot \boldsymbol{P}_w)^{2\,*)} = |\boldsymbol{F}|. \tag{1.92}$$

Therefore, the curved surface area corresponding to the region R on the uw plane is:

$$S = \iint_R |\boldsymbol{F}|^{\frac{1}{2}}\, du dw. \tag{1.93}$$

1.3.3 Determining Conditions for a Tangent Vector to a Curve on a Surface

As shown in the preceding section, since the unit tangent vector of a curve on a curved surface is given by Eq. (1.89), the condition that determines the unit tangent vector $\boldsymbol{t}$ is:

$$\dot{\boldsymbol{u}} \boldsymbol{F} \dot{\boldsymbol{u}}^T > 0. \tag{1.94}$$

In the case $\boldsymbol{P}_u^2 \neq 0$, changing the form of the equation slightly gives:

$$\begin{aligned} \dot{\boldsymbol{u}} \boldsymbol{F} \dot{\boldsymbol{u}}^T &= [\dot{u}\ \dot{w}] \begin{bmatrix} \boldsymbol{P}_u^2 & \boldsymbol{P}_u \cdot \boldsymbol{P}_w \\ \boldsymbol{P}_u \cdot \boldsymbol{P}_w & \boldsymbol{P}_w^2 \end{bmatrix} \begin{bmatrix} \dot{u} \\ \dot{w} \end{bmatrix} = \boldsymbol{P}_u^2 \dot{u}^2 + 2\boldsymbol{P}_u \cdot \boldsymbol{P}_w \dot{u}\dot{w} + \boldsymbol{P}_w^2 \dot{w}^2 \\ &= \boldsymbol{P}_u^2 \left(\dot{u} + \frac{\boldsymbol{P}_u \cdot \boldsymbol{P}_w}{\boldsymbol{P}_u^2} \dot{w} \right)^2 + \frac{\boldsymbol{P}_u^2 \boldsymbol{P}_w^2 - (\boldsymbol{P}_u \cdot \boldsymbol{P}_w)^2}{\boldsymbol{P}_u^2} \dot{w}^2 \\ &= \boldsymbol{P}_u^2 \left(\dot{u} + \frac{\boldsymbol{P}_u \cdot \boldsymbol{P}_w}{\boldsymbol{P}_u^2} \dot{w} \right)^2 + \frac{|\boldsymbol{P}_u \times \boldsymbol{P}_w|^2}{\boldsymbol{P}_u^2} \dot{w}^2 > 0 \quad (\boldsymbol{P}_u^2 \neq 0). \end{aligned} \tag{1.95}$$

This equation implies that if the conditions

$$\dot{\boldsymbol{u}} \neq \boldsymbol{0} \quad \text{and} \quad \boldsymbol{P}_u \times \boldsymbol{P}_w \neq \boldsymbol{0} \tag{1.96}$$

are satisfied, the unit tangent vectors are determined for all curves $\boldsymbol{u} = \boldsymbol{u}(t)$. If the second condition is satisfied but the first is not, then, as can be seen from Eq. (1.81) and (1.83), the tangent plane and normal line are determined, but the unit tangent vector $\boldsymbol{t}$ is not determined due to twisting of the curve $\boldsymbol{u} = \boldsymbol{u}(t)$. If the first condition is satisfied but the second is not, there can be a cusp or the u-curve and the w-curve can be parallel, with the result that the tangent plane is undetermined[7].

---

*) Using the vector identity $(\boldsymbol{A} \times \boldsymbol{B})(\boldsymbol{C} \times \boldsymbol{D}) = (\boldsymbol{AC})(\boldsymbol{BD}) - (\boldsymbol{AD})(\boldsymbol{BC})$

1.3.4 Curvature of a Surface

From Eq. (1.9) we have:

$$\dot{\boldsymbol{P}} = \dot{s}\boldsymbol{P}' = \dot{s}\boldsymbol{t}.$$

Differentiating by t we obtain the equation:

$$\begin{aligned}\ddot{\boldsymbol{P}} &= \ddot{s}\boldsymbol{t} + \dot{s}\dot{\boldsymbol{t}} = \ddot{s}\boldsymbol{t} + \dot{s}^2\boldsymbol{t}' \\ &= \ddot{s}\boldsymbol{t} + \dot{s}^2\kappa\boldsymbol{n}.\end{aligned} \tag{1.97}$$

Now let us find $\ddot{\boldsymbol{P}}$ for the curve $\boldsymbol{u}(t) = [u(t)\ w(t)]$ on the curved surface $\boldsymbol{P}(u, w)$. From Eq. (1.81) we have:

$$\dot{\boldsymbol{P}} = \boldsymbol{P}_u\dot{u} + \boldsymbol{P}_w\dot{w}.$$

Therefore:

$$\begin{aligned}\ddot{\boldsymbol{P}} &= \frac{d\boldsymbol{P}_u}{dt}\dot{u} + \boldsymbol{P}_u\ddot{u} + \frac{d\boldsymbol{P}_w}{dt}\dot{w} + \boldsymbol{P}_w\ddot{w} \\ &= \boldsymbol{P}_{uu}\dot{u}^2 + \boldsymbol{P}_{uw}\dot{u}\dot{w} + \boldsymbol{P}_u\ddot{u} + \boldsymbol{P}_{ww}\dot{w}^2 + \boldsymbol{P}_{wu}\dot{w}\dot{u} + \boldsymbol{P}_w\ddot{w} \\ &= \boldsymbol{P}_{uu}\dot{u}^2 + \boldsymbol{P}_{uw}\dot{u}\dot{w} + \boldsymbol{P}_{wu}\dot{u}\dot{w} + \boldsymbol{P}_{ww}\dot{w}^2 + \boldsymbol{P}_u\ddot{u} + \boldsymbol{P}_w\ddot{w}.\end{aligned} \tag{1.98}$$

Taking the inner product of the unit normal vector $\boldsymbol{e}$ to the curved surface and $\ddot{\boldsymbol{P}}$ from Eq. (1.97), since $\boldsymbol{e}$ and $\boldsymbol{t}$ are perpendicular with each other:

$$\boldsymbol{e} \cdot \ddot{\boldsymbol{P}} = \dot{s}^2\kappa\boldsymbol{n} \cdot \boldsymbol{e}. \tag{1.99}$$

Also taking the inner product of the unit normal vector $\boldsymbol{e}$ and $\ddot{\boldsymbol{P}}$ from Eq. (1.98), since $\boldsymbol{e}$ is perpendicular to both $\boldsymbol{P}_u$ and $\boldsymbol{P}_w$:

$$\begin{aligned}\boldsymbol{e} \cdot \ddot{\boldsymbol{P}} &= \boldsymbol{e} \cdot \boldsymbol{P}_{uu}\dot{u}^2 + \boldsymbol{e} \cdot \boldsymbol{P}_{uw}\dot{u}\dot{w} + \boldsymbol{e} \cdot \boldsymbol{P}_{wu}\dot{u}\dot{w} + \boldsymbol{e} \cdot \boldsymbol{P}_{ww}\dot{w}^2 \\ &= [\dot{u}\ \dot{w}]\begin{bmatrix}\boldsymbol{e} \cdot \boldsymbol{P}_{uu} & \boldsymbol{e} \cdot \boldsymbol{P}_{uw} \\ \boldsymbol{e} \cdot \boldsymbol{P}_{wu} & \boldsymbol{e} \cdot \boldsymbol{P}_{ww}\end{bmatrix}\begin{bmatrix}\dot{u} \\ \dot{w}\end{bmatrix} \\ &\equiv \dot{\boldsymbol{u}}\boldsymbol{G}\dot{\boldsymbol{u}}^T\end{aligned} \tag{1.100}$$

where:

$$\boldsymbol{G} = \begin{bmatrix}\boldsymbol{e} \cdot \boldsymbol{P}_{uu} & \boldsymbol{e} \cdot \boldsymbol{P}_{uw} \\ \boldsymbol{e} \cdot \boldsymbol{P}_{wu} & \boldsymbol{e} \cdot \boldsymbol{P}_{ww}\end{bmatrix}. \tag{1.101}$$

From Eq. (1.99) and (1.100) we obtain:

$$\dot{s}^2\kappa\boldsymbol{n} \cdot \boldsymbol{e} = \dot{\boldsymbol{u}}\boldsymbol{G}\dot{\boldsymbol{u}}^T. \tag{1.102}$$

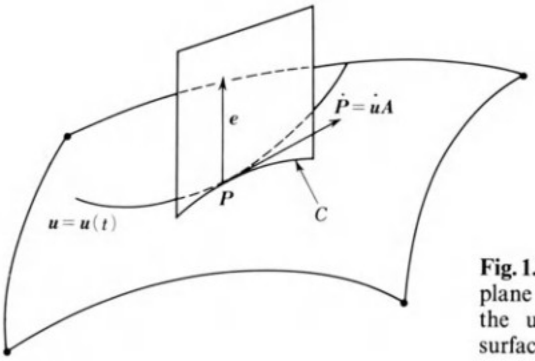

Fig. 1.27. The intersection curve C of the plane containing the tangent vector $\dot{\boldsymbol{P}}$ and the unit normal vector $\boldsymbol{e}$ with a curved surface

The matrix $\boldsymbol{G}$ is called the second fundamental matrix of the curved surface. Normally, in the curved surface representation encountered in CAD, it often happens that $\boldsymbol{P}_{uw}=\boldsymbol{P}_{wu}$. In such a case, $\boldsymbol{G}$ is a symmetrical matrix.

Let a space curve $\boldsymbol{u}=\boldsymbol{u}(t)$ be given on the curved surface $\boldsymbol{P}(u, w)$ and let C be the curve formed by the intersection of the curved surface with the plane which includes the tangent vector $\dot{\boldsymbol{P}}=\dot{\boldsymbol{u}}\boldsymbol{A}$ at a point P on the curve and the unit normal vector $\boldsymbol{e}$ (refer to Fig. 1.27). The curvature of the curve C is called the normal curvature relative to the direction $\dot{\boldsymbol{u}}\boldsymbol{A}$ at point P. The normal curvature is the projected length of the curvature vector of the curve $\boldsymbol{u}$ to $\boldsymbol{e}$. Letting κ_n be the normal curvature, from Eq. (1.102) we have:

$$\dot{s}^2\kappa_n=\dot{\boldsymbol{u}}\boldsymbol{G}\dot{\boldsymbol{u}}^T$$

$$\therefore\ \kappa_n=\frac{\dot{\boldsymbol{u}}\boldsymbol{G}\dot{\boldsymbol{u}}^T}{\dot{s}^2}=\frac{\dot{\boldsymbol{u}}\boldsymbol{G}\dot{\boldsymbol{u}}^T}{\dot{\boldsymbol{u}}\boldsymbol{F}\dot{\boldsymbol{u}}^T}. \tag{1.103}$$

The sign of κ_n is plus if the curve C is concave in the direction of $\boldsymbol{e}$, negative if it is convex. As shown in Fig. 1.27, $\kappa_n<0$ at point P.

In general, if the direction of the intersection curve at point P changes, the curvature κ_n will also change. The direction in which κ_n takes an extreme value is called the principal direction of the normal curvature. In Eq. (1.103), if we take:

$$\xi=\dot{u},\quad \eta=\dot{w},\quad L=\boldsymbol{e}\cdot\boldsymbol{P}_{uu},\quad M=\boldsymbol{e}\cdot\boldsymbol{P}_{uw}=\boldsymbol{e}\cdot\boldsymbol{P}_{wu},$$
$$N=\boldsymbol{e}\cdot\boldsymbol{P}_{ww},\quad E=\boldsymbol{P}_u^2,\quad F=\boldsymbol{P}_u\cdot\boldsymbol{P}_w,\quad G=\boldsymbol{P}_w^2$$

then:

$$L\xi^2+2M\xi\eta+N\eta^2-\kappa_n(E\xi^2+2F\xi\eta+G\eta^2)=0. \tag{1.104}$$

To find the extreme value of κ_n, take the partial derivatives with respect to ξ and η and set $\partial\kappa_n/\partial\xi=0$ and $\partial\kappa_n/\partial\eta=0$ to obtain:

$$\left.\begin{array}{l}(L-\kappa_nE)\xi+(M-\kappa_nF)\eta=0\\(M-\kappa_nF)\xi+(N-\kappa_nG)\eta=0\end{array}\right\}. \tag{1.105}$$

Eliminating ξ and η from these equations gives:

$$(EG-F^2)\kappa_n^2-(EN+GL-2FM)\kappa_n+LN-M^2=0. \tag{1.106}$$

This quadratic equation always has two real solutions $\kappa_{n\max}$ and $\kappa_{n\min}$. $\kappa_{n\max}$ and $\kappa_{n\min}$ are the maximum and minimum values of the normal curvature, called the principal curvatures.

From the relation between the roots and the coefficients we have:

$$\begin{aligned} K \equiv \kappa_{n\max}\kappa_{n\min} &= \frac{LN-M^2}{EG-F^2} = \frac{(\boldsymbol{e}\cdot\boldsymbol{P}_{uu})(\boldsymbol{e}\cdot\boldsymbol{P}_{ww})-(\boldsymbol{e}\cdot\boldsymbol{P}_{uw})^2}{\boldsymbol{P}_u^2\boldsymbol{P}_w^2-(\boldsymbol{P}_u\cdot\boldsymbol{P}_w)} \\ &= \frac{|\boldsymbol{G}|}{|\boldsymbol{F}|} \end{aligned} \tag{1.107}$$

$$\begin{aligned} 2H \equiv \kappa_{n\min}+\kappa_{n\max} &= \frac{EN+GL-2FM}{EG-F^2} \\ &= \frac{\boldsymbol{P}_u^2(\boldsymbol{e}\cdot\boldsymbol{P}_{ww})-2(\boldsymbol{P}_u\cdot\boldsymbol{P}_w)(\boldsymbol{e}\cdot\boldsymbol{P}_{uw})+\boldsymbol{P}_w^2(\boldsymbol{e}\cdot\boldsymbol{P}_{uu})}{|\boldsymbol{F}|}. \end{aligned} \tag{1.108}$$

K is called the total curvature or the Gauss curvature, while H is called the mean curvature. It is easy to show that the two directions in which the principal curvatures are obtained are perpendicular to each other.

1.3.5 Calculation of a Point on a Surface

Many of the curved surface patch equations which are normally used are of the bi-cubic surface type:

$$\boldsymbol{P}(u,w)=\sum_{i=0}^{3}\sum_{j=0}^{3}\boldsymbol{A}_{3-i,3-j}u^i w^j \tag{1.109}$$

$$\begin{aligned} &=(\boldsymbol{A}_{00}w^3+\boldsymbol{A}_{01}w^2+\boldsymbol{A}_{02}w+\boldsymbol{A}_{03})u^3+(\boldsymbol{A}_{10}w^3+\boldsymbol{A}_{11}w^2+\boldsymbol{A}_{12}w+\boldsymbol{A}_{13})u^2 \\ &\quad+(\boldsymbol{A}_{20}w^3+\boldsymbol{A}_{21}w^2+\boldsymbol{A}_{22}w+\boldsymbol{A}_{23})u+\boldsymbol{A}_{30}w^3+\boldsymbol{A}_{31}w^2+\boldsymbol{A}_{32}w+\boldsymbol{A}_{33} \end{aligned} \tag{1.110}$$

$$=[u^3\ u^2\ u\ 1]\begin{bmatrix}\boldsymbol{A}_{00} & \boldsymbol{A}_{01} & \boldsymbol{A}_{02} & \boldsymbol{A}_{03}\\ \boldsymbol{A}_{10} & \boldsymbol{A}_{11} & \boldsymbol{A}_{12} & \boldsymbol{A}_{13}\\ \boldsymbol{A}_{20} & \boldsymbol{A}_{21} & \boldsymbol{A}_{22} & \boldsymbol{A}_{23}\\ \boldsymbol{A}_{30} & \boldsymbol{A}_{31} & \boldsymbol{A}_{32} & \boldsymbol{A}_{33}\end{bmatrix}\begin{bmatrix}w^3\\ w^2\\ w\\ 1\end{bmatrix}. \tag{1.111}$$

For a curved surface of this type, just as in the case of a curve, a point on a curved surface can be calculated rapidly by finite difference calculation.

Taking w to be fixed in Eq. (1.110), we have:

$$\boldsymbol{P}(u, w) = \boldsymbol{A}u^3 + \boldsymbol{B}u^2 + \boldsymbol{C}u + \boldsymbol{D}$$

where:

$$\begin{aligned}
\boldsymbol{A} &= \boldsymbol{A}_{00}w^3 + \boldsymbol{A}_{01}w^2 + \boldsymbol{A}_{02}w + \boldsymbol{A}_{03}\\
\boldsymbol{B} &= \boldsymbol{A}_{10}w^3 + \boldsymbol{A}_{11}w^2 + \boldsymbol{A}_{12}w + \boldsymbol{A}_{13}\\
\boldsymbol{C} &= \boldsymbol{A}_{20}w^3 + \boldsymbol{A}_{21}w^2 + \boldsymbol{A}_{22}w + \boldsymbol{A}_{23}\\
\boldsymbol{D} &= \boldsymbol{A}_{30}w^3 + \boldsymbol{A}_{31}w^2 + \boldsymbol{A}_{32}w + \boldsymbol{A}_{33}
\end{aligned}$$

which is the equation of a cubic curve. Then, using the finite difference matrix in Eq. (1.48), a point on a curve on the curved surface for which w is fixed can be found.

Letting δ be the finite difference increment in the u-direction and denoting a forward finite difference by Δ, the finite difference matrix for $u=0$ is, from Eq. (1.48):

$$\begin{bmatrix} \boldsymbol{P}_{0,w} \\ \frac{1}{\delta}\Delta \boldsymbol{P}_{0,w} \\ \frac{1}{\delta^2}\Delta^2 \boldsymbol{P}_{0,w} \\ \frac{1}{\delta^3}\Delta^3 \boldsymbol{P}_{0,w} \end{bmatrix} = \begin{bmatrix} \boldsymbol{D} \\ \boldsymbol{A}\delta^2 + \boldsymbol{B}\delta + \boldsymbol{C} \\ 6\boldsymbol{A}\delta + 2\boldsymbol{B} \\ 6\boldsymbol{A} \end{bmatrix} = \begin{bmatrix} \boldsymbol{A}_{30}w^3 + \boldsymbol{A}_{31}w^2 + \boldsymbol{A}_{32}w + \boldsymbol{A}_{33} \\ (\delta^2\boldsymbol{A}_{00} + \delta\boldsymbol{A}_{10} + \boldsymbol{A}_{20})w^3 + (\delta^2\boldsymbol{A}_{01} + \delta\boldsymbol{A}_{11} + \boldsymbol{A}_{21})w^2 \\ \quad + (\delta^2\boldsymbol{A}_{02} + \delta\boldsymbol{A}_{12} + \boldsymbol{A}_{22})w + \delta^2\boldsymbol{A}_{03} + \delta\boldsymbol{A}_{13} + \boldsymbol{A}_{23} \\ (6\delta\boldsymbol{A}_{00} + 2\boldsymbol{A}_{10})w^3 + (6\delta\boldsymbol{A}_{01} + 2\boldsymbol{A}_{11})w^2 \\ \quad + (6\delta\boldsymbol{A}_{02} + 2\boldsymbol{A}_{12})w + 6\delta\boldsymbol{A}_{03} + 2\boldsymbol{A}_{13} \\ 6\boldsymbol{A}_{00}w^3 + 6\boldsymbol{A}_{01}w^2 + 6\boldsymbol{A}_{02}w + 6\boldsymbol{A}_{03} \end{bmatrix} \tag{1.112}$$

Therefore, the finite difference matrix for $w=0$ is:

$$\begin{bmatrix} \boldsymbol{P}_{0,0} \\ \frac{1}{\delta}\Delta \boldsymbol{P}_{0,0} \\ \frac{1}{\delta^2}\Delta^2 \boldsymbol{P}_{0,0} \\ \frac{1}{\delta^3}\Delta^3 \boldsymbol{P}_{0,0} \end{bmatrix} = \begin{bmatrix} \boldsymbol{A}_{33} \\ \delta^2\boldsymbol{A}_{03} + \delta\boldsymbol{A}_{13} + \boldsymbol{A}_{23} \\ 6\delta\boldsymbol{A}_{03} + 2\boldsymbol{A}_{13} \\ 6\boldsymbol{A}_{03} \end{bmatrix}. \tag{1.113}$$

Next, in Eq. (1.112), let us take the finite difference in the w-direction at $w=0$. Letting δ also be the finite difference increment in this direction and denoting the forward finite difference in this direction by ∇, then the first order finite differences are:

$$\begin{bmatrix} \frac{1}{\delta}\nabla \boldsymbol{P}_{0,0} \\ \frac{1}{\delta^2}\nabla(\Delta \boldsymbol{P}_{0,0}) \\ \frac{1}{\delta^3}\nabla(\Delta^2 \boldsymbol{P}_{0,0}) \\ \frac{1}{\delta^4}\nabla(\Delta^3 \boldsymbol{P}_{0,0}) \end{bmatrix} = \begin{bmatrix} \boldsymbol{A}_{30}\delta^2+\boldsymbol{A}_{31}\delta+\boldsymbol{A}_{32} \\ \begin{matrix}(\delta^2\boldsymbol{A}_{00}+\delta\boldsymbol{A}_{10}+\boldsymbol{A}_{20})\delta^2+(\delta^2\boldsymbol{A}_{01}+\delta\boldsymbol{A}_{11}+\boldsymbol{A}_{21})\delta \\ +\delta^2\boldsymbol{A}_{02}+\delta\boldsymbol{A}_{12}+\boldsymbol{A}_{22}\end{matrix} \\ \begin{matrix}(6\,\delta\boldsymbol{A}_{00}+2\boldsymbol{A}_{10})\delta^2+(6\,\delta\boldsymbol{A}_{01}+2\boldsymbol{A}_{11})\delta \\ +6\,\delta\boldsymbol{A}_{02}+2\boldsymbol{A}_{12}\end{matrix} \\ 6\,\boldsymbol{A}_{00}\delta^2+6\,\boldsymbol{A}_{01}\delta+6\,\boldsymbol{A}_{02} \end{bmatrix}. \tag{1.114}$$

The second and third order finite differences are:

$$\begin{bmatrix} \frac{1}{\delta^2}\nabla^2 \boldsymbol{P}_{0,0} \\ \frac{1}{\delta^3}\nabla^2(\Delta \boldsymbol{P}_{0,0}) \\ \frac{1}{\delta^4}\nabla^2(\Delta^2 \boldsymbol{P}_{0,0}) \\ \frac{1}{\delta^5}\nabla^2(\Delta^3 \boldsymbol{P}_{0,0}) \end{bmatrix} = \begin{bmatrix} 6\,\boldsymbol{A}_{30}\delta+2\boldsymbol{A}_{31} \\ 6(\delta^2\boldsymbol{A}_{00}+\delta\boldsymbol{A}_{10}+\boldsymbol{A}_{20})\delta+2(\delta^2\boldsymbol{A}_{01}+\delta\boldsymbol{A}_{11}+\boldsymbol{A}_{21}) \\ 6(6\delta\boldsymbol{A}_{00}+2\boldsymbol{A}_{10})\delta+2(6\delta\boldsymbol{A}_{01}+2\boldsymbol{A}_{11}) \\ 36\,\boldsymbol{A}_{00}\delta+12\boldsymbol{A}_{01} \end{bmatrix} \tag{1.115}$$

$$\begin{bmatrix} \frac{1}{\delta^3}\nabla^3 \boldsymbol{P}_{0,0} \\ \frac{1}{\delta^4}\nabla^3(\Delta \boldsymbol{P}_{0,0}) \\ \frac{1}{\delta^5}\nabla^3(\Delta^2 \boldsymbol{P}_{0,0}) \\ \frac{1}{\delta^6}\nabla^3(\Delta^3 \boldsymbol{P}_{0,0}) \end{bmatrix} = \begin{bmatrix} 6\boldsymbol{A}_{30} \\ 6(\delta^2\boldsymbol{A}_{00}+\delta\boldsymbol{A}_{10}+\boldsymbol{A}_{20}) \\ 6(6\delta\boldsymbol{A}_{00}+2\boldsymbol{A}_{10}) \\ 36\,\boldsymbol{A}_{00} \end{bmatrix}. \tag{1.116}$$

Let us name the 4×3 matrices on the right-hand sides of Eqs. (1.113), (1.114), (1.115) and (1.116), respectively as finite difference matrix A, finite difference matrix B, finite difference matrix C and finite difference matrix D (Fig. 1.28).

Calculations on the curve $\boldsymbol{P}(u, 0)$ in the u-direction at $w=0$ can be carried out by finite differences using matrix A, that is, Eq. (1.113). Next, to find the finite difference matrix to be used to calculate the curve $\boldsymbol{P}(u, \delta)$, as shown in Fig. (1.28) perform finite difference calculations for each element corresponding to matrices A, B, C and D. Therefore, to generate a family of curves extending along the u-direction separated by a parametric distance γ ($\delta=1/2^m$,

$\gamma = 1/2^n$, $m \geqq n$) in the w-direction, it is sufficient to perform 1 curve-generating finite difference operation in the u-direction for every 2^{m-n} finite difference operations between matrices (Fig. 1.29).

Next, to find a family of curves extending in the w-direction, as shown in Fig. 1.30 matrix transpositions are performed using the vectors of finite difference matrices A, B, C and D. In other words, the process described above can be performed with the order of u and w reversed; this corresponds to the transformations $A_{ij} \leftrightarrow A_{ji}$ in the finite difference matrices.

1.3.6 Subdivision of Surface Patches

Let us now divide up a curved surface patch, using a bi-cubic surface described by Eq. (1.111) (Fig. 1.31).

First, let us find equations to describe the surface patch $\boldsymbol{P}(u^*, w^*)$ $(0 \leqq u^* \leqq 1;\ 0 \leqq w^* \leqq 1)$ within the bi-cubic surface patch $\boldsymbol{P}(u, w)$ surrounded by $u = u_0$, $u = u_1$, $w = w_0$ and $w = w_1$. To do this the following parameter transformation must be performed in Eq. (1.111).

$$u = u_0 + u^*(u_1 - u_0) \tag{1.117}$$

$$w = w_0 + w^*(w_1 - w_0). \tag{1.118}$$

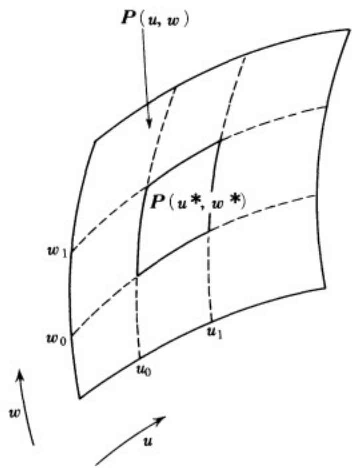

Fig. 1.31. Division of a surface patch (1)

Substituting (1.117) and (1.118) into (1.111), and using the result for parametric transformation of a curve (Eq. (1.55)), gives:

$$\boldsymbol{P}(u^*, w^*) = [u^{*3}\ u^{*2}\ u^*\ 1]$$

$$\times\begin{bmatrix}(u_1-u_0)^3 & 0 & 0 & 0\\ 3(u_1-u_0)^2u_0 & (u_1-u_0)^2 & 0 & 0\\ 3(u_1-u_0)u_0^2 & 2(u_1-u_0)u_0 & u_1-u_0 & 0\\ u_0^3 & u_0^2 & u_0 & 1\end{bmatrix}\begin{bmatrix}\boldsymbol{A}_{00} & \boldsymbol{A}_{01} & \boldsymbol{A}_{02} & \boldsymbol{A}_{03}\\ \boldsymbol{A}_{10} & \boldsymbol{A}_{11} & \boldsymbol{A}_{12} & \boldsymbol{A}_{13}\\ \boldsymbol{A}_{20} & \boldsymbol{A}_{21} & \boldsymbol{A}_{22} & \boldsymbol{A}_{23}\\ \boldsymbol{A}_{30} & \boldsymbol{A}_{31} & \boldsymbol{A}_{32} & \boldsymbol{A}_{33}\end{bmatrix}$$

$$\times\begin{bmatrix}(w_1-w_0)^3 & 3(w_1-w_0)^2w_0 & 3(w_1-w_0)w_0^2 & w_0^3\\ 0 & (w_1-w_0)^2 & 2(w_1-w_0)w_0 & w_0^2\\ 0 & 0 & w_1-w_0 & w_0\\ 0 & 0 & 0 & 1\end{bmatrix}\begin{bmatrix}w^{*3}\\ w^{*2}\\ w^*\\ 1\end{bmatrix}$$

$$(0 \leqq u^* \leqq 1;\quad 0 \leqq w^* \leqq 1). \tag{1.119}$$

Using Eq. (1.119), the curved surface formula for the case in which the surface patch $\boldsymbol{P}(u, w)$ in Fig. 1.32 is divided into 3 sections is obtained as follows:

- Formula for curved surface section A:
  in Eq. (1.119), set $u_0 = u_s$, $u_1 = 1$, $w_0 = 0$, $w_1 = 1$.
- Formula for curved surface section B:
  in Eq. (1.119), set $u_0 = 0$, $u_1 = u_s$, $w_0 = 0$, $w_1 = w_s$.
- Formula for curved surface section C:
  in Eq. (1.119), set $u_0 = 0$, $u_1 = u_s$, $w_0 = w_s$, $w_1 = 1$.

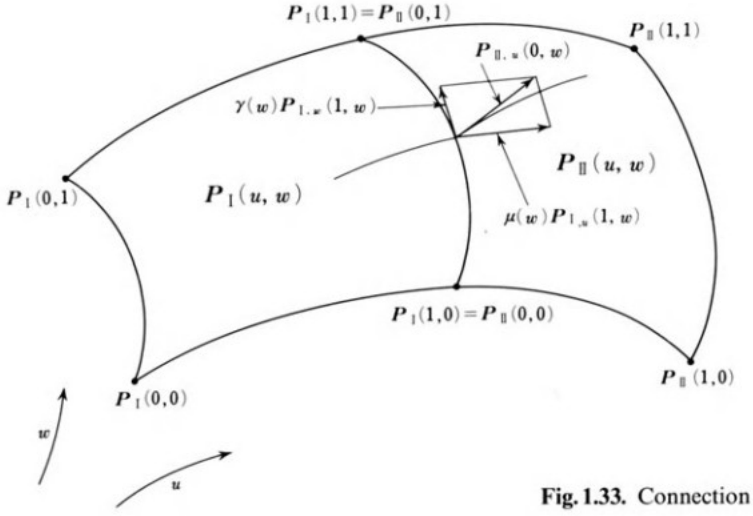
1.3.7 Connection of Surface Patches

Let us consider the problem of connecting surface patch $\boldsymbol{P}_{\text{II}}(u, w)$ along its curve $u=0$ continuously to surface patch $\boldsymbol{P}_{\text{I}}(u, w)$ along its curve $u=1$ (Fig. 1.33).

First, the condition for the boundary curves of both patches to coincide is:

$$\boldsymbol{P}_{\text{II}}(0, w)=\boldsymbol{P}_{\text{I}}(1, w) \quad (0 \leqq w \leqq 1). \tag{1.120}$$

Next, on the boundary curve between both patches, in order for the slope to be continuous in the direction across the boundary curve it is necessary for



$\boldsymbol{P}_{\text{I}}(1,1)=\boldsymbol{P}_{\text{II}}(0,1)$
$\boldsymbol{P}_{\text{II}}(1,1)$
$\boldsymbol{P}_{\text{II},u}(0, w)$
$\gamma(w)\boldsymbol{P}_{\text{I},w}(1, w)$
$\boldsymbol{P}_{\text{II}}(u, w)$
$\boldsymbol{P}_{\text{I}}(0,1)$
$\boldsymbol{P}_{\text{I}}(u, w)$
$\mu(w)\boldsymbol{P}_{\text{I},u}(1, w)$
$\boldsymbol{P}_{\text{I}}(1,0)=\boldsymbol{P}_{\text{II}}(0,0)$
$\boldsymbol{P}_{\text{II}}(1,0)$
$\boldsymbol{P}_{\text{I}}(0,0)$
w
u

Fig. 1.33. Connection of surface patches

the tangent plane $\boldsymbol{P}_{\mathrm{II}}(0, w)$ $(0 \leqq w \leqq 1)$ to coincide with the tangent plane $\boldsymbol{P}_{\mathrm{I}}(1, w)$ $(0 \leqq w \leqq 1)$. In this case, the direction of the normal vector is continuous; that is, taking $\mu(w)$ to be a positive scalar function, we have:

$$\boldsymbol{P}_{\mathrm{II},u}(0, w) \times \boldsymbol{P}_{\mathrm{II},w}(0, w) = \mu(w)\, \boldsymbol{P}_{\mathrm{I},u}(1, w) \times \boldsymbol{P}_{\mathrm{I},w}(1, w) \; (0 \leqq w \leqq 1). \tag{1.121}$$

Since $\boldsymbol{P}_{\mathrm{II},w}(0, w) = \boldsymbol{P}_{\mathrm{I},w}(1, w)$, if $\gamma(w)$ is an arbitrary scalar function we have:

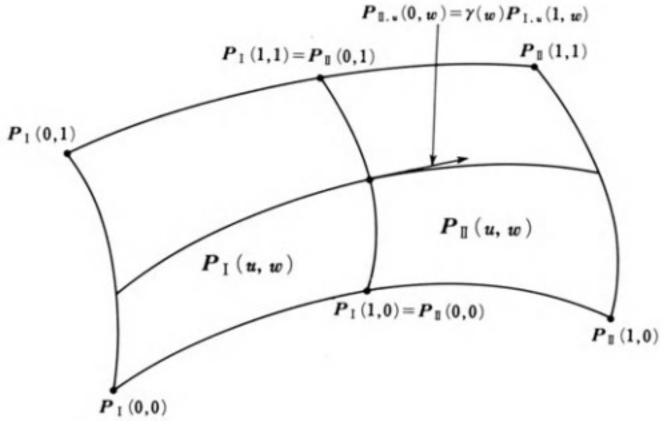
$$\boldsymbol{P}_{\mathrm{II},u}(0, w) = \mu(w)\, \boldsymbol{P}_{\mathrm{I},u}(1, w) + \gamma(w)\, \boldsymbol{P}_{\mathrm{I},w}(1, w) \;\; (0 \leqq w \leqq 1). \tag{1.122}$$

The implication of Eq. (1.122) is that $\boldsymbol{P}_{\mathrm{II},u}(0, w)$ of the second surface patch lies on the tangent plane of the first surface patch along the boundary curve.

Taking $\gamma(w) = 0$ as a special case, we obtain:

$$\boldsymbol{P}_{\mathrm{II},u}(0, w) = \mu(w)\, \boldsymbol{P}_{\mathrm{I},u}(1, w) \;\; (0 \leqq w \leqq 1). \tag{1.123}$$

In this case, the u-curve is smoothly connected across the boundary curve between the two surface patches (Fig. 1.34). This is a slope continuity condition and is a more severe condition than in the case of Eq. (1.122).



$P_{\mathrm{II},u}(0, w) = \gamma(w) P_{\mathrm{I},u}(1, w)$
$P_{\mathrm{I}}(1,1) = P_{\mathrm{II}}(0,1)$
$P_{\mathrm{II}}(1,1)$
$P_{\mathrm{I}}(0,1)$
$P_{\mathrm{II}}(u, w)$
$P_{\mathrm{I}}(u, w)$
$P_{\mathrm{I}}(1,0) = P_{\mathrm{II}}(0,0)$
$P_{\mathrm{II}}(1,0)$
$P_{\mathrm{I}}(0,0)$

Fig. 1.34. Special case of connection by slope continuity (w-curves are continuous)

The condition expressed by Eq. (1.120) requires that on the boundary curve, the degree of w on $\boldsymbol{P}_{\mathrm{II}}(u, w)$ must agree with the degree of w on $\boldsymbol{P}_{\mathrm{I}}(u, w)$. This does not constrain the degree of w over all of the patch $\boldsymbol{P}_{\mathrm{II}}(u, w)$. The degree of w on $\boldsymbol{P}_{\mathrm{II}}(u, w)$ can be specified to have an arbitrary value n not lower than the degree of w on $\boldsymbol{P}_{\mathrm{I}}(u, w)$ as long as it agrees with the degree on $\boldsymbol{P}_{\mathrm{I}}(u, w)$ on the boundary curve.

In addition, surface patches can be connected as shown in Fig. 1.35 by means of a suitable parametric transformation.

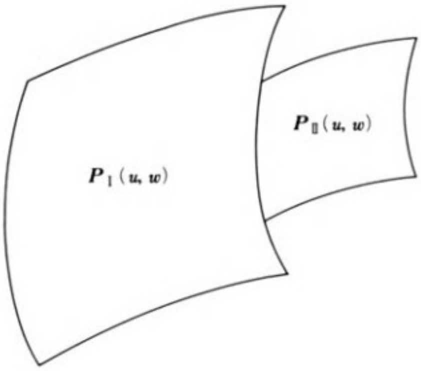


Fig. 1.35. Special case of patch connection

1.3.8 Degeneration of a Surface Patch

It is possible for 2 coincident vertices of the 4 corners of a surface patch to form a triangular surface patch (Fig. 1.36). Curve $\boldsymbol{P}(0, w)$ of this surface patch becomes a single point $\boldsymbol{D}$ regardless of the value which w takes from 0 to 1. In other words, the boundary curve degenerates to a point. When performing shape processing, for example in NC processing, when, for example, a tool path is calculated it is necessary to find the normal vector at every point on the surface. Normally, a normal vector on a surface is found as the vector product of tangent vectors in two parametric directions. However, at point $\boldsymbol{D}$ the vector product becomes:

$$\boldsymbol{P}_u(0, w) \times \boldsymbol{P}_w(0, w). \tag{1.124}$$

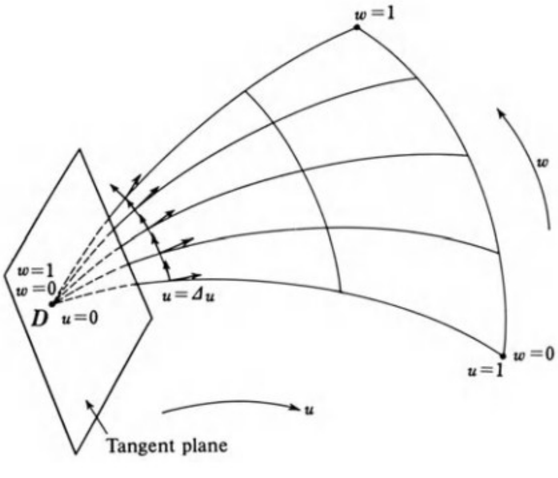

Fig. 1.36. A surface patch that has degenerated to a triangular shape

Since $\boldsymbol{P}_w(0, w) = \boldsymbol{0}$, the normal vector at point $\boldsymbol{D}$ cannot be determined by this method. In such a case, the normal vector is determined as a limit, as follows.

The unit normal vector $\boldsymbol{e}$ on the curve $u = \Delta u$ is:

$$\boldsymbol{e} = \frac{\boldsymbol{P}_u(\Delta u, w) \times \boldsymbol{P}_w(\Delta u, w)}{|\boldsymbol{P}_u(\Delta u, w) \times \boldsymbol{P}_w(\Delta u, w)|}. \tag{1.125}$$

We also have:

$$\boldsymbol{P}_u(\Delta u, w) \fallingdotseq \boldsymbol{P}_u(0, w) + \Delta u\, \boldsymbol{P}_{uu}(0, w) \tag{1.126}$$

$$\begin{aligned} \boldsymbol{P}_w(\Delta u, w) &\fallingdotseq \boldsymbol{P}_w(0, w) + \Delta u\, \boldsymbol{P}_{uw}(0, w) \\ &= \Delta u\, \boldsymbol{P}_{uw}(0, w). \end{aligned} \tag{1.127}$$

Substituting the relations in Eqs. (1.126) and (1.127) into (1.125) and taking the limit gives, for the unit normal vector at point $\boldsymbol{D}$:

$$\begin{aligned} \boldsymbol{e}_D &= \lim_{\Delta u \to 0} \boldsymbol{e} = \lim_{\Delta u \to 0} \frac{\boldsymbol{P}_u(0, w) \times \boldsymbol{P}_{uw}(0, w) + \Delta u\, \boldsymbol{P}_{uu}(0, w) \times \boldsymbol{P}_{uw}(0, w)}{|\boldsymbol{P}_u(0, w) \times \boldsymbol{P}_{uw}(0, w) + \Delta u\, \boldsymbol{P}_{uu}(0, w) \times \boldsymbol{P}_{uw}(0, w)|} \\ &= \frac{\boldsymbol{P}_u(0, w) \times \boldsymbol{P}_{uw}(0, w)}{|\boldsymbol{P}_u(0, w) \times \boldsymbol{P}_{uw}(0, w)|}. \end{aligned} \tag{1.128}$$

In order for the unit normal vector to be determined uniquely, formula (1.128) must have a unique value for any arbitrary w from 0 to 1.

In other words, when a triangular patch is expressed as an ordinary quadrangular patch, the unit normal vector at the degenerate point $\boldsymbol{D}$ cannot be found by normal means; it must be found using (1.128). And in order for formula (1.128) to be uniquely determined, special care must be taken (refer to Sects. 3.39 and 5.2.4).

1.3.9 Calculation of a Normal Vector on a Surface

A normal vector $\boldsymbol{N}$ at a point on a curved surface is calculated as follows:

$$\begin{aligned} \boldsymbol{N} &= \frac{\partial \boldsymbol{P}(u, w)}{\partial u} \times \frac{\partial \boldsymbol{P}(u, w)}{\partial w} \\ &= \left[\frac{\partial(y, z)}{\partial(u, w)} \; \frac{\partial(z, x)}{\partial(u, w)} \; \frac{\partial(x, y)}{\partial(u, w)} \right] \\ &\equiv [J_x \;\; J_y \;\; J_z]. \end{aligned} \tag{1.129}$$

The Jacobians such as $\dfrac{\partial(y, z)}{\partial(u, w)}$ are defined as follows:

$$\frac{\partial(y,z)}{\partial(u,w)} \equiv J_x = \begin{vmatrix} \dfrac{\partial y}{\partial u} & \dfrac{\partial z}{\partial u} \\ \dfrac{\partial y}{\partial w} & \dfrac{\partial z}{\partial w} \end{vmatrix}.$$

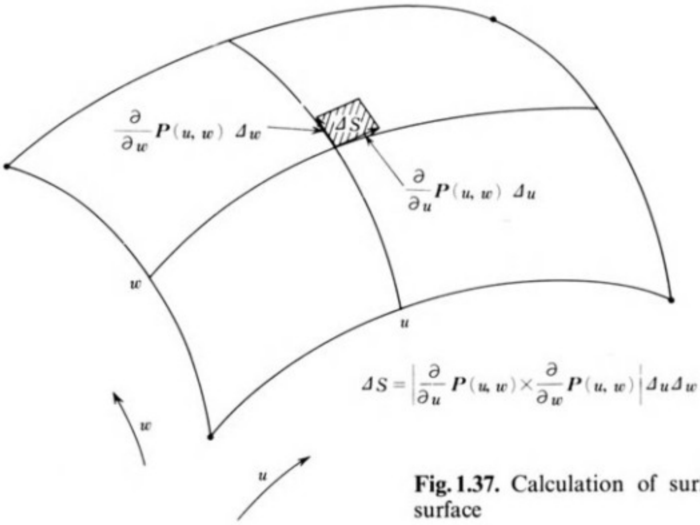
In a special case, for example, when a triangular patch is represented as a quadrangular patch, one boundary line degenerates to a point. At this point the Jacobian becomes singular and the normal vector cannot be found by the above method (refer to Sect. 1.3.8).

The unit normal vector $\boldsymbol{e}$ is:

$$\boldsymbol{e} = \left[\frac{J_x}{\sqrt{J_x^2+J_y^2+J_z^2}} \quad \frac{J_y}{\sqrt{J_x^2+J_y^2+J_z^2}} \quad \frac{J_z}{\sqrt{J_x^2+J_y^2+J_z^2}} \right]. \tag{1.130}$$

1.3.10 Calculation of Surface Area and Volume of a Surface

To find the surface area of a curved surface, the first fundamental matrix can be used and the calculation performed with Eq. (1.93), but Jacobians can also be used, as follows.



$\frac{\partial}{\partial w}\boldsymbol{P}(u,w)\ \Delta w$
ΔS
$\frac{\partial}{\partial u}\boldsymbol{P}(u,w)\ \Delta u$
w
u
$\Delta S = \left|\frac{\partial}{\partial u}\boldsymbol{P}(u,w) \times \frac{\partial}{\partial w}\boldsymbol{P}(u,w)\right| \Delta u \Delta w$
w
u

Fig. 1.37. Calculation of surface area of a curved surface

The surface area ΔS of an infinitesimal parallel quadrangle formed by the infinitesimal tangent vectors $\dfrac{\partial}{\partial u}\boldsymbol{P}(u,w)\,\Delta u$ and $\dfrac{\partial}{\partial w}\boldsymbol{P}(u,w)\,\Delta w$ in the u- and w-directions is (Fig. 1.37):

$$\Delta S = \left| \frac{\partial}{\partial u} \boldsymbol{P}(u, w) \times \frac{\partial}{\partial w} \boldsymbol{P}(u, w) \right| \Delta u \Delta w = |\boldsymbol{N}| \Delta u \Delta w$$
$$= \sqrt{J_x^2 + J_y^2 + J_z^2}\ \Delta u \Delta w. \tag{1.131}$$

The surface area S over the entire surface patch is then obtained as follows:

$$S = \int dS$$
$$= \int_0^1 \int_0^1 \sqrt{J_x^2 + J_y^2 + J_z^2}\ du dw. \tag{1.132}$$

Next, let us find the volume V of the space enclosed when a curved surface patch is projected onto the xy plane (Fig. 1.38). The projected area ΔS_z obtained by projecting an infinitesimal area on the xy plane is obtained by setting $J_x = J_y = 0$ in Eq. (1.131):

$$\Delta S_z = J_z \Delta u \Delta w.$$

This gives the following expression for the volume V enclosed by the column formed when ΔS is projected onto the xy plane:

$$\Delta V = z(u, w)\, \Delta S_z = z(u, w)\, J_z \Delta u \Delta w.$$

Accordingly, the total volume V becomes:

$$V = \int_0^1 \int_0^1 z(u, w)\, J_z du dw. \tag{1.133}$$

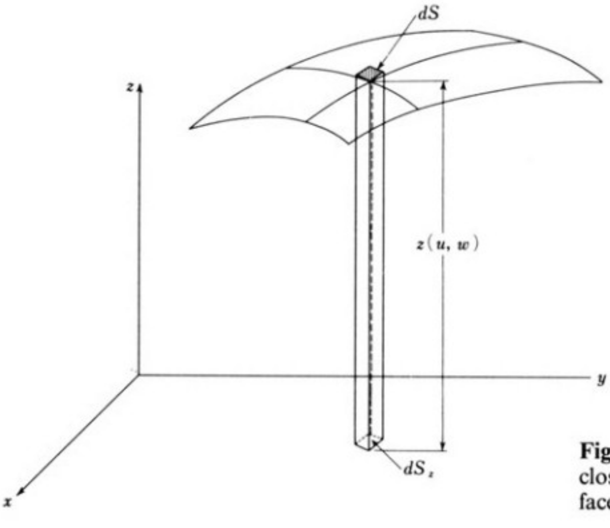


Fig. 1.38. Volume of the space enclosed by projecting a curved surface onto the xy plane

1.3.11 Offset Surfaces

The following equation can be used to generate a point on the curved surface $\boldsymbol{P}_0(u, w)$ that is offset a distance d with respect to the curved surface $\boldsymbol{P}(u, w)$.

$$\boldsymbol{P}_0(u, w) = \boldsymbol{P}(u, w) + \boldsymbol{e}(u, w)\, d. \tag{1.134}$$

In this equation, $\boldsymbol{e}(u, w)$ is the unit normal vector in the offset direction at point $\boldsymbol{P}(u, w)$.

To express $\boldsymbol{P}_0(u, w)$ as a bi-cubic surface in the format of Eq. (1.111), point $\boldsymbol{P}_0(u, w)$ can be calculated for the points corresponding to points $u, w = 0$, 1/3, 2/3, 1 on the curved surface $\boldsymbol{P}(u, w)$; then the bi-cubic surface passing through these 16 points can be found by solving simultaneous equations (Fig. 1.39). This curved surface is an approximation to the offset curved surface.

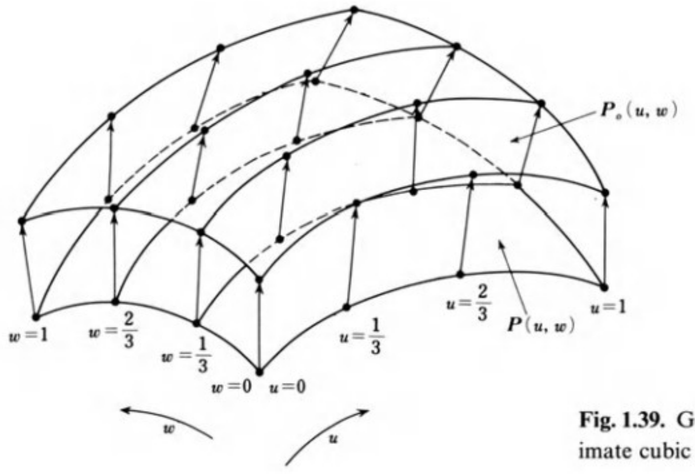

Fig. 1.39. Generation of an approximate cubic offset surface

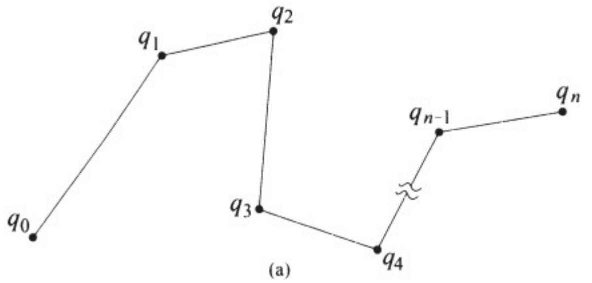
Chapter 21

Polyhedron Subdivisions

This chapter is included to show a simple application of the Four-dimensional Processing to surface generation by polyhedron subdivision, and to show an example of how generality of representational capability is increased by a simple homogenization.



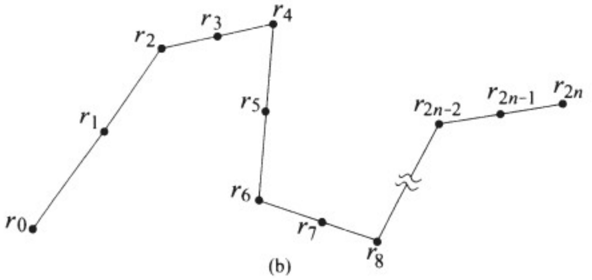


Figure 21.1: Chaikin's algorithm (1).

21.1 Chaikin's Algorithm

G.M. Chaikin proposed a method of generating curves procedurally, using a very simple geometrical algorithm, without depending on mathematical repre-

F. Yamaguchi, *Computer-Aided Geometric Design*

sentations [9]. Suppose that a polygon $q_0q_1\dots q_n$ is given, as in Fig. 21.1(a). Find the midpoints of all of the sides, and relabel the initially given vertices and these points as $r_0, r_1, \dots, r_{2n}$ (Fig. 21.1(b)).

Fig. 21.2(a) shows just the vertex $b(r_i)$ of the initial polygon and the midpoints $a(r_{i-1})$ and $c(r_{i+1})$ of the two sides attached to it.

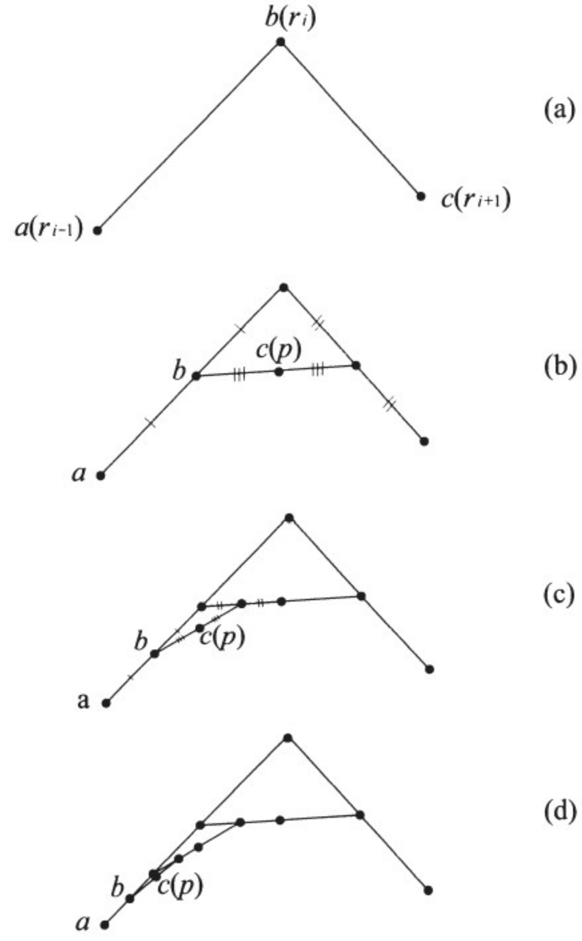

Figure 21.2: Chaikin's algorithm (2).

Letting p be the midpoint of the line segment formed by connecting the midpoints of sides ab and bc, we have:

$$\boldsymbol{p} = \frac{\frac{\boldsymbol{a}+\boldsymbol{b}}{2} + \frac{\boldsymbol{b}+\boldsymbol{c}}{2}}{2} = \frac{\boldsymbol{a} + 2\boldsymbol{b} + \boldsymbol{c}}{4}. \tag{21.1}$$

This point p becomes one point on the curve being generated. This division produces a set of 2 sides on either side of the point p. Eq.(21.1) can be applied to both of these sides. We push the set of 2 sides on the right side, for example, into stack and then apply eq.(21.1) again to the set of 2 sides on the left. This operation is repeated, pushing the set of 2 sides on the right into stack each time, until the length of the set of 2 sides on the left reaches a certain limit. At this point the contents of stack are poped up and similar operations are performed on them until stack is empty. This generates a sequence of points on the curve corresponding to $r_{i-1}r_ir_{i+1}$. If the processing above is performed for all groups of $r_{i-1}r_ir_{i+1} (i = 2, 4, \ldots, 2n-2)$, a curve corresponding to the given polygon $q_0q_1 \ldots q_n$ is generated. An example of such a curve is shown in Fig. 21.3 .

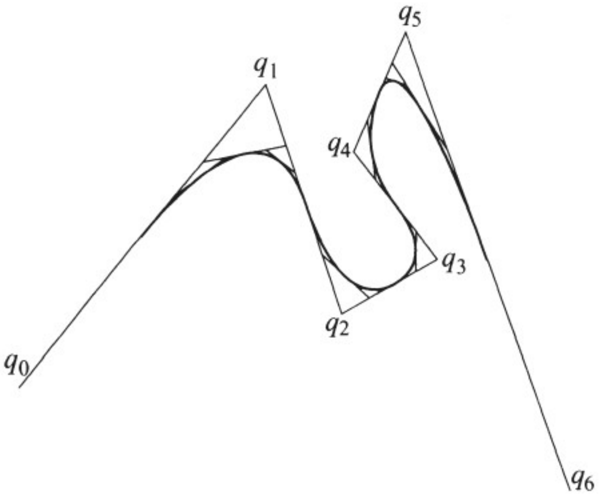

Figure 21.3: An example of a curve generated by Chaikin's method.

As can be understood from the generation process above, the curve segment is completely determined by only 3 points r_{i-1}, r_i, r_{i+1}. It has one end at r_{i-1} and the other at r_{i+1}. Its slope at r_{i-1} is in the direction of the line segment $\overrightarrow{r_{i-1}r_i}$, and its slope at r_{i+1} is in the direction of the line segment $\overrightarrow{r_ir_{i+1}}$. Since the curve passes through the point p calculated with eq.(21.1), it is evident that the curve is a parabola [1].

Let us find the equation of this parabola [48]. Writing the curve function in the form

$$\boldsymbol{p}_i(t) = [t^2 \; t \; 1] \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \\ \boldsymbol{c} \end{bmatrix}, \tag{21.2}$$

we obtain:

$$\dot{\boldsymbol{p}}_i(t) = [2t \; 1 \; 0] \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \\ \boldsymbol{c} \end{bmatrix}. \tag{21.3}$$

---

[1] See page 340 of [58].

Since we have the relations $\boldsymbol{p}_i(0)=\boldsymbol{r}_{i-1}$, $\boldsymbol{p}_i(1)=\boldsymbol{r}_{i+1}$, $\dot{\boldsymbol{p}}_i(0)=h(\boldsymbol{r}_i-\boldsymbol{r}_{i-1})$, $\dot{\boldsymbol{p}}_i(1)=k(\boldsymbol{r}_{i+1}-\boldsymbol{r}_i)$, the following equation is obtained:

$$\begin{bmatrix} \boldsymbol{r}_{i-1} \\ \boldsymbol{r}_{i+1} \\ h(\boldsymbol{r}_i-\boldsymbol{r}_{i-1}) \\ k(\boldsymbol{r}_{i+1}-\boldsymbol{r}_i) \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 1 & 1 \\ 0 & 1 & 0 \\ 2 & 1 & 0 \end{bmatrix} \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \\ \boldsymbol{c} \end{bmatrix}. \tag{21.4}$$

Converting the first matrix on the right-hand side into a square matrix gives:

$$\begin{bmatrix} \boldsymbol{r}_{i-1} \\ \boldsymbol{r}_{i+1} \\ h(\boldsymbol{r}_i-\boldsymbol{r}_{i-1}) \\ k(\boldsymbol{r}_{i+1}-\boldsymbol{r}_i) \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 \\ 2 & 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \\ \boldsymbol{c} \\ \boldsymbol{0} \end{bmatrix}. \tag{21.5}$$

This implies:

$$\begin{aligned} \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \\ \boldsymbol{c} \\ \boldsymbol{0} \end{bmatrix} &= \begin{bmatrix} 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 \\ 2 & 1 & 0 & 1 \end{bmatrix}^{-1} \begin{bmatrix} \boldsymbol{r}_{i-1} \\ \boldsymbol{r}_{i+1} \\ h(\boldsymbol{r}_i-\boldsymbol{r}_{i-1}) \\ k(\boldsymbol{r}_{i+1}-\boldsymbol{r}_i) \end{bmatrix} \\ &= \begin{bmatrix} 0 & 0 & -1/2 & 1/2 \\ -1 & 1 & 1/2 & -1/2 \\ 0 & 1 & -1/2 & -1/2 \\ 1 & -1 & 1/2 & 1/2 \end{bmatrix} \begin{bmatrix} \boldsymbol{r}_{i-1} \\ \boldsymbol{r}_{i+1} \\ h(\boldsymbol{r}_i-\boldsymbol{r}_{i-1}) \\ k(\boldsymbol{r}_{i+1}-\boldsymbol{r}_i) \end{bmatrix} \\ &= \begin{bmatrix} \frac{h}{2}\boldsymbol{r}_{i-1} - \frac{1}{2}(h+k)\boldsymbol{r}_i + \frac{k}{2}\boldsymbol{r}_{i+1} \\ -(1+\frac{h}{2})\boldsymbol{r}_{i-1} + \frac{1}{2}(h+k)\boldsymbol{r}_i + (1-\frac{k}{2})\boldsymbol{r}_{i+1} \\ \frac{h}{2}\boldsymbol{r}_{i-1} + \frac{1}{2}(k-h)\boldsymbol{r}_i + (1-\frac{k}{2})\boldsymbol{r}_{i+1} \\ (1-\frac{h}{2})\boldsymbol{r}_{i-1} + \frac{1}{2}(h-k)\boldsymbol{r}_i - (1-\frac{k}{2})\boldsymbol{r}_{i+1} \end{bmatrix}. \end{aligned} \tag{21.6}$$

Equating the 4-th rows of the matrices on both sides gives:

$$(1-\frac{h}{2})\boldsymbol{r}_{i-1} + \frac{1}{2}(h-k)\boldsymbol{r}_i - (1-\frac{k}{2})\boldsymbol{r}_{i+1} = \boldsymbol{0}, \tag{21.7}$$

which yields:

$$h=k=2. \tag{21.8}$$

Therefore:

$$\begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \\ \boldsymbol{c} \end{bmatrix} = \begin{bmatrix} \boldsymbol{r}_{i-1} - 2\boldsymbol{r}_i + \boldsymbol{r}_{i+1} \\ 2\boldsymbol{r}_i - 2\boldsymbol{r}_{i-1} \\ \boldsymbol{r}_{i-1} \end{bmatrix}. \tag{21.9}$$

Thus, the parabola function $\boldsymbol{p}_i(t)$ becomes:

$$\boldsymbol{p}_i(t) = [t^2 \ t \ 1] \begin{bmatrix} \boldsymbol{a} \\ \boldsymbol{b} \\ \boldsymbol{c} \end{bmatrix}$$

$$
\begin{aligned}
&= [t^2\ t\ 1] \begin{bmatrix} \boldsymbol{r}_{i-1} - 2\boldsymbol{r}_i + \boldsymbol{r}_{i+1} \\ 2\boldsymbol{r}_i - 2\boldsymbol{r}_{i-1} \\ \boldsymbol{r}_{i-1} \end{bmatrix} \\
&= [t^2\ t\ 1] \begin{bmatrix} 1 & -2 & 1 \\ -2 & 2 & 0 \\ 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} \boldsymbol{r}_{i-1} \\ \boldsymbol{r}_i \\ \boldsymbol{r}_{i+1} \end{bmatrix} \\
&= [(1-t)^2\ 2t(1-t)\ t^2] \begin{bmatrix} \boldsymbol{r}_{i-1} \\ \boldsymbol{r}_i \\ \boldsymbol{r}_{i+1} \end{bmatrix} \\
&\equiv [B_{0,2}(t)\ B_{1,2}(t)\ B_{2,2}(t)] \begin{bmatrix} \boldsymbol{r}_{i-1} \\ \boldsymbol{r}_i \\ \boldsymbol{r}_{i+1} \end{bmatrix}, (i=2,4,\ldots,2n-2),
\end{aligned}
\tag{21.10}
$$

where $B_{0,2}(t), B_{1,2}(t), B_{2,2}(t)$ are Bernstein polynomials of degree 2. It is clear that $p_i(t)$ is a quadratic Bézier curve segment corresponding to the sequence of vertices r_{i-1}, r_i, r_{i+1}. It is easy to confirm that the following relations hold in this case (see Fig. 21.4):

$$
\boldsymbol{p}_i(1/2) = \frac{\boldsymbol{r}_{i-1} + 2\boldsymbol{r}_i + \boldsymbol{r}_{i+1}}{4}, \quad \dot{\boldsymbol{p}}_i(1/2) = \boldsymbol{r}_{i+1} - \boldsymbol{r}_{i-1}. \tag{21.11}
$$

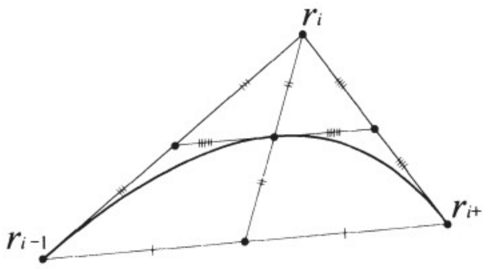

Figure 21.4: Relation between Chaikin's curve and polygon.

Let us now convert this into an expression in terms of the initially given sequence of vertices r_{i-2}, r_i, r_{i+2} rather than r_{i-1}, r_i, r_{i+1}. Since we have the relations:

$$
\begin{aligned}
\boldsymbol{r}_{i-1} &= \frac{\boldsymbol{r}_{i-2} + \boldsymbol{r}_i}{2}, \\
\boldsymbol{r}_{i+1} &= \frac{\boldsymbol{r}_i + \boldsymbol{r}_{i+2}}{2},
\end{aligned}
$$

the curve becomes:

$$
\boldsymbol{p}_i(t) = [(1-t)^2\ 2t(1-t)\ t^2] \begin{bmatrix} \boldsymbol{r}_{i-1} \\ \boldsymbol{r}_i \\ \boldsymbol{r}_{i+1} \end{bmatrix}
$$

$$= [(1-t)^2 \; 2t(1-t) \; t^2] \begin{bmatrix} 1/2 & 1/2 & 0 \\ 0 & 1 & 0 \\ 0 & 1/2 & 1/2 \end{bmatrix} \begin{bmatrix} \boldsymbol{r}_{i-2} \\ \boldsymbol{r}_i \\ \boldsymbol{r}_{i+2} \end{bmatrix}$$

$$= [\frac{1}{2}(1-t)^2 \quad -t^2+t+\frac{1}{2} \quad \frac{1}{2}t^2] \begin{bmatrix} \boldsymbol{r}_{i-2} \\ \boldsymbol{r}_i \\ \boldsymbol{r}_{i+2} \end{bmatrix}$$

$$\equiv [N_{0,3}(t) \; N_{1,3}(t) \; N_{2,3}(t)] \begin{bmatrix} \boldsymbol{r}_{i-2} \\ \boldsymbol{r}_i \\ \boldsymbol{r}_{i+2} \end{bmatrix}, (i=2,4,\ldots,2n-2).$$

If we let $i/2$ be a new subscript and call this i instead, then

$$\boldsymbol{p}_i(t) = [N_{0,3}(t) \; N_{1,3}(t) \; N_{2,3}(t)] \begin{bmatrix} \boldsymbol{q}_{i-1} \\ \boldsymbol{q}_i \\ \boldsymbol{q}_{i+1} \end{bmatrix}, (i=1,2,\ldots,n-1). \qquad (21.12)$$

This means that the function expresses a uniform B-spline curve of order 3 with respect to polygon $q_0q_1q_2\ldots q_{n-1}q_n$.

21.2 Homogenization of Chaikin's Algorithm

We shall homogenize the Chaikin's algorithm. Suppose a sequence of vectors $\boldsymbol{Q}_0, \boldsymbol{Q}_1, \ldots, \boldsymbol{Q}_n$ is given in homogeneous coordinate vectors $[w_i \; X_i \; Y_i]$, and in vector space $\mathbf{R}^3$ we shall perform exactly the same operations as we did in the preceding section.

For $r_0, r_1, \ldots, r_{2n}$ in the preceding section we use capital bold letters $\boldsymbol{R}_0, \boldsymbol{R}_1, \ldots, \boldsymbol{R}_{2n}$ this time (see Fig. 21.5(a)). By using an operation corresponding to eq.(21.1) we get a new sequence of vectors.

This subdivision generates the following homogeneous Bézier curve of degree 2, which is equivalent to a rational quadratic Bézier curve:

$$\overline{\boldsymbol{P}_i(t)} = \overline{[B_{0,2}(t) \; B_{1,2}(t) \; B_{2,2}(t)] \begin{bmatrix} \boldsymbol{R}_{i-1} \\ \boldsymbol{R}_i \\ \boldsymbol{R}_{i+1} \end{bmatrix}}, \quad (i=2,4,\ldots,2n-2), \qquad (21.13)$$

where $\boldsymbol{R}_i = [w_i \; X_i \; Y_i]$.

Or, the curve form is also represented as below (see Fig. 21.5(b)):

$$\overline{\boldsymbol{P}_i(t)} = \overline{[N_{0,3}(t) \; N_{1,3}(t) \; N_{2,3}(t)] \begin{bmatrix} \boldsymbol{Q}_{i-1} \\ \boldsymbol{Q}_i \\ \boldsymbol{Q}_{i+1} \end{bmatrix}}, \quad (i=1,2,\ldots,n-1). \qquad (21.14)$$

Eq.(21.14) is the homogeneous representation of a rational B-spline curve of order 3 (degree 2).

Geometry of Riemann Spaces

The fact that the geometry of the space in which we live is Euclidean is a very basic daily experience. This may explain why it took so long before it was realised that this may actually not be correct, and that the question of the geometry of the space around us is a matter of empirical assessment. Early in the 19th century Gauss studied the geometry of curved surfaces, and showed that all references to a flat embedding space could be eliminated. In the same way Riemann formulated in 1854 the geometry of 3D spaces. He found that Euclidean geometry is merely one possibility out of many. Riemann's method could be generalized to spaces of arbitrary dimension. The geometry of these curved Riemann spaces is wholly described within the space itself, by the use of co-ordinates and the metric tensor. No embedding is required. These geometrical concepts gradually spread beyond the mathematical incrowd, and in the last quarter of the 19th century the idea that a fourth (spatial) dimension might exist had mesmerized the public's imagination, perhaps even more so than black holes did a century later. One of the products of that period was Abbott's famous Flatland.[1] The flatland analogy is nowadays a standard technique of teachers to explain some of the intricacies of curved spaces.

The theoretical framework of Riemann spaces is also the starting point for the mathematical formulation of GR. In this chapter we discuss the tools that any student should master in order to be able to deal with GR beyond the level of handwaving. In doing so we have deliberately chosen to stay close to intuition as that outweighs the merits of rigour, certainly on first acquaintance.

2.1 Definition

A Riemann space has the following properties:

---

[1] Abbott, E.A.: 1884, *Flatland: A Romance of many Dimensions, by a Square*, Seeley & Co. (London).

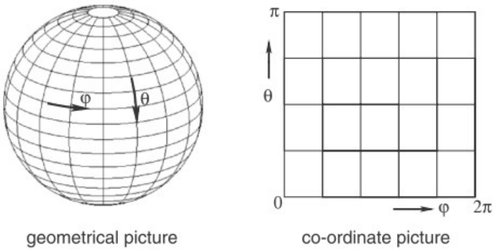

Fig. 2.1. A geometrical picture and the corresponding co-ordinate picture of the space defined by (2.2). Co-ordinate pictures will be frequently used.

1. Any point can be identified by a set of co-ordinates $\{x^\mu\}$; the number of independent x^μ is called the dimension.
2. It is possible to define continuously differentiable functions of $\{x^\mu\}$, in particular one-to-one co-ordinate transformations $\{x^\mu\} \leftrightarrow \{\overline{x}^\nu\}$.
3. There is a metric that specifies the distance $\mathrm{d}s^2$ between two nearby points x^μ and $x^\mu + \mathrm{d}x^\mu$:

$$\mathrm{d}s^2 = g_{\alpha\beta}\,\mathrm{d}x^\alpha \mathrm{d}x^\beta \quad ; \qquad g_{\alpha\beta} = g_{\beta\alpha} \; . \tag{2.1}$$

An antisymmetric part of $g_{\alpha\beta}$ does not contribute to $\mathrm{d}s^2$. Example: a spherical surface with radius 1 and co-ordinates θ, φ:

$$\mathrm{d}s^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2 \; . \tag{2.2}$$

Notation: $\mathrm{d}\theta^2 \equiv (\mathrm{d}\theta)^2$, $\mathrm{d}\varphi^2 \equiv (\mathrm{d}\varphi)^2$, but $\mathrm{d}s^2 = (\mathrm{d}s)^2$ only if $\mathrm{d}s^2 > 0$ as in (2.2). But the metric is in general not positive definite! In this simple case the geometrical structure may be visualised through embedding in an Euclidean space of one higher dimension, but for Riemann spaces of higher dimension this is no longer possible. Moreover, a Riemann space of dimension D cannot always be embedded in a flat space of dimension $D+1$. It is often useful to draw a *co-ordinate picture* of a suitably chosen subspace, even though it contains no information on the geometry, see Fig. 2.1.

An important point is that the metric determines the local structure of the space, but reveals nothing about its global (topological) structure. A plane, a cone and a cylinder all have the same metric $\mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}y^2$, but entirely different global structures.

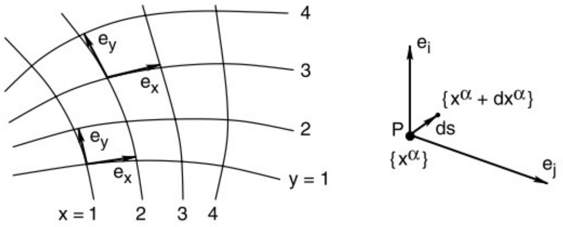

Fig. 2.2. Co-ordinate lines and base vectors spanning the tangent space. The choice of the co-ordinates is entirely free, and in practice dictated by the question which co-ordinates are the most expedient to use.

2.2 The tangent space

In each point we construct a set of base vectors tangent to the co-ordinate lines, as in Fig. 2.2. The arrow points towards increasing x^i. The base vectors span the flat tangent space, which has the same dimension as Riemann space. This construction evidently requires the existence of a flat embedding space, but that can be avoided as follows. Consider the curves $\{x^\alpha(p)\}$ through a point P in Riemann space (p = curve parameter), and construct $A^\sigma = [\mathrm{d}x^\sigma/\mathrm{d}p]_P$. These vectors A^σ span the abstract tangent space of P, which exists independent of any embedding. Usually, however, the abstract tangent space may be identified with the tangent space constructed in Fig. 2.2. For our discussion there is no real advantage in making the distinction and we shall work with the intuitive picture of Fig. 2.2.

We may use any metric we like in the tangent space, but there exists a preferred metric. Consider an infinitesimal section of Riemann space. This section is flat and virtually coincides with the tangent space. To an infinitesimal vector $\mathrm{d}\boldsymbol{s} = \mathrm{d}x^\alpha \boldsymbol{e}_\alpha$ *in the tangent space* we may therefore assign the length of the line element $\mathrm{d}s$ *in Riemann space*, i.e. we require $\mathrm{d}\boldsymbol{s} \cdot \mathrm{d}\boldsymbol{s} = \mathrm{d}s^2$:

$$\begin{aligned} \mathrm{d}\boldsymbol{s} \cdot \mathrm{d}\boldsymbol{s} \;&=\; (\mathrm{d}x^\alpha \boldsymbol{e}_\alpha) \cdot (\mathrm{d}x^\beta \boldsymbol{e}_\beta) \;=\; \boldsymbol{e}_\alpha \cdot \boldsymbol{e}_\beta \; \mathrm{d}x^\alpha \mathrm{d}x^\beta \\ &=\; g_{\alpha\beta} \; \mathrm{d}x^\alpha \mathrm{d}x^\beta \ , \end{aligned} \tag{2.3}$$

and it follows that

$$g_{\alpha\beta} \;\equiv\; \boldsymbol{e}_\alpha \cdot \boldsymbol{e}_\beta \ . \tag{2.4}$$

Here $\cdot$ represents the vector inner product. This may be the usual inner product, for example when we deal with 2D surfaces embedded in a flat R_3. But in case of the Minkowski spacetime of SR, and in GR, the inner product is not positive definite, and we may have that $\boldsymbol{A}\cdot\boldsymbol{A}<0$ (for spacelike vectors). By taking $\mathrm{d}x^\alpha = 1$ in (2.3) and all other $\mathrm{d}x^\beta = 0$ we see that $\boldsymbol{e}_\alpha\cdot\boldsymbol{e}_\alpha = \mathrm{d}\boldsymbol{s}\cdot\mathrm{d}\boldsymbol{s}$ (no summation). It follows that the 'length' of $\boldsymbol{e}_\alpha$ corresponds to a jump $\Delta x^\alpha = 1$, at constant value of the other co-ordinates. Due to the curvature this is of course only approximately correct. These base vectors are called a co-ordinate basis because they are defined entirely by the co-ordinates and the metric. The length of the base vectors depends on the choice of the co-ordinates, and is in general a function of position. Consider for example polar co-ordinates in a plane, Fig. 2.3. The length of $\boldsymbol{e}_\mathrm{r}$ is constant, while $|\boldsymbol{e}_\varphi| \propto r$:

$$\mathrm{d}s^2 \;=\; \underset{\substack{\uparrow \\ \boldsymbol{e}_\mathrm{r}\cdot\boldsymbol{e}_\mathrm{r}}}{1}\cdot\mathrm{d}r^2 \;+\; \underset{\substack{\uparrow \\ \boldsymbol{e}_\varphi\cdot\boldsymbol{e}_\varphi}}{r^2}\mathrm{d}\varphi^2\ . \tag{2.5}$$

Now that we have defined the basis we may construct finite vectors $\boldsymbol{A} = A^\alpha\boldsymbol{e}_\alpha$ in the tangent space through the usual parallelogram construction. These so called contravariant components A^α are the components of $\boldsymbol{A}$ along the basis.

The next step is to define another (covariant) representation A_α of $\boldsymbol{A}$ by demanding that $\boldsymbol{A}\cdot\boldsymbol{A} = A_\alpha A^\alpha$, for every $\boldsymbol{A}$:

$$\boldsymbol{A}\cdot\boldsymbol{A} \;=\; (A^\alpha\boldsymbol{e}_\alpha)\cdot(A^\beta\boldsymbol{e}_\beta) \;=\; g_{\alpha\beta}\,A^\beta A^\alpha \;\equiv\; A_\alpha A^\alpha\ , \tag{2.6}$$

which leads to:

$$A_\alpha = g_{\alpha\beta}A^\beta\ . \tag{2.7}$$

In a more advanced treatment a distinction is made between tensors as geometrical objects, their contravariant representation located in an abstract tangent space, and the dual tangent space, in which the covariant representations reside. In the current, more primitive context the following interpretation suggests itself. Since $A_\gamma = g_{\gamma\beta}A^\beta = \boldsymbol{e}_\gamma\cdot\boldsymbol{e}_\beta A^\beta = (A^\beta\boldsymbol{e}_\beta)\cdot\boldsymbol{e}_\gamma = \boldsymbol{A}\cdot\boldsymbol{e}_\gamma$, it follows that A_γ is the projection of $\boldsymbol{A}$ on $\boldsymbol{e}_\gamma$. Hence, the contravariant components A^β are the components of $\boldsymbol{A}$ along the base vectors $\boldsymbol{e}_\beta$ (parallelogram construction), while the covariant component A_α is the projection of $\boldsymbol{A}$ on the base vector $\boldsymbol{e}_\alpha$, Fig. 2.3, right:

$$\text{contravariant }(A^\beta):\ \ \boldsymbol{A}\ = A^\beta\boldsymbol{e}_\beta\ , \tag{2.8}$$

$$\text{covariant }\ (A_\alpha):\ \ A_\alpha = \boldsymbol{A}\cdot\boldsymbol{e}_\alpha\ . \tag{2.9}$$

Finally, the concept of *index raising and lowering.* We can lower an index with the help of (2.7). The inverse operation of raising is defined as:

$$A^\gamma \;=\; g^{\gamma\alpha}A_\alpha\ . \tag{2.10}$$

The meaning of $g^{\gamma\alpha}$ can be gleaned from:

$$A^\gamma \;=\; g^{\gamma\alpha}A_\alpha \;=\; g^{\gamma\alpha}g_{\alpha\nu}A^\nu\ , \tag{2.11}$$

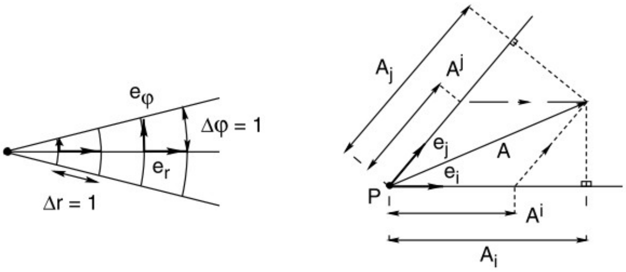

Fig. 2.3. Left: polar co-ordinates and the base vectors $\boldsymbol{e}_{\mathrm{r}}$ and $\boldsymbol{e}_{\varphi}$. Right: interpretation of the contravariant and covariant representation of a vector $\boldsymbol{A}$.

so that $g^{\gamma\alpha}g_{\alpha\nu} = \delta^{\gamma}_{\nu}$, i.e. $\{g^{\gamma\alpha}\}$ is the inverse of $\{g_{\alpha\nu}\}$. In summary:

$$\left.\begin{array}{lrcl} \text{index lowering :} & A_\alpha &=& g_{\alpha\beta}A^\beta \ , \\ \text{index raising :} & A^\gamma &=& g^{\gamma\nu}A_\nu \ , \\ & \{g^{\gamma\nu}\} &=& \{g_{\alpha\beta}\}^{-1} \ . \end{array}\right\} \tag{2.12}$$

We have silently adopted the *summation convention*: if an index occurs twice, once as a lower and once as an upper index, summation over that index is implied. Note that the rules for index raising and lowering are always valid, and have nothing to do with the question whether one is dealing with a tensor or not. The tensor concept is related to behaviour under co-ordinate transformations, which was not an issue above, and to which we turn our attention now.

2.3 Tensors

We are now in a position to do linear algebra in the tangent space, but we leave that aside and study the effect of co-ordinate transformations. Consider two overlapping sets of co-ordinates $\{x^\mu\}$ and $\{x^{\mu'}\}$. The notation is sloppy – it would be more appropriate to write $\{\overline{x}^\mu\}$ instead of $\{x^{\mu'}\}$, but $\{x^{\mu'}\}$ is much more expedient if used with care. A displacement $\delta x^{\mu'}$ is related to a displacement δx^ν through:

$$\delta x^{\mu'} = \frac{\partial x^{\mu'}}{\partial x^\nu}\,\delta x^\nu \equiv x^{\mu'}_{\ ,\nu}\,\delta x^\nu \ . \tag{2.13}$$

Notation:

$$X_{,\nu} \equiv \frac{\partial X}{\partial x^{\nu}} \; ; \qquad X_{,\nu\rho} \equiv \frac{\partial^2 X}{\partial x^{\nu} \partial x^{\rho}} \; , \quad \text{etc.} \tag{2.14}$$

where X can be anything (A_{α}, $g^{\alpha\beta}, ...$). We may freely interchange indices behind the comma: $X_{,\alpha\beta\gamma} = X_{,\alpha\gamma\beta} = X_{,\gamma\alpha\beta}$ etc.

Any set A^{μ} transforming according to (2.13) is called a contravariant tensor of rank 1:

$$A^{\mu'} = x^{\mu'}_{,\nu}\, A^{\nu} \quad \leftrightarrow \quad A^{\nu} \;\; \text{contravariant.} \tag{2.15}$$

Hence δx^{ν} is a contravariant tensor. Tensors of rank 1 are often referred to as vectors, and henceforth we shall use the word vector in this sense only. A function such as the temperature distribution $T(x)$ is called a *scalar*, a tensor of rank zero. Its value in a point is independent of the co-ordinate system, i.e. invariant for co-ordinate transformations: $T'(x') = T(x)$, where T' is the new function prescription. The derivative of a scalar Q,

$$B_{\mu} = \frac{\partial Q}{\partial x^{\mu}} \equiv Q_{,\mu} \tag{2.16}$$

transforms like $B_{\mu'} = Q'_{,\mu'} = Q_{,\nu}\, x^{\nu}_{,\mu'} = x^{\nu}_{,\mu'}\, B_{\nu}$. Every B_{ν} that transforms in this way is called a covariant vector or tensor of rank 1:

$$B_{\mu'} = x^{\nu}_{,\mu'}\, B_{\nu} \quad \leftrightarrow \quad B_{\nu} \;\; \text{covariant.} \tag{2.17}$$

From two covariant vectors we can form $T_{\mu\nu} = A_{\mu} B_{\nu}$, a covariant tensor of rank 2. More general tensors can be constructed through summation, $T_{\mu\nu} = A_{\mu} B_{\nu} + C_{\mu} D_{\nu} + ...$ This process may be continued: $T_{\alpha\beta} C^{\gamma}$ and $A_{\mu} C^{\nu} B_{\rho}$ are mixed tensors of rank 3 (provided T, A, B and C are tensors themselves). The indices of tensors of higher rank transform according to (2.15) resp. (2.17), for example:

$$T^{\alpha'}{}_{\beta'\gamma'}{}^{\delta'} = x^{\alpha'}_{,\mu}\, x^{\nu}_{,\beta'}\, x^{\sigma}_{,\gamma'}\, x^{\delta'}_{,\tau}\, T^{\mu}{}_{\nu\sigma}{}^{\tau} \; . \tag{2.18}$$

There is no other choice because (2.18) must hold for the special tensor $T^{\alpha}{}_{\beta\gamma}{}^{\delta} = P^{\alpha} Q_{\beta} R_{\gamma} S^{\delta}$, and the transformation rules for vectors have already been fixed! Note that we get a glimpse here of how the Lorentz transformations of SR will be generalised in GR: relation (1.7) of SR will be replaced by (2.15). This transformation is still locally linear, but different in each point of Riemann space as the $\{x^{\mu'}{}_{,\nu}\}$ are functions of position. The single global Lorentz transformation will be replaced by a mesh of local Lorentz transformations.

The horizontal position of the indices is important: $T^{\mu}{}_{\nu}$ is different from $T_{\nu}{}^{\mu}$! The summation over double indices is called *contraction*. It lowers the rank by two. For example $T^{\mu}{}_{\mu}$, $T^{\alpha}{}_{\beta\alpha}{}^{\gamma}$, $P_{\alpha\beta}\, Q^{\beta\gamma}$, $T^{\alpha}{}_{\beta\alpha}{}^{\beta}$ (double contraction). Double indices are *dummies*: $T^{\alpha}{}_{\alpha} = T^{\mu}{}_{\mu}$, dummies may occur only twice, once as an upper and once as a lower index. If you encounter expressions like $C^{\mu\mu}$, $P^{\alpha\beta}Q^{\alpha}_{\;\gamma}$ or $P_{\alpha\beta}\,Q^{\alpha\gamma}\,R_{\delta\alpha}$ then you have made a mistake somewhere!

Index raising and lowering, finally, is done by factors $g_{\alpha\beta}$ or $g^{\mu\nu}$ for each upper/lower index, e.g.:

$$\left.\begin{aligned} T^{\mu\nu} &= g^{\mu\alpha}\,T_{\alpha}^{\ \ \nu}\ , \\ T^{\alpha}{}_{\beta}{}^{\gamma\delta} &= g^{\alpha\mu}\,g_{\beta\nu}\,g^{\delta\sigma}\;T_{\mu}{}^{\nu\gamma}{}_{\sigma}\ , \quad \text{etc.} \end{aligned}\right\} \tag{2.19}$$

Again, like in (2.18), we have hardly any other choice here, because (2.19) must hold for the special tensors $T^{\mu\nu} = P^{\mu}Q^{\nu}$ and $T^{\alpha}{}_{\beta}{}^{\gamma\delta} = P^{\alpha}Q_{\beta}R^{\gamma}S^{\delta}$, and the rules for index raising and lowering for vectors have already been fixed. We are now in a position that we can raise and lower indices at liberty. We emphasise once more that the rules (2.12) and (2.19) for index gymnastics are generally valid, also for non-tensors. For example, $Q_{\mu\nu} = A_{\mu,\nu}$ is not a tensor (exercise 2.4), and yet $Q^{\mu}{}_{\nu} = g^{\mu\alpha}Q_{\alpha\nu}$.

Exercise 2.1: The unit tensor is defined as $\delta^{\alpha}{}_{\beta} = 1$ for $\alpha = \beta$, otherwise 0. Prove that $\delta^{\alpha}{}_{\beta}$ is a tensor, and that $\delta^{\alpha}{}_{\beta} = \delta_{\beta}{}^{\alpha}$, so that we may write δ^{α}_{β} without risk of confusion. Show that $\delta_{\alpha\beta} = g_{\alpha\beta}$. Is $\eta_{\alpha\beta}$ a tensor? And $g_{\alpha\beta}$? One could define $\delta_{\alpha\beta} = 1$ for $\alpha = \beta$, and 0 otherwise, but then $\delta_{\alpha\beta}$ is not a tensor.

Hint: $\delta^{\alpha'}{}_{\beta'}$ must be equal to $x^{\alpha'}{}_{,\nu}\,x^{\mu}{}_{,\beta'}\,\delta^{\nu}{}_{\mu}$, or $\delta^{\alpha'}{}_{\beta'} = x^{\alpha'}{}_{,\nu}\,x^{\nu}{}_{,\beta'} = x^{\alpha'}_{\ ,\beta'}$ (chain rule) $= 1$ for $\alpha' = \beta'$ otherwise 0. Hence $\delta^{\alpha}{}_{\beta}$ is tensor. And $\delta_{\beta}{}^{\alpha} = g_{\beta\mu}\,g^{\alpha\nu}\delta^{\mu}{}_{\nu} = g_{\beta\mu}\,g^{\alpha\mu} = g^{\alpha\mu}g_{\mu\beta} = 1$ for $\alpha = \beta$, otherwise 0, i.e. identical to $\delta^{\alpha}{}_{\beta}$; $\delta_{\alpha\beta} = g_{\alpha\nu}\delta^{\nu}_{\beta} = g_{\alpha\beta}$; $\eta_{\alpha\beta}$ is a tensor in SR only, i.e. under Lorentz transformations; $g_{\alpha\beta}$ tensor: use (2.1), require that $\mathrm{d}s^2$ is also tensor in GR (invariant scalar), and $\mathrm{d}x^{\alpha}$ is tensor, then exercise 2.3. Other definition $\delta_{\alpha\beta}$: $\delta_{\alpha'\beta'} = x^{\nu}{}_{,\alpha'}\,x^{\mu}{}_{,\beta'}\,\delta_{\nu\mu}$? No, because the chain rule can no longer be used.

Exercise 2.2: If $T^{\alpha\beta}$ and $P^{\mu}{}_{\nu}$ are tensors then $P^{\mu}{}_{\mu}$ is a scalar, but $T^{\alpha\alpha}$ is not. The inner product $A_{\nu}B^{\nu}$ of two vectors is a scalar.

Hint: $P^{\mu'}{}_{\mu'} = x^{\mu'}{}_{,\alpha}\,x^{\beta}{}_{,\mu'}\,P^{\alpha}{}_{\beta}$, then the chain rule.

Exercise 2.3: Quotient theorem: If $A^{\lambda}P_{\lambda\mu\nu}$ is a tensor for arbitrary vector A^{λ}, then $P_{\lambda\mu\nu}$ is a tensor; $\mu\nu$ may be replaced with an arbitrary sequence of upper / lower indices.

Hint: $A^\lambda P_{\lambda\mu\nu}$ is a tensor, i.e. $A^{\lambda'} P_{\lambda'\mu'\nu'} = x^\alpha_{,\mu'}\, x^\beta_{,\nu'}\, A^\sigma P_{\sigma\alpha\beta}$ (λ' and σ are dummies!), then substitute $A^\sigma = x^\sigma_{,\lambda'}\, A^{\lambda'}$, etc.

Exercise 2.4: The derivative $A_{\mu,\nu}$ of a covariant vector A_μ is not a tensor, as it transforms according to:

$$A_{\mu',\nu'} \;=\; A_{\alpha,\beta}\, x^\alpha_{,\mu'}\, x^\beta_{,\nu'} \;+\; A_\alpha\, x^\alpha_{,\mu'\nu'}\;. \tag{2.20}$$

The problem is in the second term of (2.20). In SR only linear (Lorentz) transformations are allowed. In that case the second term is zero and $A_{\mu,\nu}$ is a tensor.

Hint: Start from $A_{\mu',\nu'} = (x^\alpha_{,\mu'}\, A_\alpha)_{,\nu'}$, then use the product rule.

Exercise 2.5: Prove $T_\alpha{}^\nu A_\nu \;=\; T_{\alpha\nu}A^\nu\,;\; T_\alpha{}^\alpha \;=\; T^\alpha{}_\alpha\,;\; g^\nu{}_\nu \;=\; 4\,;\;\; \eta^\nu{}_\nu \;=\; g^{00} - g^{11} - g^{22} - g^{33}$.

Hint: We know that $g^\nu{}_\nu = g^{\nu\alpha}g_{\alpha\nu} = \delta^\nu_\nu = 4$. The following may be illuminating: the scalar $g^\nu{}_\nu$ is invariant, compute in a freely falling frame: $g^\nu{}_\nu = \eta^\nu{}_\nu$, SR holds in that frame: $\eta^\nu{}_\nu = \eta^{\nu\alpha}\eta_{\alpha\nu} = 4$. But in GR: $\eta^\nu{}_\nu = g^{\nu\alpha}\eta_{\alpha\nu} =$ etc.

2.4 Parallel transport and Christoffel symbols

Consider a particle at position P in Riemann space, Fig. 2.4. The vectors associated with it (velocity, spin, ..) reside in the tangent space of P. At some later time the particle has moved to position Q, but the tangent space of Q does not coincide with that of P. To be able to do dynamics, we must develop a way to compare vectors in the different tangent spaces along the worldline of the particle. In other words, we need something against which to gauge the concept of ‘change’. This is what parallel transport in GR is about.

Fig. 2.4 shows the curve $x^\sigma(p)$ in Riemann space. The vector $\boldsymbol{A}$ is always in the tangent space, but the tangent spaces of P, Q, R, .. are disjunct, and comparison of $\boldsymbol{A}(P)$ with $\boldsymbol{A}(Q)$ or $\boldsymbol{A}(R)$ is not possible. To this end we define a *connection* between tangent spaces, that is, a mathematical prescription telling us how a vector $\boldsymbol{A}(P)$ lies in the tangent space of Q if we ‘transport’ it along a given path from P to Q. This can be done in a variety of ways, but much of the mathematical freedom that we have is eliminated by the physical

Fig. 2.4. Conceptual definition of parallel displacement of a vector along a curve $x^\sigma(p)$ in Riemann space: first an ordinary parallel displacement in the flat embedding space (resulting in the dashed arrows) followed by projection on the local tangent space. The process is repeated in infinitesimal steps.

requirement that we recover what we ordinarily do when we transport a vector parallel to itself in a flat space. Imagine the Riemann space embedded in a flat space of higher dimension. We know how to move $\boldsymbol{A}(P)$ around parallel to itself in this embedding space, because it is flat. Having arrived in Q, the result is projected onto the local tangent space. To order $O(\mathrm{d}x^\alpha)$ projection does not change the length of the vector: the projection angle γ is $O(\mathrm{d}x^\alpha)$, but $\cos\gamma = 1$ up to $O(\mathrm{d}x^\alpha)$. This process is now repeated with infinitesimal steps, and generates the coloured vector field $\boldsymbol{A}'$ in Fig. 2.4, starting from $\boldsymbol{A}(P)$. In this way we have generalized the concept of parallel transport to curved spaces, in such a way that it reduces to normal parallel transport for flat spaces. Not surprisingly, it is also the definition that turns out to work in GR. The result of the transport operation depends on the path, see Fig. 2.5. However, when $\boldsymbol{e}$ in Fig. 2.5 is parallel-transported along a small curve on the sphere there is virtually no change, because there is hardly any curvature felt (exercise 2.17).

We now formalise our intuitive approach. The difference $\mathrm{d}\boldsymbol{A} = \boldsymbol{A}(Q) - \boldsymbol{A}(P)$ is not defined, but up to order $O(\mathrm{d}x^\alpha)$ we have that $\mathrm{d}\boldsymbol{A} \simeq \boldsymbol{A}(Q) - \boldsymbol{A}'(Q)$, and this is useful as both vectors lie in the same tangent space. The vector $\mathrm{d}\boldsymbol{A}$ may be interpreted as the intrinsic change of $\boldsymbol{A}$, after correction for the 'irrelevant' change in the orientation of the tangent space:

$$\mathrm{d}\boldsymbol{A} \simeq \boldsymbol{A}(Q) - \boldsymbol{A}'(Q) \tag{2.21}$$

$$= \mathrm{d}(A^\mu \boldsymbol{e}_\mu) = (\mathrm{d}A^\mu)\boldsymbol{e}_\mu + A^\mu(\mathrm{d}\boldsymbol{e}_\mu) \,. \tag{2.22}$$

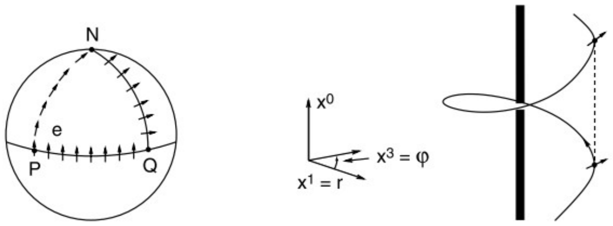

Fig. 2.5. Left: Parallel displacement of the vector $\boldsymbol{e}$ along PNQ and along PQ produces entirely different results. To the right, the geodesic precession of a top in orbit around a central mass, see text.

Here, $\mathrm{d}\boldsymbol{A}$ has been split into two contributions: the change $\mathrm{d}A^\mu \equiv A^\mu(Q) - A^\mu(P)$ of the contravariant components of $\boldsymbol{A}$, and a contribution from the change of the base vectors. On general grounds we anticipate $\mathrm{d}\boldsymbol{e}_\mu$ to be proportional to both $\{\mathrm{d}x^\beta\}$ and $\{\boldsymbol{e}_\alpha\}$:

$$\mathrm{d}\boldsymbol{e}_\mu = \Gamma^\alpha_{\ \mu\beta}\, \mathrm{d}x^\beta\, \boldsymbol{e}_\alpha \ . \tag{2.23}$$

$\Gamma^\alpha_{\ \mu\beta}$ is called the *Christoffel symbol of the second kind*, and as may be expected it is intimately related to the metric tensor:

$$\Gamma^\mu_{\ \nu\sigma} = \tfrac{1}{2} g^{\mu\lambda} \left(g_{\lambda\nu,\sigma} + g_{\lambda\sigma,\nu} - g_{\nu\sigma,\lambda} \right) \equiv g^{\mu\lambda}\, \Gamma_{\lambda\nu\sigma} \ . \tag{2.24}$$

The = sign is proved in § 2.5. The ≡ sign defines the *Christoffel symbol of the first kind*, simply by raising one index with $g^{\mu\lambda}$. According to (2.23) the Christoffel symbols define the connection between the base vectors of the tangent spaces at different positions. As pointed out above, there exist more general connection coefficients than (2.24), but these play no role in GR.

Insert (2.23) in (2.22) and rename the dummy-indices:

$$\mathrm{d}\boldsymbol{A} = \left(\mathrm{d}A^\mu + \Gamma^\mu_{\ \nu\sigma} A^\nu\, \mathrm{d}x^\sigma \right) \boldsymbol{e}_\mu \equiv (\mathrm{D}A^\mu)\, \boldsymbol{e}_\mu \ . \tag{2.25}$$

The right hand side defines the intrisic change $\mathrm{D}A^\mu$, which apparently obeys the following equation:

$$\frac{\mathrm{D}A^\mu}{\mathrm{D}p} = \frac{\mathrm{d}A^\mu}{\mathrm{d}p} + \Gamma^\mu_{\ \nu\sigma} A^\nu \frac{\mathrm{d}x^\sigma}{\mathrm{d}p} \qquad \text{(contravariant);} \tag{2.26}$$

$$\frac{\mathrm{D}A_\mu}{\mathrm{D}p} = \frac{\mathrm{d}A_\mu}{\mathrm{d}p} - \Gamma^\nu_{\ \mu\sigma} A_\nu \frac{\mathrm{d}x^\sigma}{\mathrm{d}p} \qquad \text{(covariant).} \tag{2.27}$$

For the second relation (2.27) see exercise 2.8. We may apply these equations in two ways. For a *given* vector field we may compute $\mathrm{D}A^{\mu}$ or $\mathrm{D}A_{\mu}$ for a displacement $\mathrm{d}p$ along $x^{\sigma}(p)$. On the other hand, one may solve $\mathrm{D}A^{\mu}/\mathrm{D}p = 0$ or $\mathrm{D}A_{\mu}/\mathrm{D}p = 0$ starting from an initial value $A^{\mu}(P)$ or $A_{\mu}(P)$, and construct a vector field along $x^{\sigma}(p)$ for which $\mathrm{d}\boldsymbol{A} = \boldsymbol{A} - \boldsymbol{A}' = 0$. Parallel transport of a vector along $x^{\sigma}(p)$ is therefore described by the differential equation

$$\frac{\mathrm{D}A_{\mu}}{\mathrm{D}p} = 0 \qquad \text{or} \qquad \frac{\mathrm{D}A^{\mu}}{\mathrm{D}p} = 0 \ . \tag{2.28}$$

We mention a few properties of the Christoffel symbols. They are symmetrical in the last two indices:

$$\Gamma^{\mu}{}_{\nu\sigma} = \Gamma^{\mu}{}_{\sigma\nu} \ ; \qquad \Gamma_{\lambda\nu\sigma} = \Gamma_{\lambda\sigma\nu} \ . \tag{2.29}$$

By interchanging the indices in (2.24) we may infer $\Gamma_{\nu\lambda\sigma}$, and on adding that to $\Gamma_{\lambda\nu\sigma}$ one obtains

$$\Gamma_{\lambda\nu\sigma} + \Gamma_{\nu\lambda\sigma} = g_{\lambda\nu,\sigma} \ . \tag{2.30}$$

The Christoffel symbol transforms according to

$$\Gamma^{\mu'}{}_{\nu'\sigma'} = \Gamma^{\rho}{}_{\alpha\beta}\, x^{\mu'}{}_{,\rho}\, x^{\alpha}{}_{,\nu'}\, x^{\beta}{}_{,\sigma'} + x^{\mu'}{}_{,\rho}\, x^{\rho}{}_{,\nu'\sigma'} \ . \tag{2.31}$$

The proof is for diehards (see literature). The first term is what we would expect if the Christoffel symbol were a tensor, but the second term makes that it is actually not a tensor. The concept of parallel transport will be used in § 2.5 to define geodesics.

In SR the velocity and spin vector of a particle on which no forces are exerted are constant. They are transported parallel along the 'straight' orbit of the particle. The idea of GR is that a particle under the influence of gravity moves freely in a *curved* spacetime. A natural generalisation is that velocity and spin vector of the particle can be found by parallel transport along the orbit in spacetime. In this way we are able to understand the geodesic precession of a top. Fig. 2.5 shows a co-ordinate picture, with $x^0 = ct$ on the vertical axis and polar co-ordinates $x^1 = r$ and $x^3 = \varphi$ in the horizontal plane. The worldline of the top orbiting the central object (vertical bar) is a spiral. The spin 4-vector (whose spatial part is directed along the spin axis) is parallel-transported along the worldline. After one revolution the top has returned to same spatial position, but because spacetime is not flat – not visible in a co-ordinate picture – the spin vector has changed its direction. At this point one may wonder how the effect is related to the Thomas precession. We refer to Ch. 8 for a more general treatment, from which both Thomas precession and geodesic precession emerge in the appropriate limit.

Exercise 2.6: The length of a vector remains constant under parallel transport:

$$\mathrm{d}\,A^\nu A_\nu \;=\; \mathrm{d}\,(g_{\mu\nu}A^\mu A^\nu) = 0 \ .$$

Hint: First attempt: d = D = intrinsic change: $\mathrm{D}A^\nu A_\nu = (\mathrm{D}A^\nu)A_\nu + A^\nu(\mathrm{D}A_\nu) = 0$, because $\mathrm{D}A^\nu = (\mathrm{D}A^\nu/\mathrm{D}p)\,\mathrm{d}p = 0$, etc. But (2.27) must still be proven, and for that we need $\mathrm{d}\,A^\nu A_\nu = 0$. Second attempt: d = total change: $\mathrm{d}\,g_{\mu\nu}A^\mu A^\nu = 2A_\nu\mathrm{d}A^\nu + A^\mu A^\nu\, g_{\mu\nu,\sigma}\,\mathrm{d}x^\sigma$; (2.26): $\mathrm{d}A^\nu = -\Gamma^\nu_{\ \mu\sigma}\,A^\mu\mathrm{d}x^\sigma$; exercise 2.5 and (2.30): $2A_\nu\mathrm{d}A^\nu = -2\Gamma_{\nu\mu\sigma}\,A^\nu A^\mu\mathrm{d}x^\sigma = -g_{\nu\mu,\sigma}\,A^\nu A^\mu\mathrm{d}x^\sigma$.

Exercise 2.7: Prove that $\mathrm{d}\,A^\nu B_\nu \;=\; 0$ under parallel transport.

Hint: The length of $A^\nu + B^\nu$ is constant.

Exercise 2.8: For parallel transport of a covariant vector:

$$\mathrm{d}B_\mu \;=\; \Gamma^\nu_{\ \mu\sigma}\,B_\nu\,\mathrm{d}x^\sigma \ . \tag{2.32}$$

Hint: $0 \;=\; \mathrm{d}\,A^\mu B_\mu \;=\; A^\mu\,\mathrm{d}B_\mu \;+\; B_\mu\,\mathrm{d}A^\mu$, and $\mathrm{d}A^\mu$ is known.

Exercise 2.9: Prove that

$$\Gamma^\mu_{\ \nu\mu} \;=\; g_{,\nu}/2g \;=\; \tfrac{1}{2}\big(\log|g|\big)_{,\nu} \quad ; \qquad g \;=\; \det\{g_{\alpha\beta}\} \ . \tag{2.33}$$

Hint: (2.24): $\Gamma^\mu_{\ \nu\mu} = \frac{1}{2}g^{\lambda\mu}g_{\lambda\mu,\nu}$. For a matrix M we have that $\mathrm{Tr}\,(M^{-1}M_{,\nu}) = (\mathrm{Tr}\,\log M)_{,\nu} = (\log\det M)_{,\nu}$. Take $M = \{g_{\alpha\beta}\}$.

2.5 Geodesics

Intuitively, a geodesic is a line that is 'as straight as possible' on a curved surface. We say that a curve $x^\mu(p)$ is a geodesic when the tangent vector $\mathrm{d}x^\mu/\mathrm{d}p$ remains a tangent vector under parallel transport along $x^\mu(p)$. Therefore $\dot{x}^\mu \equiv \mathrm{d}x^\mu/\mathrm{d}p$ must satisfy (2.28), and we arrive at the geodesic equation:

$$\frac{\mathrm{D}}{\mathrm{D}p}\left(\frac{\mathrm{d}x^\mu}{\mathrm{d}p}\right) \;=\; 0 \quad\rightarrow\quad \ddot{x}^\mu \;+\; \Gamma^\mu_{\ \nu\sigma}\,\dot{x}^\nu\,\dot{x}^\sigma \;=\; 0\ , \tag{2.34}$$

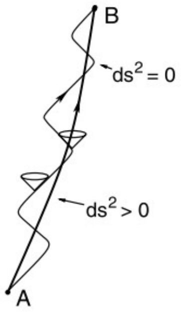

Fig. 2.6. A timelike geodesic connecting events A and B is the curve with the *maximum* possible interval length between A and B, see text.

with $\dot{} = \mathrm{d}/\mathrm{d}p$. For timelike geodesics[2] the parameter p in (2.34) is proportional to the interval length s. Proof: according to exercise 2.6 the length of $\dot{x}^\alpha = \mathrm{d}x^\alpha/\mathrm{d}p$ is constant along $x^\mu(p)$, i.e. $\dot{x}^\alpha \dot{x}_\alpha = g_{\alpha\beta}\, \dot{x}^\alpha\, \dot{x}^\beta \equiv (\mathrm{d}s/\mathrm{d}p)^2$ is constant. For timelike geodesics $\mathrm{d}s^2 > 0$, and we may take the square root to conclude that $\mathrm{d}s = \mathrm{const} \cdot \mathrm{d}p$. Later, when GR is cast into the geometrical framework developed here, this result will be connected to proper time (a physical concept that does not yet exist here): $\mathrm{d}s = c\mathrm{d}\tau$, so that

$$\mathrm{d}p \ \propto\ \mathrm{d}s \ \propto\ \mathrm{d}\tau \qquad \text{for timelike geodesics.} \tag{2.35}$$

This is important as it implies that we may, for timelike geodesics, replace the curve parameter p in (2.34) by the interval length s or the proper time τ.

Intuitively, a geodesic is also the shortest possible route between two points. For a positive definite metric this is indeed the case, but $\mathrm{d}s^2$ can be positive as well as negative in GR. Assuming that the interval $\int \mathrm{d}s = \int \dot{s}\, \mathrm{d}p$ of a timelike geodesic is an extremum (see below), it is easy to see that it should be a maximum: there always exists an arbitrarily nearby worldline that has a smaller $\int \mathrm{d}s$, by letting it jump more or less from light-cone to light-cone, as in Fig. 2.6 (see e.g. Wald (1984) § 9.3). The construction of Fig. 2.6 fails for spacelike geodesics.

---

[2] In an analogy with (1.4) we speak of a timelike (spacelike) worldline or geodesic when $\mathrm{d}s^2 > 0$ ($\mathrm{d}s^2 < 0$). A null worldline or null geodesic has $\mathrm{d}s^2 = 0$. For spacelike and null geodesics p can no longer be interpreted as an interval length.

Eq. (2.34) may also be derived from a variational principle.[3] The simplest is $\delta\int \dot{s}\,\mathrm{d}p = 0$, and this is equivalent to $\delta\int F(\dot{s})\,\mathrm{d}p = 0$ provided F is monotonous, $F' \neq 0$. We choose $\delta\int \dot{s}^2\,\mathrm{d}p = 0$, or

$$\delta\int L\,\mathrm{d}p = 0\ ; \quad L(x^\alpha, \dot{x}^\beta) = (\mathrm{d}s/\mathrm{d}p)^2 = g_{\alpha\beta}\,\dot{x}^\alpha\,\dot{x}^\beta\ . \tag{2.36}$$

The solution is determined by the Euler-Lagrange equations (Appendix C)

$$\frac{\partial L}{\partial x^\lambda} = \frac{\mathrm{d}}{\mathrm{d}p}\left(\frac{\partial L}{\partial \dot{x}^\lambda}\right)\ . \tag{2.37}$$

Now, $\partial L/\partial x^\lambda = g_{\alpha\beta,\lambda}\,\dot{x}^\alpha\dot{x}^\beta$ because only $g_{\alpha\beta}$ depends on $\{x^\mu\}$. By using $\partial\dot{x}^\alpha/\partial\dot{x}^\lambda = \delta^\alpha_\lambda$ one gets $\partial L/\partial\dot{x}^\lambda = 2g_{\alpha\lambda}\,\dot{x}^\alpha$. Substitute this in (2.37):

$$\begin{aligned} g_{\alpha\beta,\lambda}\,\dot{x}^\alpha\,\dot{x}^\beta &= 2(g_{\alpha\lambda}\,\dot{x}^\alpha)^{\cdot} \\ &= 2(g_{\alpha\lambda,\beta}\,\dot{x}^\beta\,\dot{x}^\alpha + g_{\alpha\lambda}\,\ddot{x}^\alpha)\ , \end{aligned}$$

or

$$g_{\alpha\lambda}\,\ddot{x}^\alpha + \tfrac{1}{2}(2g_{\lambda\alpha,\beta} - g_{\alpha\beta,\lambda})\,\dot{x}^\alpha\,\dot{x}^\beta = 0\ . \tag{2.38}$$

Now comes a frequently used trick: renaming of dummy indices: $2g_{\lambda\alpha,\beta}\cdot\dot{x}^\alpha\,\dot{x}^\beta = g_{\lambda\alpha,\beta}\,\dot{x}^\alpha\,\dot{x}^\beta + g_{\lambda\beta,\alpha}\,\dot{x}^\beta\,\dot{x}^\alpha = (g_{\lambda\alpha,\beta} + g_{\lambda\beta,\alpha})\,\dot{x}^\alpha\,\dot{x}^\beta$. Substitution in (2.38) and multiplication with $g^{\mu\lambda}$ gives:

$$\ddot{x}^\mu + \tfrac{1}{2}g^{\mu\lambda}\,(g_{\lambda\alpha,\beta} + g_{\lambda\beta,\alpha} - g_{\alpha\beta,\lambda})\,\dot{x}^\alpha\,\dot{x}^\beta = 0\ . \tag{2.39}$$

This is of the form of (2.34) and the factor multiplying $\dot{x}^\alpha\,\dot{x}^\beta$ must be equal to $\Gamma^\mu_{\ \alpha\beta}$, which proves (2.24). Variational calculus is a very efficient tool for this type of problem. Without much difficulty, it permits us to find the geodesic equation directly from the metric, and from this equation one may just read the Christoffel symbols $\Gamma^\mu_{\ \nu\sigma}$. This is usually a lot faster than calculating them from (2.24), and this method is therefore highly recommended.

The following result is very helpful when analysing the dynamics of a test particle in GR (assuming that its orbit is a geodesic), because it allows us to find *constants of the motion.* From the text below (2.37) we see that $\partial L/\partial x^\lambda$ vanishes if $g_{\alpha\beta,\lambda} = 0$. And then eq. (2.37) says that $\partial L/\partial\dot{x}^\lambda = 2g_{\alpha\lambda}\dot{x}^\alpha$ is constant. In terms of the *4-velocity* $u^\mu = \mathrm{d}x^\mu/\mathrm{d}p$ we have found that the covariant 4-velocity $u_\lambda = g_{\lambda\alpha}u^\alpha$ is constant:

$$g_{\alpha\beta,\lambda} = 0 \quad\rightarrow\quad u_\lambda = g_{\lambda\nu}\,\dot{x}^\nu = \text{constant} \tag{2.40}$$

with $^{\cdot} = \mathrm{d}/\mathrm{d}p$. The fact that u_λ is a constant along a geodesic if the metric is independent of x^λ – doesn't that ring a bell?

---

[3] Here we switch to another definition of geodesics without proving its equivalence with (2.34).

Exercise 2.10: Show that the geodesics of the Lorentz metric ($g_{\alpha\beta} = \eta_{\alpha\beta}$) are straight lines.

Exercise 2.11: Show that the variational problem (2.36) is equivalent to $\delta \int F(L)\, \mathrm{d}p = 0$ if F is monotonous, $F' \neq 0$.

Hint: Write down (2.37) with $L \to F(L)$; use $\partial F(L)/\partial x^\lambda = F'\, \partial L/\partial x^\lambda$, and $(F'\, \partial L/\partial \dot{x}^\lambda)^\cdot = (F')^\cdot\, \partial L/\partial \dot{x}^\lambda + F'(\partial L/\partial \dot{x}^\lambda)^\cdot$. But $(F')^\cdot = F''\mathrm{d}L/\mathrm{d}p = 0$ (L is constant on $x^\mu(p)$ because $\dot{x}^\alpha \dot{x}_\alpha$ is).

2.6 The covariant derivative

For a given vector field A^μ that is not restricted to the curve $x^\sigma(p)$ we can elaborate $\mathrm{d}A^\mu/\mathrm{d}p$ in (2.26) as $\mathrm{d}A^\mu/\mathrm{d}p = A^\mu{}_{,\sigma}\, \dot{x}^\sigma$, because we are able to compute derivatives in other directions than along the curve. This leads to the introduction of the covariant derivative

$$\frac{\mathrm{D}A^\mu}{\mathrm{D}p} = \left(A^\mu{}_{,\sigma} + \Gamma^\mu_{\nu\sigma}\, A^\nu\right) \dot{x}^\sigma \equiv A^\mu{}_{:\sigma}\, u^\sigma \ , \tag{2.41}$$

where $u^\sigma = \dot{x}^\sigma = \mathrm{d}x^\sigma/\mathrm{d}p$ and

$$A^\mu{}_{:\sigma} \equiv A^\mu{}_{,\sigma} + \Gamma^\mu_{\nu\sigma}\, A^\nu \tag{2.42}$$

is the *covariant derivative* of A^μ. It may be regarded as the 'intrinsic derivative', the derivative after correction for the meaningless change in orientation of the base vectors. In a similar way we may obtain the covariant derivative of a covariant vector from (2.27):

$$A_{\mu:\sigma} = A_{\mu,\sigma} - \Gamma^\nu_{\mu\sigma}\, A_\nu \ . \tag{2.43}$$

Important is that both $A^\mu{}_{:\sigma}$ and $A_{\mu:\sigma}$ are tensors if A^μ is a vector, even though neither of the two terms on the right hand sides of (2.42) and (2.43) are tensors themselves. The proof is a matter of combining relations (2.20) and (2.31), and is left to the reader.

Next follow a few definitions. The covariant derivative of a product XY of two tensors is:

$$(XY)_{:\sigma} = X_{:\sigma}\, Y + X\, Y_{:\sigma} \ . \tag{2.44}$$

For example:

$$
\begin{aligned}
(A_\mu B_\nu)_{:\sigma} &= (A_{\mu,\sigma} - \Gamma^\alpha_{\mu\sigma} A_\alpha) B_\nu + A_\mu (B_{\nu,\sigma} - \Gamma^\alpha_{\nu\sigma} B_\alpha) \\
&= (A_\mu B_\nu)_{,\sigma} - \Gamma^\alpha_{\mu\sigma} A_\alpha B_\nu - \Gamma^\alpha_{\nu\sigma} A_\mu B_\alpha \,. \qquad (2.45)
\end{aligned}
$$

Accordingly, we define the covariant derivative of a covariant second rank tensor as:

$$T_{\mu\nu:\sigma} = T_{\mu\nu,\sigma} - \Gamma^\alpha_{\mu\sigma} T_{\alpha\nu} - \Gamma^\alpha_{\nu\sigma} T_{\mu\alpha} \,. \qquad (2.46)$$

The recipe for tensors of higher rank should be clear by now. For example, if we need an expression for $T_\alpha{}^\beta{}_{\gamma:\sigma}$, then we merely have to work out $(P_\alpha Q^\beta R_\gamma)_{:\sigma}$ as in (2.44) and (2.45). The general pattern is $T^*_{*:\sigma} = T^*_{*,\sigma} \pm \Gamma$-term for every index. For a scalar:

$$Q_{:\sigma} = Q_{,\sigma} \,. \qquad (2.47)$$

Covariant derivatives do not commute, unlike normal derivatives ($X_{,\alpha\beta} = X_{,\beta\alpha}$ for every X). We calculate $B_{\mu:\nu:\sigma}$ by substituting $T_{\mu\nu} = B_{\mu:\nu}$ in (2.46):

$$B_{\mu:\nu:\sigma} = B_{\mu:\nu,\sigma} - \Gamma^\alpha_{\mu\sigma} B_{\alpha:\nu} - \Gamma^\alpha_{\nu\sigma} B_{\mu:\alpha} \,, \qquad (2.48)$$

which should be elaborated further with (2.43). After that, interchange ν and σ and subtract. The result of a somewhat lengthy calculation is:

$$B_{\mu:\nu:\sigma} - B_{\mu:\sigma:\nu} = B_\alpha R^\alpha{}_{\mu\nu\sigma} \qquad (2.49)$$

with

$$R^\alpha{}_{\mu\nu\sigma} = \Gamma^\alpha_{\mu\sigma,\nu} - \Gamma^\alpha_{\mu\nu,\sigma} + \Gamma^\tau_{\mu\sigma} \Gamma^\alpha_{\tau\nu} - \Gamma^\tau_{\mu\nu} \Gamma^\alpha_{\tau\sigma} \,. \qquad (2.50)$$

$R^\alpha{}_{\mu\nu\sigma}$ is called the RIEMANN tensor. It is a tensor because (2.49) is valid for every vector B_α and because the left hand side is a tensor. Then apply the quotient theorem. Apparently, covariant derivatives commute only if $R^\alpha{}_{\mu\nu\sigma} = 0$. The Riemann tensor plays a crucial role in GR because it contains all information about the curvature of space. Note the remarkable fact that according to (2.49) the difference of two consecutive covariant differentiations is proportional to the vector itself. The explanation is given in the next section.

Exercise 2.12: Show that

$$T^{\mu\nu}{}_{:\sigma} = T^{\mu\nu}{}_{,\sigma} + \Gamma^\mu_{\alpha\sigma} T^{\alpha\nu} + \Gamma^\nu_{\alpha\sigma} T^{\mu\alpha} \,. \qquad (2.51)$$

Great care is needed in using these relations. For example, let $T^{\mu\nu}$ be diagonal. Then it seems evident that $T^{1\mu}{}_{:\mu} = T^{11}{}_{:1}$, but that is not the case. Why not?

Hint: Write out $(A^\mu B^\nu)_{:\sigma}$ as in (2.45). It is due to the action of the invisible dummy index α.

Exercise 2.13: An important property is that the metric tensor behaves as a constant under covariant differentiation:

$$g_{\mu\nu:\sigma} = 0 \ . \tag{2.52}$$

Hint: Use (2.46) and (2.30).

Exercise 2.14: Prove the following compact form of the geodesic equation:

$$u^\sigma u_{\mu:\sigma} = 0 \qquad \text{or} \qquad u^\sigma u^\mu{}_{:\sigma} = 0 \ . \tag{2.53}$$

Hint: The last relation is just $0 = \mathrm{D}u^\mu/\mathrm{D}p = (2.41)$; the first relation with (2.52): $0 = g_{\lambda\mu} u^\mu{}_{:\sigma} u^\sigma = (g_{\lambda\mu} u^\mu)_{:\sigma} u^\sigma =$ etc.

Exercise 2.15: A reminder of the linear algebra aspects of tensor calculus. Given a 2D Riemann space with co-ordinates x, y, a metric and two vectors in the tangent space of the point (x, y):

$$\mathrm{d}s^2 = \mathrm{d}x^2 + 4\mathrm{d}x\mathrm{d}y + \mathrm{d}y^2 \ ; \quad A^\alpha = \begin{pmatrix} 1 \\ 4 \end{pmatrix} \ ; \quad B_\alpha = \begin{pmatrix} y \\ x \end{pmatrix} \ .$$

Write down $g_{\mu\nu}$ and $g^{\mu\nu}$ and show that all Christoffel symbols are zero. Compute A_ν and $B^\nu{}_{:\nu}$.

Hint: $g_{11} = g_{22} = 1$; $g_{12} = g_{21} = 2$, use (2.24) for the Christoffel symbols;

$$g^{\mu\nu} = \frac{1}{3} \begin{pmatrix} -1 & 2 \\ 2 & -1 \end{pmatrix} \ ; \quad A_\mu = \begin{pmatrix} 9 \\ 6 \end{pmatrix} \ ; \quad B^\nu{}_{:\nu} = \frac{4}{3} \ .$$

The Γ's being zero we have $B^\nu{}_{:\nu} = B^\nu{}_{,\nu}$.

2.7 Riemann tensor and curvature

The metric tensor does not tell us whether a space is flat, because the use of 'strange' co-ordinates is not prohibited. For example $\mathrm{d}s^2 = \mathrm{d}r^2 + r^2\mathrm{d}\varphi^2$

(planar polar co-ordinates) defines a flat space, but (2.2) defines a curved space. The metric tensor contains apparently a mix of information on co-ordinates and curvature. The intrinsic curvature properties are determined by the Riemann tensor. We shall illustrate this by transporting a vector A^μ parallel to itself along two different paths to the same final position, see Fig. 2.7. According to (2.26), $\mathrm{d}A^\mu = -f_\sigma(x)\mathrm{d}x^\sigma$ with $f_\sigma(x) = \Gamma^\mu{}_{\nu\sigma}A^\nu$ (the upper index μ is omitted for brevity as it does not change). The difference of the two final vectors is:

$$\begin{aligned}
\mathrm{d}A^\mu &= A_1^\mu - A_2^\mu \\
&= -f_\sigma(x)\mathrm{d}\xi^\sigma - f_\sigma(x+\mathrm{d}\xi)\mathrm{d}\eta^\sigma + f_\sigma(x)\mathrm{d}\eta^\sigma + f_\sigma(x+\mathrm{d}\eta)\mathrm{d}\xi^\sigma \\
&\simeq -f_\sigma\mathrm{d}\xi^\sigma - f_\sigma\mathrm{d}\eta^\sigma - f_{\sigma,\lambda}\,\mathrm{d}\xi^\lambda\mathrm{d}\eta^\sigma + f_\sigma\mathrm{d}\eta^\sigma + f_\sigma\mathrm{d}\xi^\sigma + f_{\sigma,\lambda}\,\mathrm{d}\eta^\lambda\mathrm{d}\xi^\sigma \\
&= (f_{\sigma,\lambda} - f_{\lambda,\sigma})\,\mathrm{d}\xi^\sigma\mathrm{d}\eta^\lambda\ . \qquad (2.54)
\end{aligned}$$

Now substitute $f_\sigma = \Gamma^\mu{}_{\nu\sigma}A^\nu = A^\mu{}_{:\sigma} - A^\mu{}_{,\sigma}$. The terms $A^\mu{}_{,\sigma}$ cancel, and after some index gymnastics we arrive at (exercise 2.16):

$$\begin{aligned}
\mathrm{d}A^\mu &= (A^\mu{}_{:\sigma,\lambda} - A^\mu{}_{:\lambda,\sigma})\,\mathrm{d}\xi^\sigma\mathrm{d}\eta^\lambda \\
&= g^{\mu\nu}(A_{\nu:\sigma,\lambda} - A_{\nu:\lambda,\sigma})\,\mathrm{d}\xi^\sigma\mathrm{d}\eta^\lambda \\
&= g^{\mu\nu}(A_{\nu:\sigma:\lambda} - A_{\nu:\lambda:\sigma})\,\mathrm{d}\xi^\sigma\mathrm{d}\eta^\lambda \\
&= g^{\mu\nu}R_{\alpha\nu\sigma\lambda}\,A^\alpha\,\mathrm{d}\xi^\sigma\mathrm{d}\eta^\lambda \\
&= g^{\mu\nu}R_{\nu\alpha\lambda\sigma}\,A^\alpha\,\mathrm{d}\xi^\sigma\mathrm{d}\eta^\lambda \\
&= R^\mu{}_{\alpha\lambda\sigma}\,A^\alpha\,\mathrm{d}\xi^\sigma\mathrm{d}\eta^\lambda\ . \qquad (2.55)
\end{aligned}$$

On account of (2.24) the Christoffel symbols vanish identically in a flat space with rectangular co-ordinates, since $g_{\mu\nu}$ has only constant elements. Therefore the Riemann tensor (2.50) is zero as well. The transformation properties of a tensor then ensure that $R^\alpha{}_{\mu\nu\sigma}$ is zero in a flat space for any choice of the co-ordinates.[4] In that case parallel transport along a closed path leaves a vector unchanged.[5] But in a curved space the orientation of the vector will have

---

[4] Contrary to the Christoffel symbols, which are not tensors. For example, the Christoffel symbols vanish in rectangular co-ordinates in a plane, but *not* in polar co-ordinates.

[5] Conversely, if the Riemann tensor is zero, it can be proven that there exist co-ordinates so that $g_{\mu\nu}$ is constant which implies that the space is flat, see e.g. Dirac (1975) § 12.

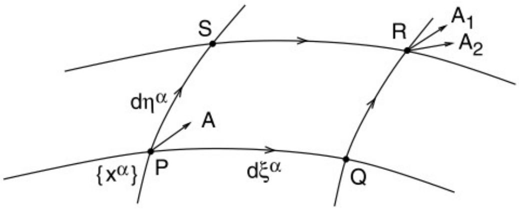

Fig. 2.7. Parallel transport of the vector ***A*** from P to R along path 1 (PQR) and path 2 (PSR) produces a different result.

changed. Once this is accepted intuitively, it is clear that the difference $\mathrm{d}A^{\mu}$ must be proportional to the length of the vector, which explains the factor A^{α} in (2.55). The derivation in (2.55) shows that the difference $\mathrm{d}A^{\mu}$ is also proportional to the difference of two consecutive covariant differentiations, and this explains why this difference is proportional to the vector itself, as in (2.49).

There are several other ways to illustrate the relation between the Riemann tensor and curvature. One is the equation for the *geodesic deviation*, see exercise 2.18. Another is the relation between *Gaussian curvature* and the Riemann tensor. Gaussian curvature refers to surfaces embedded in a flat 3D space. The curvature κ in a point P of a curve on the surface is defined as the inverse radius of the osculating circle at P. Each point has two principal curvatures κ_1 and κ_2, and the Gaussian curvature $K \equiv \kappa_1\kappa_2$ is an invariant determined by the geometry of the surface, which has several interesting properties.[6] Turning now to Riemann spaces, take two orthogonal unit vectors $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ in the tangent space of a point P which are not null. Now consider those geodesics in Riemann space that are tangent in P to the plane spanned by $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$. These geodesics subtend, locally around P, a 2D curved subspace of Riemann space. The Gaussian curvature of this 2D space at P is $R_{\alpha\mu\nu\sigma}e_1^{\alpha}e_2^{\mu}e_1^{\nu}e_2^{\sigma}$, apart from the sign.[7]

The Riemann tensor obeys several symmetry relations that reduce the number of independent components from n^4 to $n^2(n^2-1)/12$ (see literature). In 4 dimensions $R^{\alpha}{}_{\nu\rho\sigma}$ has only 20 independent components, and all contractions of $R^{\alpha}{}_{\nu\rho\sigma}$ are either zero or equal, apart from the sign. We choose the *Ricci tensor*:[8]

---

[6] E.g. Gauss's theorem on integral curvature: the sum of the three interior angles of a geodesic triangle (bounded by 3 geodesics) equals π plus the surface integral of K.

[7] For a proof of these statements see e.g. Robertson and Noonan (1969) p. 216.

$$R_{\mu\nu} \equiv R^{\alpha}{}_{\mu\nu\alpha} \qquad \text{(RICCI)}. \tag{2.56}$$

The explicit expression follows from (2.50):

$$R_{\mu\nu} \;=\; \Gamma^{\alpha}_{\mu\alpha,\nu} \;-\; \Gamma^{\alpha}_{\mu\nu,\alpha} \;-\; \Gamma^{\alpha}_{\mu\nu}\,\Gamma^{\beta}_{\alpha\beta} \;+\; \Gamma^{\alpha}_{\mu\beta}\,\Gamma^{\beta}_{\nu\alpha}\;. \tag{2.57}$$

We infer from (2.33) that $\Gamma^{\alpha}_{\mu\alpha,\nu} = \frac{1}{2}\big(\log|g|\big)_{,\mu\nu}$ so that all terms in (2.57) are symmetric in μ and in ν. Hence $R_{\mu\nu}$ is symmetric:

$$R_{\mu\nu} = R_{\nu\mu}\;. \tag{2.58}$$

We may contract once more:

$$R \;\equiv\; R^{\nu}{}_{\nu} = g^{\nu\mu}R_{\mu\nu} = R^{\alpha\beta}{}_{\beta\alpha}\;. \tag{2.59}$$

R is called the *total curvature*. Finally we introduce the *Einstein tensor* $G_{\mu\nu}$:

$$G_{\mu\nu} \;=\; R_{\mu\nu} - \tfrac{1}{2}g_{\mu\nu}R \qquad \text{(EINSTEIN)}. \tag{2.60}$$

The Einstein tensor will be useful later because its divergence is zero:

$$G^{\mu\nu}{}_{:\nu} \;=\; (R^{\mu\nu} - \tfrac{1}{2}g^{\mu\nu}R)_{:\nu} \;=\; 0\;. \tag{2.61}$$

Riemann, Ricci en Einstein tensor contain at most second derivatives of $g_{\alpha\beta}$. By substituting (2.24) in (2.50) we get:

$$\begin{aligned} R^{\alpha}{}_{\mu\nu\sigma} \;=\; &\tfrac{1}{2}g^{\alpha\beta}\left(g_{\beta\sigma,\mu\nu} \;-\; g_{\mu\sigma,\beta\nu} \;-\; g_{\beta\nu,\mu\sigma} \;+\; g_{\mu\nu,\beta\sigma}\right) \\ &+\; g^{\alpha\beta}\left(\Gamma_{\tau\beta\sigma}\,\Gamma^{\tau}_{\mu\nu} \;-\; \Gamma_{\tau\beta\nu}\,\Gamma^{\tau}_{\mu\sigma}\right)\;. \end{aligned} \tag{2.62}$$

The corresponding expressions for $R_{\mu\nu}$ and for $G_{\mu\nu}$ can be found from this by contraction. The first term contains all second-order derivatives. The first-order derivatives are in the second term. The proofs of (2.61) and (2.62) can be found in the literature, but are not important here.

Exercise 2.16: Provide the missing details of the derivation of (2.55).

Hint: Second = sign: $A^{\mu}{}_{:\sigma,\lambda} \;=\; (g^{\mu\nu}A_{\nu})_{:\sigma,\lambda} \;=\; (g^{\mu\nu}A_{\nu:\sigma})_{,\lambda} \;=\; g^{\mu\nu}{}_{,\lambda}\,A_{\nu:\sigma} \;+\; g^{\mu\nu}A_{\nu:\sigma,\lambda}$, but A^{μ} is parallel transported, hence $A_{\nu:\sigma} = 0$, etc. Third = sign: $A_{\nu:\sigma:\lambda} \;=\; A_{\nu:\sigma,\lambda}$ from (2.48). Fifth = sign: $R_{\alpha\nu\sigma\lambda} \;=\; R_{\nu\alpha\lambda\sigma}$ is a symmetry relation of the Riemann tensor.

---

[8] Other authors define $R_{\mu\nu} \;=\; R^{\alpha}{}_{\mu\alpha\nu}$, another source of sign differences. For a complete classification of all sign conventions see the red pages in Misner et al. (1971). In terms of this classification we follow the $-\;+\;-$ convention.

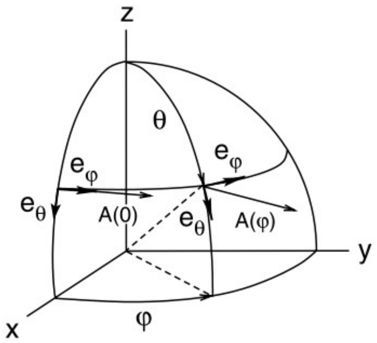

Fig. 2.8. Parallel transport of a vector $\boldsymbol{A}$ over the surface of a sphere with radius $r = 1$, see exercise 2.17.

Exercise 2.17: Consider a 2D spherical surface with radius $r = 1$, see Fig. 2.8. Calculate the Christoffel symbols and the total curvature R. Convince yourself that $R \propto r^{-2}$. Show that a vector $\boldsymbol{A}$ will rotate in the tangent space as it is parallel-transported along a circle $\theta = \theta_0$. Try to understand this with the intuitive definition of parallel transport in § 2.4. Start in $(\theta,\, \varphi) = (\theta_0,\, 0)$ with $(A^\theta,\, A^\varphi) = (0, 1/\sin\theta_0)$. Show that $A^i A_i$ is always 1, i.e. $|\boldsymbol{A}| \equiv 1$, and that after one full revolution $\boldsymbol{A}$ has rotated over an angle $2\pi\cos\theta_0$. Discuss the limiting cases $\theta_0 = \pi/2$ (geodesic!) and $\theta_0 \ll 1$.

Hint: (2.2): $g_{11} = 1,\ g_{22} = \sin^2\theta\ (\theta = 1,\ \varphi = 2)$. Do *not* use (2.24), but rather (2.37) with $L(\theta, \dot\theta, \dot\varphi) = \dot\theta^2 + \sin^2\theta\,\dot\varphi^2$:

$$\begin{aligned} \frac{\partial L}{\partial \theta} &= \Big(\frac{\partial L}{\partial \dot\theta}\Big)^{\cdot} \ \rightarrow\ \ddot\theta \,-\, \sin\theta\cos\theta\,\dot\varphi^2 \,=\, 0\ ; \\ \frac{\partial L}{\partial \varphi} &= \Big(\frac{\partial L}{\partial \dot\varphi}\Big)^{\cdot} \ \rightarrow\ \ddot\varphi \,+\, 2\,\cot\theta\,\dot\theta\dot\varphi \,=\, 0\ . \end{aligned}$$

By comparing with (2.34) we may just read the Γ's: ${\Gamma^1}_{22} = -\sin\theta\cos\theta$; ${\Gamma^2}_{12} = \cot\theta$ (double product!). All other Γ's are zero. (2.33) → ${\Gamma^\alpha}_{\mu\alpha,\nu} = (\log\sin\theta)_{,\mu\nu} \ \rightarrow\ {\Gamma^\alpha}_{1\alpha,1} = -1/\sin^2\theta$. And ${\Gamma^\alpha}_{11,\alpha} = 0$; ${\Gamma^\alpha}_{22,\alpha} = -(\sin\theta \cdot \cos\theta)_{,\theta} = \sin^2\theta - \cos^2\theta$. Algebra: $R_{11} = -1$ and $R_{22} = -\sin^2\theta$. Finally $R = g^{\mu\nu}R_{\mu\nu} = g^{11}R_{11} + g^{22}R_{22} = R_{11} + (1/\sin^2\theta)\,R_{22} = -2$. For a sphere with radius r: $R = -2/r^2$ (minus sign due to sign convention).
Parallel transport: p is proportional to the arc length (why?), so choose $p = \varphi$; (2.28)+(2.26): ${A^\mu}_{,\varphi} + {\Gamma^\mu}_{\nu\sigma}\,A^\nu {x^\sigma}_{,\varphi} = 0$ with $x^1_{,\varphi} = \mathrm{d}\theta/\mathrm{d}\varphi = 0$ and $x^2_{,\varphi} = \mathrm{d}\varphi/\mathrm{d}\varphi = 1$:

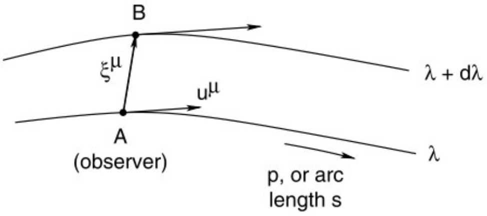

Fig. 2.9. The geodesic deviation.

$$A^{\theta}_{\ ,\varphi} = \sin\theta_0\cos\theta_0\,A^{\varphi}\ ; \qquad A^{\varphi}_{\ ,\varphi} = -\cot\theta_0\,A^{\theta}\ .$$

Eliminate A^{φ}: $A^{\theta}_{\ ,\varphi\varphi} + \cos^2\theta_0\,A^{\theta} = 0$, same equation holds for A^{φ}. Harmonic oscillator with frequency $\cos\theta_0$. Solution for given initial value:

$$A^{\theta} = \sin(\varphi\cos\theta_0)\ ; \qquad A^{\varphi} = \cos(\varphi\cos\theta_0)/\sin\theta_0\ .$$

$\boldsymbol{A}$ rotates clockwise when looking down on the tangent space from outside; $\theta_0 = \pi/2$: $A^{\theta} \equiv 0$ and $A^{\varphi} \equiv 1/\sin\theta_0 = 1$, therefore $\boldsymbol{A}$ remains a tangent vector; $\theta_0 \ll 1$ (small circle around the north pole): in that case the tangent space is always almost parallel to the equatorial plane, with base vectors $\boldsymbol{x}$ en $\boldsymbol{y}$, and $\boldsymbol{e}_{\theta} \simeq \boldsymbol{x}\cos\varphi + \boldsymbol{y}\sin\varphi$ and $\boldsymbol{e}_{\varphi} \simeq (\boldsymbol{y}\cos\varphi - \boldsymbol{x}\sin\varphi)\sin\theta_0$. For $\theta_0 \ll 1$ it follows that $\boldsymbol{A} = A^{\theta}\boldsymbol{e}_{\theta} + A^{\varphi}\boldsymbol{e}_{\varphi} \simeq \boldsymbol{y}$, so that $\boldsymbol{A}$ remains virtually unchanged with respect to a fixed frame.

Exercise 2.18: Given a set of geodesics $x^{\mu}(p,\lambda)$ where p is the curve parameter and λ labels different geodesics (λ is constant along one geodesic). Consider two neighbouring geodesics λ and $\lambda + \delta\lambda$. The points A and B are connected by the vector $\xi^{\mu} = x^{\mu}(p,\lambda+\delta\lambda) - x^{\mu}(p,\lambda) \simeq (\partial x^{\mu}/\partial\lambda)\delta\lambda \equiv e^{\mu}\delta\lambda$. Prove that:

$$\frac{\mathrm{D}^2\xi^{\mu}}{\mathrm{D}p^2} = R^{\mu}_{\ \alpha\beta\nu}\,u^{\alpha}u^{\beta}\xi^{\nu}\ ; \qquad u^{\alpha} = \dot{x}^{\alpha} = \frac{\partial x^{\alpha}}{\partial p}\ . \tag{2.63}$$

This is the equation for the geodesic deviation, that will play an important role later. In a flat space the Riemann tensor is zero, and then ξ^{μ} is a linear function of p, and for timelike geodesics also a linear function of the arc length s, as expected. In a curved space however this is no longer the case. For example, on a sphere $\xi^{\mu}(s)$ will be something like a sine-function.

Hint: The proof comes in three steps:

$$\text{(a)}\qquad \frac{\partial e^\mu}{\partial p} = \frac{\partial^2 x^\mu}{\partial p\,\partial\lambda} = \frac{\partial u^\mu}{\partial \lambda} = u^\mu{}_{,\alpha}\,\frac{\partial x^\alpha}{\partial\lambda} = u^\mu{}_{,\alpha}\, e^\alpha\ ;$$

$$\begin{aligned}
\text{(b)}\ \ e^\mu{}_{:\alpha}\, u^\alpha &\equiv \frac{\mathrm{D}e^\mu}{\mathrm{D}p} = \frac{\partial e^\mu}{\partial p} + \Gamma^\mu_{\ \alpha\beta}\, e^\alpha u^\beta \\
&= u^\mu{}_{,\alpha}\, e^\alpha + \Gamma^\mu_{\ \alpha\beta}\, e^\alpha u^\beta = u^\mu{}_{:\alpha}\, e^\alpha\ ;
\end{aligned}$$

$$\begin{aligned}
\text{(c)}\qquad \frac{\mathrm{D}^2 e^\mu}{\mathrm{D}p^2} &\equiv (e^\mu{}_{:\alpha}\, u^\alpha)_{:\beta}\, u^\beta = (u^\mu{}_{:\alpha}\, e^\alpha)_{:\beta}\, u^\beta \\
&= u^\mu{}_{:\alpha}\, e^\alpha{}_{:\beta}\, u^\beta + u^\mu{}_{:\alpha:\beta}\, e^\alpha u^\beta \\
&= u^\mu{}_{:\alpha}\, u^\alpha{}_{:\beta}\, e^\beta + u^\mu{}_{:\alpha:\beta}\, u^\alpha e^\beta + \left(u^\mu{}_{:\alpha:\beta} - u^\mu{}_{:\beta:\alpha}\right) u^\beta e^\alpha \\
&= \left(u^\mu{}_{:\alpha}\, u^\alpha\right)_{:\beta} e^\beta + g^{\mu\nu}\left(u_{\nu:\alpha:\beta} - u_{\nu:\beta:\alpha}\right) u^\beta e^\alpha \\
&= g^{\mu\nu}\, u_\sigma\, R^\sigma{}_{\nu\alpha\beta}\, u^\beta e^\alpha \\
&= R_\sigma{}^\mu{}_{\alpha\beta}\, u^\sigma u^\beta e^\alpha \\
&= R^\mu{}_{\sigma\beta\alpha}\, u^\sigma u^\beta e^\alpha\ .
\end{aligned}$$

In (c) we have twice used (b), next $u^\mu{}_{:\beta:\alpha}\, e^\alpha u^\beta = u^\mu{}_{:\alpha:\beta}\, e^\beta u^\alpha$ is added and substracted again, and then (2.53) and (2.49). The last = sign is a symmetry relation of the Riemann tensor. Because $\delta\lambda$ is constant, the equation also holds for $\xi^\mu = e^\mu \delta\lambda$.

Exercise 2.19: Be aware of some inconsistencies in the notation. We encountered one in exercise 2.12. Meet two more here. In § 2.2 and § 2.3 it was stressed that the rules for index raising and lowering are always valid. Does that mean that

$$g^{\mu\alpha} g_{\alpha\lambda,\nu} \overset{?}{=} g^\mu_{\ \lambda,\nu}\ ; \tag{2.64}$$

$$g_{\mu\alpha}\dot{u}^\alpha \overset{?}{=} \dot{u}_\mu\ . \tag{2.65}$$

Hint: In exercise 2.12 the trouble was caused by a hidden index; here we discover that the symbols without derivative had already been defined; one way to see that (2.64) cannot be correct is to note that $g^\mu_{\ \lambda,\nu} \equiv \delta^\mu_{\ \lambda,\nu} = 0$, and since $\det\{g^{\mu\alpha}\} \neq 0 \rightarrow g_{\alpha\lambda,\nu} = 0 \ \rightarrow g_{\alpha\lambda} = \text{const}$. Instead, $0 = (g^{\mu\alpha} g_{\alpha\lambda})_{,\nu} = g^{\mu\alpha}{}_{,\nu}\, g_{\alpha\lambda} + g^{\mu\alpha} g_{\alpha\lambda,\nu}$, etc. Likewise, u_μ is *defined* as $g_{\mu\alpha} u^\alpha$ so that $\dot{u}_\mu = (g_{\mu\alpha} u^\alpha)^{\cdot} = g_{\mu\alpha,\sigma}\, u^\sigma u^\alpha + g_{\mu\alpha}\dot{u}^\alpha$. Also correct is $\dot{u}_\mu = u_{\mu,\alpha}\dot{x}^\alpha = u_{\mu,\alpha} u^\alpha$.

2

Geometry of Riemann Spaces

The fact that the geometry of the space in which we live is Euclidean is a very basic daily experience. This may explain why it took so long before it was realised that this may actually not be correct, and that the question of the geometry of the space around us is a matter of empirical assessment. Early in the 19th century Gauss studied the geometry of curved surfaces, and showed that all references to a flat embedding space could be eliminated. In the same way Riemann formulated in 1854 the geometry of 3D spaces. He found that Euclidean geometry is merely one possibility out of many. Riemann's method could be generalized to spaces of arbitrary dimension. The geometry of these curved Riemann spaces is wholly described within the space itself, by the use of co-ordinates and the metric tensor. No embedding is required. These geometrical concepts gradually spread beyond the mathematical incrowd, and in the last quarter of the 19th century the idea that a fourth (spatial) dimension might exist had mesmerized the public's imagination, perhaps even more so than black holes did a century later. One of the products of that period was Abbott's famous Flatland.[1] The flatland analogy is nowadays a standard technique of teachers to explain some of the intricacies of curved spaces.

The theoretical framework of Riemann spaces is also the starting point for the mathematical formulation of GR. In this chapter we discuss the tools that any student should master in order to be able to deal with GR beyond the level of handwaving. In doing so we have deliberately chosen to stay close to intuition as that outweighs the merits of rigour, certainly on first acquaintance.

2.1 Definition

A Riemann space has the following properties:

In 1947 Nafe, Nelson and Rabi [24] reported an anomalous value by about 0.26% in the hyperfine splitting of hydrogen and deuterium, which was quickly confirmed by Nagle et al. [25], and Breit [26] suggested a possible anomaly $g \neq 2$ of the magnetic moment of the electron. Soon after, Kusch and Foley [27], by a study of the hyperfine–structure of atomic spectra in a constant magnetic field, presented the first precision determination of the magnetic moment of the electron $g_e = 2.00238(10)$ in 1948, just before the theoretical result had been settled. Together with Schwinger's result $a_e^{(2)} = \alpha/(2\pi) \simeq 0.00116$ (which accounts for 99% of the anomaly) this provided one of the first tests of the virtual quantum corrections, usually called radiative corrections, predicted by a relativistic quantum field theory. The discovery of the fine structure of the hydrogen spectrum (Lamb–shift) by Lamb and Retherford [28] and the corresponding calculations by Bethe, Kroll & Lamb and Weisskopf & French [29] was the other triumph of testing the new level of theoretical understanding with precision experiments. These successes had a dramatic impact in establishing quantum field theory as a general framework for the theory of elementary particles and for our understanding of the fundamental interactions. It stimulated the development of QED[7] in particular and the concepts of quantum field theory in general. With the

In 1947 Nafe, Nelson and Rabi [24] reported an anomalous value by about 0.26% in the hyperfine splitting of hydrogen and deuterium, which was quickly confirmed by Nagle et al. [25], and Breit [26] suggested a possible anomaly $g \neq 2$ of the magnetic moment of the electron. Soon after, Kusch and Foley [27], by a study of the hyperfine–structure of atomic spectra in a constant magnetic field, presented the first precision determination of the magnetic moment of the electron $g_e = 2.00238(10)$ in 1948, just before the theoretical result had been settled. Together with Schwinger's result $a_e^{(2)} = \alpha/(2\pi) \simeq 0.00116$ (which accounts for 99% of the anomaly) this provided one of the first tests of the virtual quantum corrections, usually called radiative corrections, predicted by a relativistic quantum field theory. The discovery of the fine structure of the hydrogen spectrum (Lamb–shift) by Lamb and Retherford [28] and the corresponding calculations by Bethe, Kroll & Lamb and Weisskopf & French [29] was the other triumph of testing the new level of theoretical understanding with precision experiments. These successes had a dramatic impact in establishing quantum field theory as a general framework for the theory of elementary particles and for our understanding of the fundamental interactions. It stimulated the development of QED[7] in particular and the concepts of quantum field theory in general. With the advent of non–Abelian gauge theories, proposed by Yang and Mills (YM) [31] in 1954, and after 't Hooft and Veltman [32] found the missing clues to understanding and handling them on the quantum level, many years later in 1971, the SM [33] (Glashow, Weinberg, Salam 1981/1987) finally emerged as a comprehensive theory of weak, electromagnetic and strong interactions. The strong interactions had emerged as Quantum Chromodynamics (QCD) [34] (Fritzsch, Gell-Mann, Leutwyler 1973), exhibiting the property of Asymptotic Freedom (AF) [35] (Gross, Politzer and Wilczek 1973). All this structure today is crucial for obtaining sufficiently precise predictions for the anomalous magnetic moment of the muon as we will see.

The most important condition for the anomalous magnetic moment to be a useful monitor for testing a theory is its unambiguous predictability within that theory. The predictability crucially depends on the following properties of the theory:

(1) it must be a local relativistic quantum field theory and
(2) it must be renormalizable.

As a consequence $g - 2$ vanishes at tree level. This means that g cannot be an independently adjustable parameter in any renormalizable QFT, which in turn implies that $g - 2$ is a calculable quantity and the predicted value can be confronted with experiments. As we will see $g - 2$ can in fact be both predicted as well as experimentally measured with very high accuracy. By confronting precise theoretical predictions with precisely measured experimental data it is possible to subject the theory to very stringent tests and to find its possible limitation.

The particle–antiparticle duality [11], also called crossing or charge conjugation property, which is a basic consequence of any relativistic local QFT, implies first and foremost that particles and antiparticles have identical masses and spins. In

---

[7] Today we understand QED as an Abelian gauge theory. This important structural property was discovered by Weyl [30] in 1929.

substances such as diamond, graphite, carbon dioxide, ammonium cyanate, and sodium carbonate are derived from minerals and have typical inorganic properties. Most of the millions of carbon compounds are classified as organic, however.

We humans are composed largely of organic molecules, and we are nourished by the organic compounds in our food. The proteins in our skin, the lipids in our cell membranes, the glycogen in our livers, and the DNA in the nuclei of our cells are all organic compounds. Our bodies are also regulated and defended by complex organic compounds.

Chemists have learned to synthesize or simulate many of these complex molecules. The synthetic products serve as drugs, medicines, plastics, pesticides, paints, and fibers. Many of the most important advances in medicine are actually advances in organic chemistry. New synthetic drugs are developed to combat disease, and new polymers are molded to replace failing organs. Organic chemistry has gone full circle. It began as the study of compounds derived from "organs," and now it gives us the drugs and materials we need to save or replace those organs.

The AbioCor® self-contained artificial heart, which is used to sustain patients who are waiting for a heart transplant. The outer shell is polycarbonate, and the valves and inner bladder are polyurethane. Both of these durable substances are synthetic organic compounds.

1-2 Principles of Atomic Structure

Before we begin our study of organic chemistry, we must review some basic principles. These concepts of atomic and molecular structure are crucial to your understanding of the structure and bonding of organic compounds.

1-2A Structure of the Atom

Atoms are made up of protons, neutrons, and electrons. Protons are positively charged and are found together with (uncharged) neutrons in the nucleus. Electrons, which have a negative charge that is equal in magnitude to the positive charge on the proton, occupy the space surrounding the nucleus (Figure 1-2). Protons and neutrons have similar masses, about 1800 times the mass of an electron. Almost all the atom's mass is in the nucleus, but it is the electrons that take part in chemical bonding and reactions.

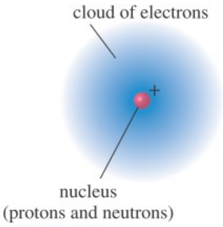

FIGURE 1-2
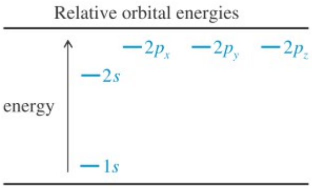
Basic atomic structure. An atom has a dense, positively charged nucleus surrounded by a cloud of electrons.

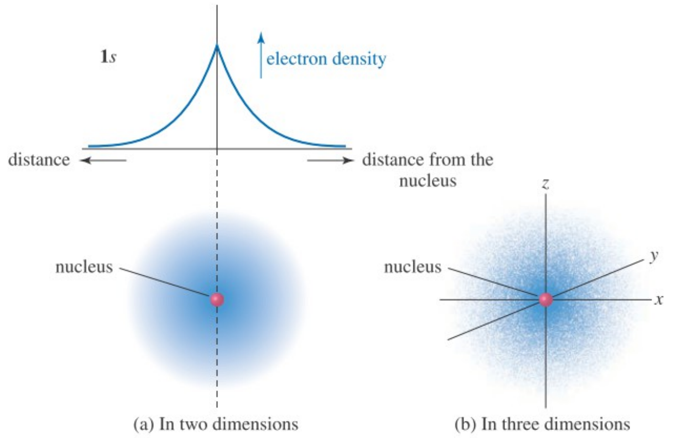
Each element is distinguished by the number of protons in the nucleus (the atomic number). The number of neutrons is usually similar to the number of protons, although the number of neutrons may vary. Atoms with the same number of protons but different numbers of neutrons are called **isotopes.** For example, the most common kind of carbon atom has six protons and six neutrons in its nucleus. Its mass number (the sum of the protons and neutrons) is 12, and we write its symbol as ^{12}C. About 1% of carbon atoms have seven neutrons; the mass number is 13, written ^{13}C. A very small fraction of carbon atoms have eight neutrons and a mass number of 14. The ^{14}C isotope is radioactive, with a half-life (the time it takes for half of the nuclei to decay) of 5730 years. The predictable decay of ^{14}C is used to determine the age of organic materials up to about 50,000 years old.

1-2B Electron Shells and Orbitals

An element's chemical properties are determined by the number of protons in the nucleus and the corresponding number of electrons around the nucleus. The electrons form bonds and determine the structure of the resulting molecules. Because they are small and light, electrons show properties of both particles and waves; in many ways, the electrons in atoms and molecules behave more like waves than like particles.

Electrons that are bound to nuclei are found in **orbitals.** Orbitals are mathematical descriptions that chemists use to explain and predict the properties of atoms and molecules. The *Heisenberg uncertainty principle* states that we can never determine exactly where the electron is; nevertheless, we can determine the **electron density,** the probability of finding the electron in a particular part of the orbital. An orbital, then, is an allowed energy state for an electron, with an associated probability function that defines the distribution of electron density in space.





(a) In two dimensions (b) In three dimensions

FIGURE 1-3
Graph and diagram of the 1*s* atomic orbital. The electron density is highest at the nucleus and drops off exponentially with increasing distance from the nucleus in any direction.

Atomic orbitals are grouped into different "shells" at different distances from the nucleus. Each shell is identified by a principal quantum number n, with $n = 1$ for the lowest-energy shell closest to the nucleus. As n increases, the shells are farther from the nucleus, are higher in energy, and can hold more electrons. Most of the common elements in organic compounds are found in the first two rows of the periodic table, indicating that their electrons are found in the first two electron shells. The first shell ($n = 1$) can hold two electrons, and the second shell ($n = 2$) can hold eight.

The first electron shell contains just the 1*s* orbital. All *s* orbitals are spherically symmetrical, meaning that they are nondirectional. The electron density is only a function of the distance from the nucleus. The electron density of the 1*s* orbital is graphed in Figure 1-3. Notice how the electron density is highest *at* the nucleus and falls off exponentially with increasing distance from the nucleus. The 1*s* orbital might be imagined as a cotton boll, with the cottonseed at the middle representing the nucleus. The density of the cotton is highest nearest the seed, and it becomes less dense at greater distances from this "nucleus."

The second electron shell consists of the 2*s* and 2*p* orbitals. The 2*s* orbital is spherically symmetrical like the 1*s* orbital, but its electron density is not a simple exponential function. The 2*s* orbital has a smaller amount of electron density close to the nucleus. Most of the electron density is farther away, beyond a region of zero electron density called a **node.** Because most of the 2*s* electron density is farther from the nucleus than that of the 1*s*, the 2*s* orbital is higher in energy. Figure 1-4 shows a graph of the 2*s* orbital.

In addition to the 2*s* orbital, the second shell also contains three 2*p* atomic orbitals, one oriented in each of the three spatial directions. These orbitals are called the $2p_x$, the $2p_y$, and the $2p_z$, according to their direction along the x, y, or z axis. The 2*p* orbitals are slightly higher in energy than the 2*s*, because the average location of the electron in a 2*p* orbital is farther from the nucleus. Each *p* orbital consists of two lobes, one on either side of the nucleus, with a **nodal plane** at the nucleus. The nodal plane is a flat (planar) region of space, including the nucleus, with zero electron density. The three 2*p* orbitals differ only in their spatial orientation, so they have identical energies. Orbitals with identical energies are called **degenerate orbitals.** Figure 1-5 shows the shapes of the three degenerate 2*p* atomic orbitals.

The *Pauli exclusion principle* tells us that each orbital can hold a maximum of two electrons, provided that their spins are paired. The first shell (one 1*s* orbital) can accommodate two electrons. The second shell (one 2*s* orbital and three 2*p* orbitals) can accommodate eight electrons, and the third shell (one 3*s* orbital, three 3*p* orbitals, and five 3*d* orbitals) can accommodate 18 electrons.

1.2 Strict and Uniform Convexity

Let X be a Banach space with dual X^*; the value of $x^* \in X^*$ at $x \in X$ is denoted by $\langle x, x^* \rangle_X$ or $\langle x, x^* \rangle$. We recall that X is said to be *strictly convex* if whenever $x, y \in X$ are such that $x \neq y$ and $\|x\| = \|y\| = 1$, and $\lambda \in (0,1)$, then $\|\lambda x + (1-\lambda)y\| < 1$. This simply means that the unit sphere in X does not contain any line segment. Note that an equivalent condition on X is that no sphere of any radius and any centre contains a line segment. For example, if $\mathbb{R}^2$ is equipped with the l_p norm it is strictly convex if $1 < p < \infty$ but not if $p = 1$ or ∞.

Proposition 1.1. *The space X is strictly convex if and only if it is the case that whenever $x, y \in X$ are such that $\|x + y\| = \|x\| + \|y\|$ then either $y = 0$ or $x = \lambda y$ for some $\lambda \geq 0$.*

Proof. Suppose that X is strictly convex and $x, y \in X \backslash \{0\}$ are such that $x \neq y$ and $\|x + y\| = \|x\| + \|y\|$. Then $\|x\| \neq \|y\|$, for otherwise $\left\| \frac{x+y}{2} \right\| = \|x\|$, contradicting the strict convexity of X. However, if $\|y\| < \|x\|$, we put $\lambda = \|y\| / \|x\|$ and observe that

$$1 \geq \left\| \frac{x}{\|x\|} + \lambda \left(\frac{y}{\|y\|} - \frac{x}{\|x\|} \right) \right\| \geq \frac{\|x+y\| - \lambda \|x\|}{\|x\|} = \frac{\|x\| + \|y\| - \lambda \|x\|}{\|x\|} = 1,$$

which means that $x = y/\lambda$. The converse is obvious. □

It is plain that every linear subspace of a strictly convex space is itself strictly convex, with the inherited norm. Here are some of the less trivial properties of such spaces.

Proposition 1.2. *Let X be a Banach space with dual X^*. Then X is strictly convex if and only if given any $x^* \in X^* \backslash \{0\}$, there is at most one $x \in X$ such that $\|x\| = 1$ and $\langle x, x^* \rangle = \|x^*\|$; if X is reflexive, such an x exists.*

Proof. Let X be strictly convex and $x^* \in X^* \backslash \{0\}$. Suppose there are two distinct such points x, say x_1 and x_2. Then if $0 < \lambda < 1$,

$$\begin{aligned} \|x^*\| &= \lambda \langle x_1, x^* \rangle + (1-\lambda) \langle x_2, x^* \rangle = \langle \lambda x_1 + (1-\lambda) x_2, x^* \rangle \\ &\leq \|x^*\| \, \|\lambda x_1 + (1-\lambda) x_2\| < \|x^*\|, \end{aligned}$$

which is absurd. Conversely, suppose that $\|x + \lambda(y - x)\| = 1$ for some $x, y \in X$ with $\|x\| = \|y\| = 1$ and some $\lambda \in (0,1)$. By the Hahn–Banach theorem, there exists $x^* \in X^*$ such that $\langle x + \lambda(y - x), x^* \rangle = 1$ and $\|x^*\| = 1$. Then $(1-\lambda) \langle x, x^* \rangle + \lambda \langle y, x^* \rangle = 1$, and since $|\langle x, x^* \rangle|, |\langle y, x^* \rangle| \leq 1$ we must have $\langle x, x^* \rangle = \langle y, x^* \rangle = 1$. By hypothesis, this implies that $x = y$, and so X is strictly convex.

Now suppose that X is reflexive and let (x_k) be a sequence in X such that $\|x_k\| = 1$ for all $k \in \mathbb{N}$ and $\|x^*\| = \lim_{k \to \infty} \langle x_k, x^* \rangle$. Since X is reflexive, there is a weakly convergent subsequence of (x_k), still denoted by (x_k) for simplicity, with weak limit x, say. Then $\|x\| \leq 1$ and $\langle x, x^* \rangle = \lim_{k \to \infty} \langle x_k, x^* \rangle = \|x^*\|$. □

Proposition 1.3. *Let X be a Banach space. Then X^* is strictly convex if and only if given any $x \in X\backslash\{0\}$, there is a unique $x^* \in X^*$ such that $\|x^*\| = 1$ and $\langle x, x^*\rangle = \|x\|$.*

Proof. Suppose that X^* is strictly convex. By the Hahn–Banach theorem, there exists $x^* \in X^*$ with $\|x^*\| = 1$ and $\langle x, x^*\rangle = \|x\|$. Suppose there exists $y^* \in X^*$, $y^* \neq x^*$, with $\|y^*\| = 1$ and $\langle x, y^*\rangle = \|x\|$. Then if $0 < \lambda < 1$,

$$\|x\| = \lambda \langle x, x^*\rangle + (1-\lambda) \langle x, y^*\rangle \leq \|\lambda x^* + (1-\lambda)y^*\| \, \|x\| < \|x\|,$$

and we have a contradiction. The proof of the converse is similar to that of the corresponding statement in Proposition 1.2. □

Proposition 1.4. *Let K be a convex subset of a strictly convex Banach space X. Then there is at most one element $x \in K$ such that*

$$\|x\| = \inf\{\|y\| : y \in K\}.$$

If, in addition, X is reflexive and K is closed and non-empty, then such a point x exists.

Proof. Suppose there exist $x, y \in K$ with $\|x\| = \|y\| = \inf\{\|z\| : z \in K\}$, $x \neq y$. Let $0 < \lambda < 1$: then $\lambda x + (1-\lambda)y \in K$, $\|\lambda x + (1-\lambda)y\| < \|x\|$ and we have a contradiction.

For the second assertion, let (x_k) be a sequence in K such that $\lim_{k\to\infty} \|x_k\| = l := \inf\{\|y\| : y \in K\}$. By reflexivity, this sequence has a subsequence, still denoted by (x_k) for convenience, such that $x_k \rightharpoonup x$ for some $x \in X$, by which we mean that (x_k) converges weakly to x in X; in fact, $x \in K$ since K is convex and closed, and hence weakly closed. Moreover, $\|x\| \leq \lim_{k\to\infty} \|x_k\| = l$. □

To measure the degree of strict convexity of a Banach space X, we define its *modulus of convexity* $\delta_X : [0,2] \to [0,1]$ by

$$\delta_X(\varepsilon) = \inf\left\{1 - \frac{1}{2}\|x+y\| : x, y \in X, \|x\| \leq 1, \|y\| \leq 1, \|x-y\| \geq \varepsilon\right\}. \tag{1.5}$$

This function is introduced so that, given any two distinct points x and y in the closed unit ball B in X, we shall have an idea of how far inside B is the midpoint of the line segment joining x to y. Note that the same function is obtained if the infimum is taken over all $x, y \in X$ with $\|x\| = \|y\| = 1$ and $\|x-y\| = \varepsilon$: see [88], Vol. II, p. 60. The Banach space X is called *uniformly convex* if for all $\varepsilon \in (0,2]$, $\delta_X(\varepsilon) > 0$. This means that X is uniformly convex if, given any $\varepsilon \in (0,2]$, $\|x+y\| \leq 2(1 - \delta_X(\varepsilon))$ whenever $x, y \in X$ are such that $\|x\| = \|y\| = 1$ and $\|x-y\| \geq \varepsilon$. It is easy to see that an equivalent condition is that whenever (x_k) and (y_k) are sequences in X such that $\|x_k\| \leq 1, \|y_k\| \leq 1$ $(k \in \mathbb{N})$ and $\lim_{k\to\infty} \|x_k + y_k\| = 2$, then $\lim_{k\to\infty} \|x_k - y_k\| = 0$. Note that δ_X is increasing on $[0,2]$, continuous on $[0,2)$ (not necessarily at 2) and $\delta_X(0) = 0$. Moreover, $\delta_X(2) = 1$ if and only if X is strictly convex.

Plainly every closed linear subspace of a uniformly convex space is uniformly convex when given the inherited norm. Moreover, it is clear that every uniformly convex space is strictly convex: as we shall see later, the converse is false. However, in finite-dimensional spaces strict convexity does imply uniform convexity, for then the fact that $1-\frac{1}{2}\|x+y\|>0$ whenever $\|x\|=\|y\|=1$ and $\|x-y\|=\varepsilon>0$ implies that $\delta_X(\varepsilon)>0$ since closed bounded sets are compact in finite-dimensional spaces. The simplest example of a uniformly convex space is any Hilbert space H, for the parallelogram law enables us to see that

$$\delta_H(\varepsilon)=1-(1-\varepsilon^2/4)^{1/2},$$

which is clearly positive for all $\varepsilon\in(0,2]$; in fact, since

$$(1-x^q)^{1/q}\le 1-x^q/q \quad (0\le x\le 1, 1<q<\infty),$$

we have

$$\delta_H(\varepsilon)\ge\varepsilon^2/8.$$

Note that in the opposite direction, for every Banach space X of dimension at least 2, it is known that

$$\delta_X(\varepsilon)\le\delta_H(\varepsilon)=1-(1-\varepsilon^2/4)^{1/2}\le C\varepsilon^2;$$

see [88], Vol. II, p. 63. In this sense, Hilbert spaces are the 'most' uniformly convex spaces.

If $1<p<\infty$, the sequence space l_p and the Lebesgue space L_p (over any set and with any measure) are uniformly convex. This was established by Clarkson [25], who introduced the notion of uniform convexity and proved the following inequalities (now known as the Clarkson inequalities) that hold for arbitrary elements $f,g\in L_p$:

$$\left(\|(f+g)/2\|_p^{p'}+\|(f-g)/2\|_p^{p'}\right)^{1/p'}\le\left(\frac{\|f\|_p^p+\|g\|_p^p}{2}\right)^{1/p} \text{ if } 1\le p\le 2, \quad (1.6)$$

and

$$\left(\|(f+g)/2\|_p^{p}+\|(f-g)/2\|_p^{p}\right)^{1/p}\le\left(\frac{\|f\|_p^p+\|g\|_p^p}{2}\right)^{1/p} \text{ if } 2\le p\le \infty. \quad (1.7)$$

Here $\|\cdot\|_p$ denotes the norm on L_p. In the cases $2\le p\le\infty$ and $1\le p\le 2$ the inequalities in (1.6) and (1.7) respectively hold in the reversed sense. He used these to obtain lower bounds for $\delta_p:=\delta_{L_p}$ of the form

$$\delta_p(\varepsilon)\ge(\varepsilon/C)^r, \quad (1.8)$$

where $r = p'$ if $1 < p \leq 2$, $r = p$ if $2 \leq p < \infty$, and C is a positive constant that depends on p. These lower bounds are not optimal when $1 < p \leq 2$; however, from them the uniform convexity of L_p when $1 < p < \infty$ follows immediately.

Estimates from below of the modulus of convexity of a Banach space of the form (1.8) are very useful, particularly if the best value of r is known, and so we present below results leading to the optimal value of r for L_p, following the approach of Ball et al. [3]. We begin with a technical lemma.

Lemma 1.1. *Let* $1 < p < \infty$ *and define* $\lambda_p : [0,\infty) \to [0,\infty)$ *by*

$$\lambda_p(t) = (1+t)^{p-1} + |1-t|^{p-1} \ sgn\ (1-t).$$

Then for all $x, y \in \mathbb{R}$,

$$|x+y|^p + |x-y|^p = \sup\{\lambda_p(t)\,|x|^p + \lambda_p(1/t)\,|y|^p : 0 < t < \infty\}$$

if $1 < p \leq 2$; *if* $2 \leq p < \infty$, *the same holds with* sup *replaced by* inf.

Proof. Suppose that $1 < p \leq 2$. By homogeneity and symmetry it is enough to deal with the case $0 < y \leq x = 1$. Put

$$f(t) = \lambda_p(t) + \lambda_p(1/t)y^p,\ 0 < t < \infty,$$

and note that $f(y) = (1+y)^p + (1-y)^p$. Moreover, if $t \neq y$, a routine calculation shows that

$$f'(t) = (p-1)\{1-(y/t)^p\}\left\{(1+t)^{p-2} - |1-t|^{p-2}\right\}.$$

Thus $f'(t) \geq 0$ if $0 < t < y$, $f'(t) \leq 0$ if $y < t < \infty$. It follows that the maximum value of f on $(0,\infty)$ occurs when $t = y$, and the desired inequality follows. The proof when $2 \leq p < \infty$ is similar. □

In [3] it is shown that Clarkson's inequalities may be obtained from this result, which also gives rise to the following theorem, due originally to Hanner [71] and from which the modulus of convexity δ_p can be estimated.

Theorem 1.1. *Suppose that* $1 < p \leq 2$ *and let* $f, g \in L_p$. *Then*

$$\|f+g\|_p^p + \|f-g\|_p^p \geq \left(\|f\|_p + \|g\|_p\right)^p + \left|\|f\|_p - \|g\|_p\right|^p.$$

If $2 \leq p < \infty$ *the inequality is reversed.*

Proof. Suppose that $1 < p \leq 2$. Then by Lemma 1.1,

$$\begin{aligned}
\|f+g\|_p^p+\|f-g\|_p^p &= \int \{|f+g|^p+|f-g|^p\} \\
&= \int \sup_{0<t<\infty} \{\lambda_p(t)\,|f|^p+\lambda_p(1/t)\,|g|^p\} \\
&\geq \sup_{0<t<\infty} \int \{\lambda_p(t)\,|f|^p+\lambda_p(1/t)\,|g|^p\} \\
&= \sup_{0<t<\infty} \{\lambda_p(t)\,\|f\|^p+\lambda_p(1/t)\,\|g\|^p\} \\
&= \left(\|f\|_p+\|g\|_p\right)^p+\left|\|f\|_p-\|g\|_p\right|^p,
\end{aligned}$$

the final step following from another application of Lemma 1.1. The case $2 \leq p < \infty$ is similar. □

Finally we give a theorem of Ball and Pisier (see [3]).

Theorem 1.2. *Suppose that* $1 < p \leq 2$ *and let* $f, g \in L_p$. *Then*

$$\|f+g\|_p^2+\|f-g\|_p^2 \geq 2\,\|f\|_p^2+2(p-1)\,\|g\|_p^2.$$

If $2 \leq p < \infty$ *the inequality is reversed.*

Proof. Suppose that $1 < p \leq 2$. We use the inequality

$$|a+b|^p+|a-b|^p \geq 2\{a^2+(p-1)b^2\}^{p/2}\ (a,b \in \mathbb{R}) \tag{1.9}$$

which is ascribed to Gross in [3]. Accepting this for the moment, note that by Hölder's inequality,

$$\|f+g\|_p^p+\|f-g\|_p^p \leq 2^{(2-p)/2}\left(\|f+g\|_p^2+\|f-g\|_p^2\right)^{p/2},$$

from which we have, by Theorem 1.1,

$$\begin{aligned}
\left(\|f+g\|_p^2+\|f-g\|_p^2\right)^{p/2} &\geq 2^{-(2-p)/2}\left\{\left(\|f\|_p+\|g\|_p\right)^p+\left|\|f\|_p-\|g\|_p\right|^p\right\} \\
&\geq 2^{p/2}\left\{\|f\|_p^2+(p-1)\,\|g\|_p^2\right\}^{p/2},
\end{aligned}$$

the final inequality following from (1.9). This gives the theorem when $1 < p \leq 2$; similar arguments work when $2 \leq p < \infty$.

To prove (1.9) it is enough to show that

$$h(t) := (1+t)^p+(1-t)^p-2\{1+(p-1)t^2\}^{p/2} \geq 0,\ 0 \leq t \leq 1. \tag{1.10}$$

Note that if $0 \le t < 1$,

$$(1+t)^p + (1-t)^p = 2 + p(p-1)t^2 + 2p(p-1)\sum_{n=2}^{\infty} \frac{(3-p)...(2n-1-p)}{(2n)!} t^{2n}$$

and

$$\{1+(p-1)t^2\}^{p/2} = 1 + \frac{p}{2}(p-1)t^2 + \sum_{n=2}^{\infty} \frac{p(2-p)...(2n-2-p)}{n!2^n}(p-1)^n t^{2n}(-1)^{n+1},$$

so that

$$h(t) = 2p(p-1)\sum_{n=2}^{\infty} \frac{(3-p)...(2n-1-p)}{(2n)!} t^{2n} + I,$$

where

$$I = 2\sum_{m=1}^{\infty} \frac{p(2-p)...(4m-2-p)}{(2m+1)!2^{2m+1}} \left\{2(2m+1) - (4m-p)(p-1)t^2\right\}(p-1)^{2m}t^{4m}.$$

Since $2(2m+1) - (4m-p)(p-1)t^2 > 0$ when $0 \le t < 1$, $h(t) \ge 0$ and (1.10) follows. □

Now these results are applied to give optimal estimates for δ_p, the modulus of convexity of L_p. First suppose that $1 < p \le 2$. Then from Theorem 1.2 with $u = f+g$ and $v = f-g$ we see that

$$\|u\|_p^2 + \|v\|_p^2 \ge 2\left\|\frac{u+v}{2}\right\|_p^2 + 2(p-1)\left\|\frac{u-v}{2}\right\|_p^2,$$

from which we have

$$\delta_p(\varepsilon) \ge 1 - (1-(p-1)(\varepsilon/2)^2)^{1/2} \ge (p-1)\varepsilon^2/8.$$

In the terminology of [110], according to which given any $r \in [2,\infty)$ a Banach space X is said to be r-uniformly convex if $\delta_X(\varepsilon) \ge (\varepsilon/C)^r$ for some positive constant C, this means that L_p is 2-uniformly convex. When $2 \le p < \infty$, direct use of Theorem 1.1 shows that $\delta_p(\varepsilon) \ge 1-(1-(\varepsilon/2)^p)^{1/p} \ge 1-(1-(\varepsilon/2)^p/p) = (\varepsilon/2)^p/p$, so that L_p is p-uniformly convex. The asymptotic behaviour of δ_p for $1 < p < \infty$ is stated in [88], Vol. II, p. 63; see also [107], p. 237.

To provide other interesting examples of uniformly convex spaces it is convenient to introduce certain spaces of l_p type. Let $I \subset \mathbb{N}$ be non-empty, and for each $i \in I$ let A_i be a Banach space; put $A = \{A_i : i \in I\}$ and let $1 < p < \infty$. Define

$$l_p(A) = \left\{ a = (a_i)_{i\in I} : a_i \in A_i, \left\|a \mid l_p(A)\right\| = \left(\sum_{i\in I} \|a_i \mid A_i\|^p\right)^{1/p} < \infty \right\}.$$

This is a linear space when given the natural definitions of addition and multiplication by scalars; it is routine to verify that it becomes a Banach space when endowed with the norm $\left\|\cdot \mid l_p(A)\right\|$. The following result is due to Day [30].

Theorem 1.3. *The space $l_p(A)$ is strictly convex if and only if each A_i is strictly convex; it is uniformly convex if and only if every A_i is uniformly convex with modulus of convexity δ_i and $\delta(\varepsilon) := \inf_{i\in I}\delta_i(\varepsilon) > 0$ for all $\varepsilon \in (0,2)$.*

Proof. First suppose that every A_i is strictly convex, and let $a,b \in l_p(A)\backslash\{0\}$ be such that $\left\|a+b \mid l_p(A)\right\| = \left\|a \mid l_p(A)\right\| + \left\|b \mid l_p(A)\right\|$. Then

$$\left(\sum_{i\in I}\|a_i+b_i \mid A_i\|^p\right)^{1/p} = \left(\sum_{i\in I}\|a_i \mid A_i\|^p\right)^{1/p} + \left(\sum_{i\in I}\|b_i \mid A_i\|^p\right)^{1/p},$$

and so, by a natural adaptation of the classical method of dealing with the case of equality in Minkowski's inequality, we see that $a = \lambda b$ for some $\lambda > 0$. By Proposition 1.1 it follows that $l_p(A)$ is strictly convex. That strict convexity of $l_p(A)$ implies that of each A_i is obvious.

Now assume that each A_i is uniformly convex and has modulus of convexity δ_i, with $\delta(\varepsilon) := \inf_{i\in I}\delta_i(\varepsilon) > 0$ for all $\varepsilon \in (0,2)$. Let $\varepsilon > 0$, ε small, and suppose initially that $a,b \in l_p(A)$ are such that $\left\|a \mid l_p(A)\right\| = \left\|b \mid l_p(A)\right\| = 1$, $\left\|a-b \mid l_p(A)\right\| > \varepsilon$ and $\|a_i \mid A_i\| = \|b_i \mid A_i\| = \beta_i$ for all $i \in I$; put $\|a_i - b_i \mid A_i\| = \gamma_i$, and note that $\gamma_i \le 2\beta_i$. Then $\|a_i + b_i \mid A_i\| < 2(1-\delta(\gamma_i/\beta_i))\beta_i$ for all $i \in I$, and so

$$\left\|a+b \mid l_p(A)\right\| \le 2\left\{\sum_{i\in I}((1-\delta(\gamma_i/\beta_i))\beta_i)^p\right\}^{1/p}.$$

Let $E = \{i \in I : \gamma_i/\beta_i > \varepsilon/4\}$ and $F = I\backslash E$. Then

$$1 = \left(\sum_{i\in I}\beta_i^p\right)^{1/p} \ge \left(\sum_{i\in F}\beta_i^p\right)^{1/p} \ge (4/\varepsilon)\left(\sum_{i\in F}\gamma_i^p\right)^{1/p}.$$

Hence

$$\left(\sum_{i\in E}\gamma_i^p\right)^{1/p} = \left(\sum_{i\in I}\gamma_i^p - \sum_{i\in F}\gamma_i^p\right)^{1/p} \ge (\varepsilon^p - (\varepsilon/4)^p)^{1/p} \ge 3\varepsilon/4,$$

so that

$$\alpha := \left(\sum_{i\in E}\beta_i^p\right)^{1/p} \ge 3\varepsilon/8.$$

It follows that

$$\begin{aligned}\left\|a+b \mid l_p(A)\right\| &\leq 2\left\{(1-\delta(\varepsilon/4))^p \sum_{i\in E}\beta_i^p + \sum_{i\in F}\beta_i^p\right\}^{1/p}\\ &\leq 2\left\{(1-\delta(\varepsilon/4))^p\alpha^p + 1-\alpha^p\right\}^{1/p}\\ &\leq 2\left\{1-(1-(1-\delta(\varepsilon/4))^p)\alpha^p\right\}^{1/p}\\ &\leq 2\left\{1-(1-(1-\delta(\varepsilon/4))^p)(3\varepsilon/8)^p\right\}^{1/p} = 2(1-\delta_0(\varepsilon)),\ \text{say,}\end{aligned}$$

which is an inequality of the required form.

Next suppose that $\left\|a \mid l_p(A)\right\| = \left\|b \mid l_p(A)\right\| = 1$ and that $\left\|a+b \mid l_p(A)\right\| > 2(1-\delta_p(\eta))$, where δ_p is the modulus of convexity of $l_p(A)$ and $\eta \in (0,2]$. Then

$$2(1-\delta_p(\eta)) \leq \left(\sum_{i\in I}(\|a_i \mid A_i\| + \|b_i \mid A_i\|)^p\right)^{1/p} \leq 2,$$

and since the sequences $(\|a_i \mid A_i\|)$ and $(\|b_i \mid A_i\|)$ are in l_p, we see that

$$\left(\sum_{i\in I}|\|a_i \mid A_i\| - \|b_i \mid A_i\||^p\right)^{1/p} < \eta.$$

Let $c=(c_i)=(b_i\|a_i \mid A_i\|/\|b_i \mid A_i\|)$, so that $\|c_i \mid A_i\| = \|a_i \mid A_i\|$ for all $i \in I$ and $\left\|b-c \mid l_p(A)\right\| = \left(\sum_{i\in I}|\|b_i \mid A_i\| - \|a_i \mid A_i\||^p\right)^{1/p} < \eta$. Thus by the earlier part of our discussion, $\left\|a-c \mid l_p(A)\right\| \leq \varepsilon/2$ if $\left\|a+c \mid l_p(A)\right\| \geq 2(1-\delta_0(\varepsilon/2))$; moreover, $\left\|a+c \mid l_p(A)\right\| \geq \left\|a+b \mid l_p(A)\right\| - \left\|c-b \mid l_p(A)\right\| > 2(1-\delta_p(\eta)-\eta/2)$. Choose $\eta \in (0,\varepsilon/2)$ so that $\delta_p(\eta)+\eta/2 < \delta_0(\varepsilon/2)$. Then $\left\|a+b \mid l_p(A)\right\| > 2(1-\delta_p(\eta))$ implies that $\left\|a+c \mid l_p(A)\right\| > 2(1-\delta_0(\varepsilon/2))$, which in turn implies that $\left\|a-c \mid l_p(A)\right\| < \varepsilon/2$. Thus $\left\|a-b \mid l_p(A)\right\| \leq \left\|a-c \mid l_p(A)\right\| + \left\|b-c \mid l_p(A)\right\| < \varepsilon$. Set $\delta_p^{'}(\varepsilon) = \delta_p(\eta) > 0$: then $\left\|a-b \mid l_p(A)\right\| < \varepsilon$ if $\left\|a \mid l_p(A)\right\| = \left\|b \mid l_p(A)\right\| = 1$ and $\left\|a+b \mid l_p(A)\right\| > 2(1-\delta_p^{'}(\varepsilon))$. This establishes the uniform convexity of $l_p(A)$.

Finally, suppose that $l_p(A)$ is uniformly convex. Consideration of the points $a = (\delta_{ij}) \in A$, where δ_{ij} is the Kronecker delta, shows that each A_j is uniformly convex. □

If each $A_i = L_{p_i}$, then since by our earlier results the modulus of convexity of L_{p_i} satisfies

$$\delta_{L_{p_i}}(\varepsilon) \geq \left(\frac{p_i-1}{8}\right)\varepsilon^2 \text{ if } 1<p_i\leq 2, \text{ and } \delta_{L_{p_i}}(\varepsilon) \geq (\varepsilon/2)^{p_i}/p_i \text{ if } 2<p_i<\infty,$$

it follows that $l_p(A)$ is uniformly convex if and only if the sequence $\{p_i\}$ is bounded away from 1 and ∞.

As a further immediate application of this result we deal with Sobolev spaces. Let Ω be an open subset of $\mathbb{R}^n$, let $p \in (1,\infty)$ and suppose that $k \in \mathbb{N}$. The Sobolev space $W_p^k(\Omega)$ is the linear space of all (equivalence classes of) functions $u \in D^\alpha u$ such that for all $\alpha = (\alpha_j) \in \mathbb{N}_0^n$ with $|\alpha| := \alpha_1 + ... + \alpha_n \leq k$, the distributional derivative $D^\alpha u := \frac{\partial^{|\alpha|} u}{\partial x_1^{\alpha_1} ... \partial x_n^{\alpha_n}}$ belongs to $L_p(\Omega)$. Endowed with the norm

$$\left\| u \mid W_p^k(\Omega) \right\| := \left(\sum_{|\alpha| \leq k} \left\| D^\alpha u \mid L_p(\Omega) \right\|^p \right)^{1/p}$$

it becomes a Banach space, which is isometrically isomorphic to a closed linear subspace V of the product of $N := \#\{\alpha \in \mathbb{N}_0^n : |\alpha| \leq k\}$ copies of $L_p(\Omega)$, the isomorphism being established by the map $u \longmapsto (D^\alpha u)_{|\alpha| \leq k}$. With $I = \{1, 2, ..., N\}$ and $A_j = L_p(\Omega)$ for all $j \in I$, it is plain that this product is just $l_p(A)$, and in view of Theorem 1.3, $l_p(A)$ is uniformly convex. Thus V is uniformly convex, and therefore so is $W_p^k(\Omega)$. We have thus proved

Corollary 1.1. *For all $p \in (1,\infty)$ and all $k \in \mathbb{N}$, the Sobolev space $W_p^k(\Omega)$ is uniformly convex.*

Remark 1.1. (i) In [29] and [30] the spaces $l_p(A)$ are used to show that strict convexity does not imply uniform convexity, and indeed that there are separable, reflexive, strictly convex Banach spaces that are not isomorphic to any uniformly convex space. When $A = \{l_{p_j} : j \in \mathbb{N}\}$, $l_p(A)$ is isomorphic to a uniformly convex space if and only if the sequence (p_j) is bounded away from 1 and ∞. A result more general than Theorem 1.3 is given in [31], the idea being to replace the l_p structure of the space $l_p(A)$ by means of a more general norm.

(ii) In [30] an analogue of Theorem 1.3 is given for spaces of Lebesgue type. Let $1 < p < \infty$, let X be a Banach space, let Ω be an open subset of $\mathbb{R}^n$ and denote by $L_p(X)$ the space of all functions $f : \Omega \to X$ such that

$$\left\| f \mid L_p(X) \right\| := \left(\int_\Omega \| f(x) \mid X \|^p \, dx \right)^{1/p} < \infty.$$

Then [30] shows that $L_p(X)$, endowed with the norm $\left\| \cdot \mid L_p(X) \right\|$, is uniformly convex if and only if X is uniformly convex. The same holds with any measure space instead of Ω and Lebesgue measure. An application of this result will be made in Chap. 3.

We now give some useful properties of uniformly convex spaces.

Proposition 1.5. *Let X be uniformly convex and let (x_k) be a sequence in X that converges weakly to $x \in X$, with $\|x_k\| \to \|x\|$. Then $\|x_k - x\| \to 0$.*

Proof. As the result is trivial if $x = 0$ we assume that $x \neq 0$; we may plainly also assume that for all $k \in \mathbb{N}$, $x_k \neq 0$. Put $\xi_k = 1 - \|x\| / \|x_k\|$; $\xi_k \to 0$ as $k \to \infty$. Set

$y_k = x_k / \|x_k\|$, $y = x/\|x\|$ and note that $y_k = (1-\xi_k)x_k/\|x\|$ converges weakly to y. Moreover, $\|y_k\| = \|y\| = 1$. By the Hahn–Banach theorem, there exists $y^* \in X^*$ such that $\langle y, y^* \rangle_X = 1 = \|y^*\|$. Hence

$$2 \geq \|y_k + y\| \geq \langle y_k + y, y^* \rangle_X \to 2\langle y, y^* \rangle_X = 2,$$

so that $\lim_{k\to\infty} \|y_k + y\| = 2$. Since X is uniformly convex, $\lim_{k\to\infty}\|y_k - y\| = 0$, and as $x_k - x = \|x_k\| y_k - \|x\| y$, it follows easily that $\|x_k - x\| \to 0$. ☐

Theorem 1.4. *Every uniformly convex space is reflexive.*

Proof. This classical result is due to D.P. Milman [98]; here we give the short proof contained in [88], Vol. II, Prop. 1.e.3. Suppose that X is uniformly convex, let $J : X \to X^{**}$ be the canonical map, let B, B^{**} be the closed unit balls in X, X^{**} respectively and denote by σ the weak topology $\sigma(X^{**}, X^*)$. Let $x^{**} \in X^{**}$, $\|x^{**}\| = 1$. Then since $J(B)$ is σ-dense in B^{**} (see [15], Chap. IV, Sect. 5), there is a generalised sequence $\{x_\alpha\}_{\alpha\in A}$ $(x_\alpha \in B)$ such that $Jx_\alpha \overset{\sigma}{\to} x^{**}$. Since $Jx_\alpha + Jx_\beta \overset{\sigma}{\to} 2x^{**}$, the weak lower-semicontinuity of the norm shows that $\lim_{\alpha,\beta} \left\|Jx_\alpha + Jx_\beta\right\| = 2$, and hence

$$\lim_{\alpha,\beta} \left\|x_\alpha + x_\beta\right\| = 2. \tag{1.11}$$

As X is uniformly convex, it follows from (1.11) that $\lim_{\alpha,\beta}\left\|x_\alpha - x_\beta\right\| = 0$, so that for some $x \in B$, $\lim_\alpha \|x_\alpha - x\| = 0$. Thus $\lim_\alpha \|Jx_\alpha - Jx\| = 0$ and hence $x^{**} = Jx$: X must be reflexive. ☐

Together with Proposition 1.4 this gives

Proposition 1.6. *Let K be a closed, convex, non-empty subset of a uniformly convex space X. Then K has a unique element of minimal norm.*

Now let X be uniformly convex and let $K \subset X$ be closed, convex and non-empty. Given any $x \in X$, the set $K - \{x\} := \{y - x : y \in K\}$ is closed and convex and so has a unique element $w(x)$ of minimal norm, by Proposition 1.6. Clearly $w(x) = z(x) - x$ for some unique $z(x) \in K$ and

$$\|z(x) - x\| = \inf\{\|y - x\| : y \in K\} = d(x, K).$$

In other words, there is a unique point $P_K x := z(x)$ of K such that $d(x,K) = \|x - P_K x\|$. The mapping $P_K : X \to K$ is called the *projection map of X onto K*; plainly $P_K x = x$ if and only if $x \in K$.

Proposition 1.7. *Let K be a closed, convex, non-empty subset of a uniformly convex space X. Then the projection map P_K is continuous.*

Proof. Suppose the result is false. Then there exist $x \in X$, a sequence (x_n) in X and $\varepsilon > 0$ such that $\lim_{n\to\infty} x_n = x$ and $\|P_K x_n - P_K x\| \geq \varepsilon$ for all $n \in \mathbb{N}$. Since $|d(x,K) - d(x_n,K)| \leq \|x_n - x\|$, it follows that

$$|\|x_n - P_K x_n\| - \|x - P_K x\|| \leq \|x_n - x\| \to 0 \text{ as } n \to \infty.$$

As $(P_K x_n)$ is bounded, it has a weakly convergent subsequence, still denoted by $(P_K x_n)$ for convenience, with weak limit z, say. Since K is closed and convex, it is weakly closed and so $z \in K$. Moreover, $x_n - P_K x_n \rightharpoonup x - z$ and

$$\|x - z\| \leq \liminf_{n\to\infty} \|x_n - P_K x_n\| = \|x - P_K x\|,$$

which implies that $z = P_K x$. Hence

$$x_n - P_K x_n \rightharpoonup x - P_K x \text{ and } \|x_n - P_K x_n\| \to \|x - P_K x\|.$$

By Proposition 1.5, the uniform convexity of X now implies that $x_n - P_K x_n \to x - P_K x$, so that $P_K x_n \to P_K x$: contradiction. □

If X is a Hilbert space H with inner product $(\cdot,\cdot)$, this last result can be sharpened, for then

$$\|P_K x - P_K y\| \leq \|x - y\| \text{ for all } x, y \in H.$$

To establish this, note that for all $w \in K$ and all $x \in H$,

$$\|x - P_K x\| \leq \|x - w\|.$$

Thus if $\lambda \in (0,1)$,

$$\|x - P_K x\|^2 \leq \|x - (1-\lambda) P_K x - \lambda P_K y\|^2 = \|x - P_K x + \lambda (P_K x - P_K y)\|^2.$$

Hence

$$0 \leq 2 \text{ re } (x - P_K x, P_K x - P_K y) + \lambda \|P_K x - P_K y\|^2.$$

Similarly,

$$0 \leq 2 \text{ re } (y - P_K y, P_K y - P_K x) + \lambda \|P_K x - P_K y\|^2.$$

Addition of these inequalities gives

$$\text{re } (x - y + P_K y - P_K x, P_K x - P_K y) \geq -\lambda \|P_K x - P_K y\|^2.$$

Letting $\lambda \to 0$ we see that

$$\text{re } (x - y, P_K y - P_K x) \geq \|P_K x - P_K y\|^2,$$

from which the result follows easily.

A map $\mu : [0,\infty) \to [0,\infty)$ that is continuous, strictly increasing and satisfies $\mu(0) = 0$, $\lim_{t\to\infty} \mu(t) = \infty$, is called a *gauge function*. A map J from a Banach space X to 2^{X^*}, the set of all subsets of X^*, is said to be a *duality map on X with gauge function* μ if

$$J(x) = \{x^* \in X^* : \langle x, x^* \rangle = \|x^*\| \|x\|, \|x^*\| = \mu(\|x\|)\}.$$

Note that by the Hahn–Banach theorem, for each $x \in X$ the set $J(x)$ is non-empty. It is also convex. To justify this, let $x^*, y^* \in J(x)$ and $\lambda \in (0,1)$. Put $z^* = \lambda x^* + (1-\lambda) y^*$ and observe that

$$\langle x, z^* \rangle = \lambda \langle x, x^* \rangle + (1-\lambda) \langle x, y^* \rangle = \mu(\|x\|) \|x\|.$$

Hence $\|z^*\| \geq \mu(\|x\|)$. However,

$$\|z^*\| \leq \lambda \|x^*\| + (1-\lambda) \|y^*\| = \mu(\|x\|)$$

and so $\|z^*\| = \mu(\|x\|)$. Thus $z^* \in J(x)$ and the proof is complete.

Let X be a Banach space with strictly convex dual X^* and let J be a duality map on X with gauge function μ. Then for each $x \in X$, the set $J(x)$ consists of precisely one point. In fact, for each $x \in X$, the points in $J(x)$ lie on the sphere in X^* with centre 0 and radius $\mu(\|x\|)$. If $J(x)$ contained two distinct points, the midpoint of the line segment joining them would be in the convex set $J(x)$, which is impossible as X^* is strictly convex.

In view of this result, we shall regard a duality map J on X as a map from X to X^* when X^* is strictly convex. It is known (see [19], pp. 42–43 and [94], p. 176) that if X and X^* are strictly convex, then J is an injective map of X onto X^* that is strictly monotone (that is, $\langle x-y, Jx-Jy \rangle > 0$ if $x, y \in X, x \neq y$); it is weakly continuous in the sense that if $x_k \to x_0$ in X, then Jx_k converges weak* in X^* to Jx_0 (the convergence is strong if, in addition, X^* is uniformly convex); the map $J^{-1} : X^* \to X$ is a duality map on X^* with gauge function μ^{-1} if, in addition, X is reflexive, X^{**} being identified with X. When X is a Hilbert space, so that X^* may be identified with X, the most natural duality map on X is the identity map, corresponding to the gauge function μ with $\mu(t) = t$.

When $1 < p < \infty$ and $\mu(t) = t^{p-1}$, it may be checked that the duality map J on $L_p(\Omega)$ (where Ω is, say, a domain in $\mathbb{R}^n$) with gauge function μ is given by

$$J(u) = |u|^{p-2} u. \tag{1.12}$$

The duality map J on l_p with the same gauge function μ is defined by $J((x_k)) = (|x_k|^{p-2} x_k)$. Duality maps on Sobolev spaces will be discussed later.

Next we turn to differentiability. Let F be a real-valued function on a Banach space X. We say that F is *Gâteaux-differentiable* at $x_0 \in X$ if there exists $x^* \in X^*$ such that

$$\langle h, x^* \rangle = \lim_{t \to 0} \frac{F(x_0 + th) - F(x_0)}{t} \text{ for all } h \in X. \tag{1.13}$$

The limit above is called the *derivative of F in the direction h*; the functional x^* is denoted by grad $F(x_0)$ and will be referred to as the *gradient* or *Gâteaux derivative* of F at x_0. Another notion of differentiability of F is that of Fréchet: F is said to be *Fréchet-differentiable* at x_0 if there exists a functional $F'(x_0) \in X^*$, called the (Fréchet) derivative of F at x_0, such that

$$\frac{|F(x_0+h)-F(x_0)-\langle h, F'(x_0)\rangle|}{\|h\|} \to 0 \text{ as } \|h\| \to 0. \tag{1.14}$$

Clearly Fréchet-differentiability implies Gâteaux-differentiability, with equality of grad $F(x_0)$ and $F'(x_0)$; in the reverse direction, it can be shown that if grad $F(x)$ exists throughout some neighbourhood of x_0 and is continuous at x_0, then F is Fréchet-differentiable at x_0 and grad $F(x_0) = F'(x_0)$. As Gâteaux derivatives are often easier to calculate than Fréchet derivatives, this result is quite useful.

The case when $F(x) = \|x\|$ $(x \in X)$ is of particular interest.

Proposition 1.8. *Let X be a Banach space with norm $\|\cdot\|$. Then $\|\cdot\|$ is Gâteaux-differentiable on $X\backslash\{0\}$ if and only if X^* is strictly convex.*

Proof. For the moment we suppose that X is real. Let $x, h \in X$. If $0 < s < t$, then the convexity of $y \mapsto \|x+y\|$ implies that

$$\|x+sh\|-\|x\| = \left\|x+\frac{s}{t}th+(1-\frac{s}{t})\cdot 0\right\| - \|x\| \leq \frac{s}{t}\|x+th\| - \|x\|,$$

which shows that $t \mapsto t^{-1}(\|x+th\|-\|x\|)$ is monotone increasing in $t>0$. Moreover, $t^{-1}(\|x+th\|-\|x\|)$ is bounded below, for use of the triangle inequality shows that

$$t^{-1}(\|x+th\|-\|x\|) \geq -\|h\|.$$

Hence $\phi_+(h) := \lim_{t\to 0+} t^{-1}(\|x+th\|-\|x\|)$ exists for all $x, h \in X$, as does $\phi_-(h) := \lim_{t\to 0+} t^{-1}(\|x\|-\|x-th\|)$. Since

$$\|x+th\|-\|x\| \geq \|x\|-\|x-th\|,$$

we see that $\phi_-(h) \leq \phi_+(h)$.

If $x^* \in X^*$ is such that $\|x^*\| = 1$ and $\langle x, x^*\rangle = \|x\|$, then

$$\langle h, x^*\rangle = \frac{\langle x-x+th, x^*\rangle}{t} \geq \frac{\|x\|-\|x-th\|}{t},$$

and so $\phi_-(h) \leq \langle h, x^*\rangle$; similarly, $\langle h, x^*\rangle \leq \phi_+(h)$. Put

$$M^*(x) = \{x^* \in X^* : \phi_-(h) \leq \langle h, x^*\rangle \leq \phi_+(h) \text{ for all } h \in X\}.$$

We claim that

$$M^*(x) = \{x^* \in X^* : \|x^*\| = 1 \text{ and } \langle x, x^*\rangle = \|x\|\}.$$

To justify this, let $x^* \in M^*(x)$ and observe that $\phi_-(x) \leq \langle x, x^* \rangle \leq \phi_+(x)$, while clearly $\phi_-(x) = \phi_+(x) = \|x\|$. Hence $\langle x, x^* \rangle = \|x\|$ and also $\|x^*\| = 1$. The claim is justified.

Now suppose that $\|\cdot\|$ is Gâteaux-differentiable on $X \backslash \{0\}$ and let $x \in X \backslash \{0\}$. Then the functionals ϕ_- and ϕ_+ introduced above coincide, which implies that $\langle h, x^* \rangle = \phi_-(h)$ for all $h \in X$ and hence that $M^*(x)$ has exactly one element. By Proposition 1.3, X^* is strictly convex.

Conversely, suppose that X^* is strictly convex and let $x \in X \backslash \{0\}$. Then $M^*(x)$ consists of a single element, x^* say. We claim that this implies that $x^* = \phi_- = \phi_+$. For fixed $y_0 \in X$ define a functional x_1^* on the space spanned by y_0 according to the prescription $\langle \lambda y_0, x_1^* \rangle = \lambda \phi_+(y_0)$. If $\lambda \geq 0$, $\phi_+(\lambda y_0) = \lambda \phi_+(y_0)$, while if $\lambda < 0$,

$$\lambda \phi_+(y_0) = -|\lambda| \phi_+(y_0) = |\lambda| \phi_-(-y_0) \leq |\lambda| \phi_+(-y_0) = \phi_+(\lambda y_0).$$

Hence $\langle \lambda y_0, x_1^* \rangle \leq \phi_+(\lambda y_0)$ for all $\lambda \in \mathbb{R}$. Moreover, ϕ_+ is subadditive, since for $0 < t \leq s$,

$$\begin{aligned}\phi_+(y_1 + y_2) &\leq (t/2)^{-1} \left\{ \left\| x + \frac{t}{2} y_1 + \frac{t}{2} y_2 \right\| - \|x\| \right\} \\ &= t^{-1} \{ \|2x + t y_1 + t y_2\| - 2\|x\| \} \\ &\leq t^{-1} \{ \|x + t y_1\| - \|x\| \} + s^{-1} \{ \|x + s y_2\| - \|x\| \}.\end{aligned}$$

It follows from the Hahn–Banach theorem that there is a linear extension $x_0^* \in X^*$ of x_1^* such that $\langle y, x_0^* \rangle \leq \phi_+(y)$ on X. Thus $|\langle y, x_0^* \rangle| \leq \|y\|$ for all $y \in X$ and so $x_0^* \in X^*$. Moreover, $\langle -y, x_0^* \rangle \geq -\phi_+(y) = \phi_-(y)$ on X : we conclude that $x_0^* = x^*$. Repetition of this argument with ϕ_- instead of ϕ_+ shows that $\phi_-(y) = \langle y, x^* \rangle = \phi_+(y)$ for all $y \in X$, which means that $\|\cdot\|$ is Gâteaux-differentiable on $X \backslash \{0\}$.

When X is complex the arguments are similar, with re x^* instead of x^*. □

Remark 1.2. (i) Proposition 1.8 leads to the description as *smooth* those spaces X for which X^* is strictly convex; the arguments above show that for such spaces X, if $x \in X \backslash \{0\}$, then grad $\|x\|$ is the unique element $x^* \in X^*$ such that $\langle x, x^* \rangle = \|x\|$ and $\|x^*\| = 1$. This implies that the map $J : X \to X^*$ given by $Jx = \mu(\|x\|)\text{grad}\,\|x\|$ $(x \neq 0)$, $J0 = 0$, is the duality map on X with gauge function μ.

(ii) If X^* is uniformly convex and X is real, it can be shown (see, for example, [96], Lemma II.5.7) that grad $\|x\|$ is the Fréchet derivative of $\|\cdot\|$ at x for each $x \in X \backslash \{0\}$.

The Gâteaux derivative of the norm is quite easy to determine directly in some important cases. For example, suppose that $1 < p < \infty$ and consider the sequence space l_p, with norm $\|x\| = \left(\sum_1^\infty |x_k|^p\right)^{1/p}$. It is easy to see that as $t \to 0$, then for all $x, h \in X$ with $x \neq 0$,

$$t^{-1} \sum_1^\infty \{ |x_k + t h_k|^p - |x_k|^p \} \to p \sum_1^\infty |x_k|^{p-1} \text{ sgn } x_k \cdot h_k.$$

From this we have

$$\text{grad } \|x\| = p^{-1}\|x\|^{1-p} \text{ grad } \|x\|^p = \left(\|x\|^{1-p}|x_k|^{p-1} \text{ sgn } x_k\right), x \neq 0. \tag{1.15}$$

In a similar way it can be shown that the Gâteaux derivative of the norm $\|x\| = \left(\int_\Omega |x(\xi)|^p d\xi\right)^{1/p}$ on $L_p(\Omega)$, where Ω is, for example, an open subset of $\mathbb{R}^n$, is given by

$$(\text{grad } \|x\|)(\xi) = \|x\|^{1-p}|x(\xi)|^{p-1}\text{sgn } x(\xi), \xi \in \Omega. \tag{1.16}$$

Of course, (1.15) and (1.16) also follow immediately from our earlier calculations of duality maps for l_p and $L_p(\Omega)$.

Further illustrations of the usefulness of Proposition 1.8 can be given by means of polar sets. Given any closed linear subspace M of X, we write

$$M^0 = \{x^* \in X^* : \langle x, x^*\rangle_X = 0 \text{ for all } x \in M\},$$

and call this the polar set of M; similarly, if N is a closed linear subspace of X^*, we set

$${}^0N = \{x \in X : \langle x, x^*\rangle_X = 0 \text{ for all } x^* \in N\}.$$

Corresponding notation is used with respect to linear subspaces of other Banach spaces and their duals. The polar set M^0 of any closed linear subspace M of X is isometrically isomorphic to $(X/M)^*$: in fact, with the canonical map of X onto X/M denoted by ϕ, the adjoint ϕ^* of ϕ is an isometric isomorphism of $(X/M)^*$ onto M^0 (see, for example, [15], Chap. IV, Section 5, Prop. 9). Note also that if X is reflexive, then $(M^0)^*$ is isometrically isomorphic to X/M and X/M is reflexive.

Proposition 1.9. *Let M be a closed linear subspace of a reflexive Banach space X. If X is strictly convex, so are M and X/M; if X^* is strictly convex, so are $(X/M)^*$ and M^0.*

Proof. Suppose first that X is strictly convex. Then clearly so is M. Since X is reflexive, the norm on X^*, and hence that on M^0 and thus on $(X/M)^*$ (which is isometrically isomorphic to M^0) is Gâteaux-differentiable at all non-zero points. Hence by Proposition 1.8, the reflexive space X/M is strictly convex. If X^* is strictly convex, then so is its closed subspace M^0, and as $(X/M)^*$ is isometrically isomorphic to M^0, the result follows. □

Remark 1.3. In [32] the relationship between uniform convexity of a Banach space X and that of its quotient spaces is analysed. Let $\mathscr{M}$ be the family of all closed linear subspaces $M \neq \{0\}$ of X. It turns out that X is uniformly convex if and only if all the quotient spaces X/M $(M \in \mathscr{M})$ are uniformly convex, with a common modulus of convexity; the same holds if $\mathscr{M}$ is replaced by $\{M \in \mathscr{M} : \dim(X/M) = 2\}$. This paper also discusses the interaction between uniform convexity and dual spaces. To explain this, we introduce the modulus of smoothness of X : this is the function $\rho_X : (0,\infty) \to [0,\infty)$ defined by

$$\rho_X(\varepsilon) = \sup\left\{ \frac{\|x+y\|+\|x-y\|}{2} - 1 : \|x\| = 1, \|y\| = \varepsilon \right\}.$$

Since

$$2\|x\| = \|(x+y)+(x-y)\| \leq \|x+y\| + \|x-y\|$$

it follows that $\rho_X(\varepsilon) \geq 0$.

The space X is called *uniformly smooth* if

$$\lim_{\varepsilon \to 0} \rho_X(\varepsilon)/\varepsilon = 0.$$

Note that in the definition of $\rho_X(\varepsilon)$ the supremum may be taken over all $x, y \in X$ with $\|x\| \leq 1$ and $\|y\| \leq \varepsilon$ without affecting the outcome. Uniform smoothness means that if x and y are on the unit sphere and lie in a narrow cone, then $\|x+y\|$ is close to 2; loosely speaking, the unit ball of X does not have any corners. Hilbert spaces H are the 'most' uniformly smooth spaces in the sense that

$$\rho_X(\varepsilon) \geq \rho_H(\varepsilon) \text{ for all } \varepsilon > 0.$$

Observe also that X is uniformly smooth if and only if

$$\lim_{t \to 0} \frac{\|x+ty\| - \|x\|}{t} \text{ exists, uniformly on } \{(x,y) : \|x\| = \|y\| = 1\}.$$

The main result of [32] is that X is uniformly convex (respectively, uniformly smooth) if and only if X^* is uniformly smooth (respectively, uniformly convex). For a discussion of this and related notions we refer to [33] (Chap. VII, Sect. 2), [3] and [107], 5.5.2. Further insight may be obtained by means of the concept of super-reflexivity. To explain this we need some terminology: given Banach spaces X and Y, the space X is said to be *finitely representable in* Y if, for each finite-dimensional subspace X_n of X and each $\lambda > 1$, there is an isomorphism T_n of X_n into Y for which

$$\lambda^{-1}\|x\|_X \leq \|T_n x\|_Y \leq \lambda\|x\|_X \text{ for all } x \in X_n.$$

A Banach space X is called *super-reflexive* if no nonreflexive Banach space is finitely representable in X. Each of the following properties is equivalent to super-reflexivity of X (see, for example, [107], 5.5.2.4) :

(a) X^* is super-reflexive.
(b) X has an equivalent norm with respect to which it is uniformly convex.
(c) X^* has an equivalent norm with respect to which it is uniformly convex.
(d) X has an equivalent norm with respect to which it is uniformly smooth.

Given a super-reflexive Banach space X with a Schauder basis $(x_n)_{n\in\mathbb{N}}$, where $\|x_n\|_X = 1$ for all $n \in \mathbb{N}$, it can be shown (see [76] and [70]; see also [61], Chap. 9, Theorem 9.25) that there exist $p, q \in (1, \infty)$ and $K > 0$ such that for every $x = \sum_{n=1}^{\infty} \alpha_n x_n \in X$,

$$K^{-1}\left(\sum_{n=1}^{\infty}|\alpha_n|^q\right)^{1/q} \le \|x\|_X \le K\left(\sum_{n=1}^{\infty}|\alpha_n|^p\right)^{1/p}.$$

In particular, if X is uniformly convex, then there exists $q \in (1,\infty)$ such that for every $x \in X$ the biorthogonal functionals x_n^* corresponding to the x_n satisfy $(x_n^*(x)) \in l_q$.

We see from the proof of Proposition 1.8 that given any Banach space X and any $x,h \in X$, then

$$(x,h)_+ := \|x\| \lim_{t\to 0+} t^{-1}(\|x+th\|-\|x\|) \text{ and } (x,h)_- := \lim_{t\to 0+} t^{-1}(\|x\|-\|x-th\|) \tag{1.17}$$

both exist. Now suppose that $\|\cdot\|$ is Gâteaux-differentiable on $X\backslash\{0\}$. Then $(x,h)_+ = (x,h)_-$ for all $x,h \in X$; we define $(x,h)_X$ to be this common value and call it the *semi-inner product* of x and h. Thus

$$(x,h)_X = \|x\| \langle h, \text{grad } \|x\|\rangle_X, \text{ for } x,h \in X,\ x \neq 0. \tag{1.18}$$

We define $(0,h)_X = 0$ for all $h \in X$. Note that $(x,h)_X$ depends linearly on h and that $(x,x)_X = \|x\|^2$; however, in general, $(x,h)_X \neq (h,x)_X$. By way of illustration we note that when $X = L_p(\Omega)$ and $1 < p < \infty$,

$$(x,h)_X = \|x\|^{2-p}\int_{\Omega}|x(\xi)|^{p-2}\overline{x(\xi)}h(\xi)d\xi. \tag{1.19}$$

This leads us to the notion of orthogonality of elements of a Banach space. Following James [75], we give

Definition 1.1. Let X be a Banach space and let $x,h \in X$. Then x is said to be orthogonal to h, written $x \perp h$, if

$$\|x+\lambda h\| \ge \|x\| \text{ for all } \lambda \in \mathbb{R}; \tag{1.20}$$

x is orthogonal to a subset H of X if $x \perp h$ for all $h \in H$. Orthogonality of subsets M_1, M_2 of X, written $M_1 \perp M_2$, is defined in the obvious way.

Note that in general orthogonality is not symmetric, that is, $x \perp h$ does not imply $h \perp x$. Indeed (see [75]), if X is strictly convex with $\dim X \ge 3$, then if orthogonality is symmetric, X must be an inner-product space.

The linkage between orthogonality and semi-inner products is given by the next result, contained in [75].

Theorem 1.5. *Let X be a Banach space with norm $\|\cdot\|$ that is Gâteaux-differentiable at every non-zero point, and let $x,h \in X$. Then $x \perp h$ if and only if $(x,h)_X = 0$. Moreover, given $x \in X\backslash\{0\}$ and $y \in X$, there is precisely one $\lambda \in \mathbb{R}$ such that $x \perp \lambda x + y$ and this is given by*

$$\langle y, grad\ \|x\|\rangle = -\lambda\,\|x\|. \tag{1.21}$$

Finally we mention decompositions of X and X^*, involving this notion of orthogonality, given by Alber [2]. We say that X is the James orthogonal sum of closed linear subspaces M_1, M_2, written $X = M_1 \uplus M_2$, if (a) each $x \in X$ has a unique decomposition $x = m_1 + m_2$, where $m_1 \in M_1$, $m_2 \in M_2$; (b) $M_1 \cap M_2 = \{0\}$; (c) $M_1 \perp M_2$. His result is the following

Theorem 1.6. *Let M be a closed linear subspace of a uniformly convex and uniformly smooth Banach space X; denote by $J_X : X \to X^*$ the duality map with gauge function μ given by $\mu(t) = t$ $(t \geq 0)$. Then*

$$X = M \uplus J_X^{-1} M^0 \text{ and } X^* = M^0 \uplus J_X M.$$

Further decomposition results will be given in the next section.

1.3 Representations of Compact Linear Operators

Let H be a Hilbert space and suppose that $A : H \to H$ is compact and self-adjoint. Then for all $x \in H$,

$$Ax = \sum_n \lambda_n (x, \phi_n) \phi_n,$$

where the λ_n are eigenvalues of A, each repeated according to multiplicity and ordered by decreasing modulus, while the ϕ_n are orthonormal eigenvectors of A corresponding to the eigenvalues λ_n; here $(\cdot,\cdot)$ denotes the inner product in H. Moreover, if the kernel of A is trivial, then the ϕ_n form a complete orthonormal set in H. All this is classical, as is its extension (by Erhard Schmidt) to arbitrary compact linear operators acting between (possibly different) Hilbert spaces; for details of the proofs see [41], Chap. II, Sect. 5, for example. It turns out (see [44]) that results of a broadly similar character to these can be obtained in a Banach space setting, under some restrictions on the spaces; we describe this work below and make applications in later chapters.

Throughout this section it will be supposed that X and Y are real, reflexive Banach spaces with norms $\|\cdot\|_X$ and $\|\cdot\|_Y$, respectively, and that $T : X \to Y$ is compact and linear. The results to be given also hold for complex spaces, but with minor technical complications in the proofs that we prefer to avoid here. We begin with a simple result.

Proposition 1.10. *There exists $x_1 \in X$, with $\|x_1\|_X = 1$, such that $\|T\| = \|Tx_1\|_Y$.*

Proof. We may assume that $T \neq 0$ as otherwise the result is obvious. Let $\{w_k\}$ be a sequence of elements of X with $\|w_k\|_X = 1$ for all $k \in \mathbb{N}$ and $\lim_{k\to\infty} \|Tw_k\|_Y = \|T\|$. Since $\{w_k\}$ is bounded and X is reflexive, there is a weakly convergent subsequence of $\{w_k\}$, still denoted by $\{w_k\}$ for convenience, with weak limit $w \in X$. As T is compact, $Tw_k \to Tw$. Thus $\|w\|_X \leq \liminf_{k\to\infty} \|w_k\|_X = 1$ and $\|Tw\|_Y = \|T\|$, from which it is immediate that $\|w\|_X = 1$. Now take $x_1 = w$. $\square$

2. Curved Space-time

- photons propagate along geodesic curves:

$$\boxed{\frac{\mathrm{d}^2 x^\mu}{\mathrm{d}\lambda^2} + \Gamma^\mu{}_{\nu\rho}\,\frac{\mathrm{d}x^\nu}{\mathrm{d}\lambda}\,\frac{\mathrm{d}x^\rho}{\mathrm{d}\lambda} = 0}$$

($\Gamma^\mu{}_{\nu\rho}$: Christoffel symbols; λ: affine parameter)

- photon momentum can be written:

$$\boxed{p^\mu = \frac{\mathrm{d}x^\mu}{\mathrm{d}\lambda}}$$

- weakly perturbed metric ($c^2\,\Phi$: Newtonian potential):

$$\boxed{\mathrm{d}s^2 = (1 + 2\,\Phi)\;\mathrm{d}t^2 - S^2(t)\;(1 - 2\,\Phi)\;\mathrm{d}\vec{x}^{\,2}}$$

- change of photon momentum:

$$\boxed{\frac{1}{p}\frac{\mathrm{d}p}{\mathrm{d}t} = -\left(\frac{1}{S(t)}\frac{\mathrm{d}S}{\mathrm{d}t} - \frac{\partial\Phi}{\partial t} + \frac{c}{S(t)}\,\vec{\gamma}\,\frac{\partial\Phi}{\partial\vec{x}}\right)}$$

with $\gamma^i = p^i/|\vec{p}\,|$

3. Collision Terms

- collisions between photons and electrons: Compton scattering
- photon energy at recombination: $k_{\mathrm{B}}T \sim 0.3\ \mathrm{eV} \ll m_e c^2$; Compton scattering can be approximated by Thomson scattering:

$$\boxed{\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{3}{16\pi}\,\sigma_{\mathscr{T}}\left(1+\cos^2\theta\right)}$$

- collision term:

$$\boxed{C[f] = \frac{3}{16\pi}\,\sigma_{\mathscr{T}}\,c\,n_e\int(f'-f)\left(1+\cos^2\theta\right)\mathrm{d}^2\Omega}$$

- additional equations describing matter flow: hydrodynamic equations (continuity, Euler equation)

Curvature

The second covariant derivative $\nabla\nabla\Phi$ is a $\binom{0}{2}$ tensor, the components of which can be computed using Eq. 3.35

$$\nabla_\beta\nabla_\alpha\Phi \equiv \Phi_{,\beta;\alpha} = \Phi_{,\beta,\alpha} - \Phi_{,\mu}\Gamma^{\mu}_{\beta\alpha}\,. \tag{3.37}$$

In a LIF, since $\Gamma^{\mu}_{\beta\alpha} = 0$, covariant and ordinary derivative coincide, and Eq. 3.37 becomes

$$\nabla_\alpha\nabla_\beta\Phi = \Phi_{,\beta;\alpha} = \Phi_{,\beta,\alpha}\,, \tag{3.38}$$

and since ordinary partial derivatives commute, i.e. $\Phi_{,\beta,\alpha} = \Phi_{,\alpha,\beta}$, it follows that in a LIF

$$\nabla_\alpha\nabla_\beta\Phi = \nabla_\beta\nabla_\alpha\Phi\,. \tag{3.39}$$

This equation shows that the tensor $\nabla\nabla\Phi$ is symmetric, and since symmetry is a tensorial property, it must hold in any frame; therefore from Eqs. 3.39 and 3.37 we find

$$\Phi_{,\beta,\alpha} - \Phi_{,\mu}\Gamma^{\mu}_{\beta\alpha} = \Phi_{,\alpha,\beta} - \Phi_{,\mu}\Gamma^{\mu}_{\alpha\beta} \tag{3.40}$$

in any coordinate system. It follows that for any Φ

$$\Phi_{,\mu}\Gamma^{\mu}_{\beta\alpha} = \Phi_{,\mu}\Gamma^{\mu}_{\alpha\beta}\,, \tag{3.41}$$

and consequently

$$\Gamma^{\mu}_{\beta\alpha} = \Gamma^{\mu}_{\alpha\beta}\,, \tag{3.42}$$

i.e. *Christoffel's symbols are symmetric in the lower indices.*

3.4 TRANSFORMATION RULES FOR CHRISTOFFEL'S SYMBOLS

According to Eq. 1.38 (or to Eq. 3.9), Christoffel's symbols are

$$\Gamma^{\rho}_{\tau\sigma} = \frac{\partial x^\rho}{\partial \xi^\mu}\frac{\partial^2 \xi^\mu}{\partial x^\tau \partial x^\sigma}\,.$$

Let us consider a general coordinate transformation $x^\mu = x^\mu(x^{\alpha'})$. In the new frame Christoffel's symbols are

$$\begin{aligned}
\Gamma^{\lambda'}_{\mu'\nu'} &= \frac{\partial x^{\lambda'}}{\partial \xi^\alpha}\frac{\partial^2 \xi^\alpha}{\partial x^{\mu'}\partial x^{\nu'}} = \\
&= \frac{\partial x^{\lambda'}}{\partial x^\rho}\frac{\partial x^\rho}{\partial \xi^\alpha}\frac{\partial}{\partial x^{\mu'}}\left(\frac{\partial \xi^\alpha}{\partial x^\sigma}\frac{\partial x^\sigma}{\partial x^{\nu'}}\right) = \\
&= \frac{\partial x^{\lambda'}}{\partial x^\rho}\frac{\partial x^\rho}{\partial \xi^\alpha}\left[\frac{\partial^2 \xi^\alpha}{\partial x^\tau \partial x^\sigma}\frac{\partial x^\tau}{\partial x^{\mu'}}\frac{\partial x^\sigma}{\partial x^{\nu'}} + \frac{\partial \xi^\alpha}{\partial x^\sigma}\frac{\partial^2 x^\sigma}{\partial x^{\mu'}\partial x^{\nu'}}\right] = \\
&= \frac{\partial x^{\lambda'}}{\partial x^\rho}\frac{\partial x^\tau}{\partial x^{\mu'}}\frac{\partial x^\sigma}{\partial x^{\nu'}}\Gamma^{\rho}_{\tau\sigma} + \frac{\partial x^{\lambda'}}{\partial x^\rho}\frac{\partial^2 x^\rho}{\partial x^{\mu'}\partial x^{\nu'}}\,.
\end{aligned} \tag{3.43}$$

It should be noted that if Christoffel's symbols were the components of a tensor, only the first term in the last row of Eq. 3.43 would be present (see Eq. 2.158). Therefore, as pointed out in Sec. 3.1, Christoffel's symbols are not the components of a tensor.

However, the $\Gamma^{\gamma}_{\alpha\beta}$'s transform as tensors for *linear transformations*, i.e. for coordinate transformations of the form $x'^\mu = \Lambda^{\mu'}{}_\alpha x^\alpha$ where $\Lambda^{\mu'}{}_\alpha$ are constants. Indeed in this case $\frac{\partial^2 x^\rho}{\partial x^{\mu'}\partial x^{\nu'}} = 0$.

Box 3-B

Exercise

Compute Christoffel's symbols $\Gamma^{\mu}_{\alpha\beta}$ using the affine connection

$$\frac{\partial \vec{e}_{(\alpha)}}{\partial x^{\beta}} = \Gamma^{\mu}_{\alpha\beta}\vec{e}_{(\mu)}\,. \tag{3.44}$$

Let us consider for example a two-dimensional flat space in polar coordinates, i.e. $(x^{1'}, x^{2'}) \equiv (r, \theta)$; the basis vectors are related to the coordinate basis associated to Cartesian coordinates by Eqs. 2.73

$$\begin{aligned} \vec{e}_{(1')} &= \vec{e}_{(r)} = \cos\theta\vec{e}_{(1)} + \sin\theta\vec{e}_{(2)}\,, \\ \vec{e}_{(2')} &= \vec{e}_{(\theta)} = -r\sin\theta\vec{e}_{(1)} + r\cos\theta\vec{e}_{(2)}\,. \end{aligned} \tag{3.45}$$

We shall indicate $(\vec{e}_{(1)}, \vec{e}_{(2)})$ with $(\vec{e}_{(x)}, \vec{e}_{(y)})$, and $(\vec{e}_{(1')}, \vec{e}_{(2')})$ with $(\vec{e}_{(r)}, \vec{e}_{(\theta)})$. From Eqs. 3.45 we find

$$\frac{\partial \vec{e}_{(r)}}{\partial r} = \frac{\partial}{\partial r}(\cos\theta\vec{e}_{(x)} + \sin\theta\vec{e}_{(y)}) = 0\,, \tag{3.46}$$

and consequently, from Eq. 3.44

$$\Gamma^{\mu}_{rr}\vec{e}_{(\mu)} = \Gamma^{r}_{rr}\vec{e}_{(r)} + \Gamma^{\theta}_{rr}\vec{e}_{(\theta)} = 0 \longrightarrow \Gamma^{r}_{rr} = \Gamma^{\theta}_{rr} = 0\,. \tag{3.47}$$

Moreover

$$\begin{aligned} \frac{\partial \vec{e}_{(r)}}{\partial \theta} &= \frac{\partial}{\partial \theta}(\cos\theta\vec{e}_{(x)} + \sin\theta\vec{e}_{(y)}) = \\ &= -\sin\theta\vec{e}_{(x)} + \cos\theta\vec{e}_{(y)} = \frac{1}{r}\vec{e}_{(\theta)}\,; \end{aligned}$$

therefore

$$\frac{1}{r}\vec{e}_{(\theta)} = \Gamma^{\mu}_{r\theta}\vec{e}_{(\mu)} = \Gamma^{r}_{r\theta}\vec{e}_{(r)} + \Gamma^{\theta}_{r\theta}\vec{e}_{(\theta)} \longrightarrow \Gamma^{r}_{r\theta} = 0 \;\;,\;\; \Gamma^{\theta}_{r\theta} = \frac{1}{r}\,. \tag{3.48}$$

Proceeding along these lines it is easy to show that

$$\Gamma^{r}_{\theta r} = 0\,,\; \Gamma^{\theta}_{\theta r} = \frac{1}{r}\,,\; \Gamma^{r}_{\theta\theta} = -r\,,\; \Gamma^{\theta}_{\theta\theta} = 0\,. \tag{3.49}$$

3.5 THE COVARIANT DERIVATIVE OF TENSORS

Following the approach adopted in Sec. 3.2 we shall now define the covariant derivative of tensors of any rank. Let us consider, as an example, the covariant derivative of a $\binom{0}{2}$ tensor. Given the tensor $\mathbf{T} = T_{\alpha\beta}\,\tilde{\omega}^{(\alpha)} \otimes \tilde{\omega}^{(\beta)}$ and a vector $\vec{V}$, let $\tilde{q}$ be the one-form obtained by contracting $\mathbf{T}$ with $\vec{V}$, i.e., in components

$$q_{\alpha} = T_{\alpha\beta}V^{\beta}\,. \tag{3.50}$$

According to Eq. 3.35 the covariant derivative of $\tilde{q}$ is a $\binom{0}{2}$ tensor with components

$$\nabla_{\mu}q_{\alpha} = q_{\alpha,\mu} - \Gamma^{\sigma}_{\mu\alpha}q_{\sigma}\,, \tag{3.51}$$

This is a tensor equation, and must hold in any coordinate frame; therefore, in a generic frame the equation of motion of the free particle is

$$u^\alpha u^\mu{}_{;\alpha} = 0\,. \tag{3.121}$$

If we expand the covariant derivative

$$u^\alpha u^\mu{}_{;\alpha} = u^\alpha u^\mu{}_{,\alpha} + u^\alpha \Gamma^\mu{}_{\alpha\beta} u^\beta\,, \tag{3.122}$$

and replace $u^\mu = dx^\mu/d\lambda$, Eq. 3.121 becomes

$$\frac{d^2x^\mu}{d\lambda^2} + \Gamma^\mu_{\alpha\beta}\frac{dx^\alpha}{d\lambda}\frac{dx^\beta}{d\lambda} = 0\,, \tag{3.123}$$

which is the geodesic equation, Eq. 3.114. Thus, the geodesic equation can also be written in the form 3.121, which describes the parallel transport of the tangent vector $\vec{u}$ along the geodesic. This means that if we parallely transport the tangent vector from a point $\mathbf{p}$ to a point $\mathbf{p}'$ along the geodesic line, the transported vector in $\mathbf{p}'$ will be tangent to the curve. Consequently, a curve $\mathcal{C}$ with tangent vector $\vec{u}$ is a geodesic if

$$\nabla_{\vec{u}}\ \vec{u} = 0\,. \tag{3.124}$$

Therefore, *geodesics are those curves which parallel-transport their own tangent vectors.*

The parameter along the geodesic is not unique. Let s be a new parameter; since $\frac{d}{d\lambda} = \frac{d}{ds}\frac{ds}{d\lambda}$, Eq. 3.123 becomes

$$\frac{d^2x^\alpha}{ds^2} + \Gamma^\alpha_{\mu\nu}\left[\frac{dx^\mu}{ds}\frac{dx^\nu}{ds}\right] = -\left[\frac{d^2s}{d\lambda^2}\Big/\left(\frac{ds}{d\lambda}\right)^2\right]\frac{dx^\alpha}{ds}\,. \tag{3.125}$$

This equation reduces to Eq. 3.123 only if s is related to λ by a linear transformation

$$s = a\lambda + b, \qquad a, b = \text{const}\,, \tag{3.126}$$

in which case the right-hand side of Eq. 3.125 vanishes. The parameters for which the geodesic equation takes the form 3.123 are called **affine parameters** and are all related by a linear transformation.

Eq. 3.121 describes timelike, spacelike, and null geodesics. If the geodesic is timelike, i.e. $\vec{u}\cdot\vec{u} < 0$, it represents the wordline of a massive particle; in this case, by performing the linear transformation in Eq. 3.126 it is possible to change the affine parameter in such a way that the new parameter is the particle proper time (see Box 2-F) multiplied by c, i.e. the parameter τ appearing in Eq. 3.114. With this choice, $\vec{u}\cdot\vec{u} = -1$. If the geodesic is a null curve, i.e. $\vec{u}\cdot\vec{u} = 0$, it represents the wordline of a massless particle; in this case it is not possible to choose the proper time as affine parameter, because it cannot be defined; the geodesic can be parametrized with a different affine parameter, for instance with the arc length. If the geodesic is spacelike, i.e. $\vec{u}\cdot\vec{u} > 0$, it does not represent the worldline of a physical particle.

3.9 FERMI COORDINATES

In this section we shall show how to construct a coordinate frame adapted to an observer. This frame is especially useful to describe physical experiments.

An observer in General Relativity is characterized by a timelike curve, $\tau \mapsto \gamma(\tau)$, where τ is the proper time (times c). The tangent vector to the curve is the four-velocity of the

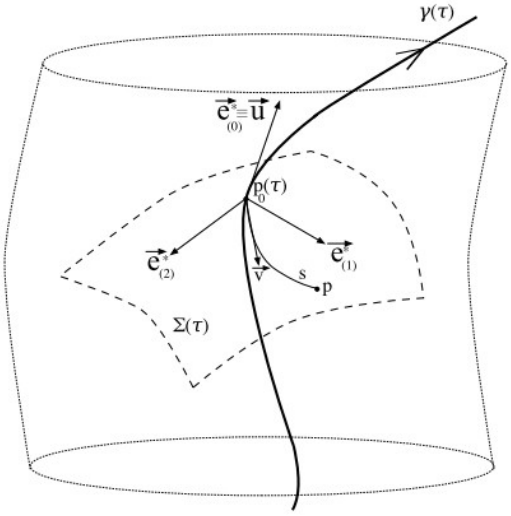

Figure 3.5: Fermi coordinates adapted to an observer. For simplicity, we do not show one of the three space dimensions.

observer $\vec{u}$, and $\vec{u} \cdot \vec{u} = -1$. The observer can either be freely-falling (i.e. with vanishing acceleration $a^\mu = u^\nu u^\mu{}_{;\nu} = 0$) or accelerated ($a^\mu \neq 0$).

It is possible to define, in a region close to the curve (a "worldtube" surrounding γ), coordinates $\{x^{*\mu}\}$ adapted to the observer, called the *Fermi coordinates*, as follows (see Fig. 3.5):

- At any point of the curve $\mathbf{p}_0(\tau) \in \gamma$, we can define a basis $\{\vec{e}^{\,*}_{(\mu)}\}$ of the vector space $\mathbf{T}_{\mathbf{p}_0}$ such that $\vec{e}^{\,*}_{(0)} \equiv \vec{u}$, and $\vec{e}^{\,*}_{(i)}$ $(i = 1, \ldots, 3)$ are orthogonal to $\vec{e}^{\,*}_{(0)}$ and to each other. In addition, we impose that $\vec{e}^{\,*}_{(i)}$ have norm one. Thus, the basis is orthonormal ($\vec{e}^{\,*}_{(\mu)} \cdot \vec{e}^{\,*}_{(\nu)} = \eta_{\mu\nu}$), and the timelike basis vector coincides with the four-velocity of the observer.

- At each value of τ, the three spacelike vectors $\vec{e}^{\,*}_{(i)}$ locally define a three-dimensional spacelike surface Σ, to which they are tangent in $\mathbf{p}_0(\tau)$.

- Given a point $\mathbf{p}$ in the worldtube, such that $\mathbf{p} \in \Sigma(\tau)$, let us consider a spacelike geodesic from $\mathbf{p}_0(\tau)$ to $\mathbf{p}$ on the surface $\Sigma(\tau)$. Let $\vec{v}$ be the tangent vector in $\mathbf{p}_0(\tau)$ to this geodesic with unit length. Since the geodesic belongs to $\Sigma(\tau)$, $\vec{v}$ is a linear combination of the three spacelike vectors $\vec{e}^{\,*}_{(i)}$ $(i = 1, \ldots, 3)$, i.e.

$$\vec{v} = v^i \vec{e}^{\,*}_{(i)} \,. \tag{3.127}$$

- Let s be the affine parameter of the geodesic from $\mathbf{p}_0(\tau)$ to $\mathbf{p}$. We define the Fermi coordinates of the point $\mathbf{p}$ as follows:

$$x^{*0} = \tau \,, \qquad x^{*i} = s v^i \,. \tag{3.128}$$

  It can be shown that s is also the proper length of the path (as defined in Eq. 2.211) of this spacelike geodesic between $\mathbf{p}_0$ and $\mathbf{p}$.

- Repeating the same procedure for all points of the observer worldline, we can define, in the entire worldtube, the Fermi coordinate system $\{x^{*\mu}\}$ adapted to the observer worldline.

It can be shown that (with an appropriate choice of the three-dimensional basis $\{\vec{e}^{*}_{(i)}\}$ for each surface $\Sigma(\tau)$) the spacetime metric in Fermi coordinates is

$$ds^2 = -(1 + 2a_\mu x^{*\mu})(dx^{*0})^2 + \delta_{ij} dx^{*i} dx^{*j} + O(x^{*2})\,, \tag{3.129}$$

where a^ν are the components of the observer's four-acceleration. If the observer is freely-falling ($\vec{a} = 0$), $ds^2 = \eta_{\mu\nu} + O(x^{*2})$, and this coordinate system coincides with the LIF centered in $\mathbf{p}_0$. Indeed, in a LIF the metric coincides with Minkowski's metric modulo *quadratic* terms in the coordinates. If, instead, the observer is accelerated, the deviation of the metric 3.129 from Minkowski's metric is *linear* in the coordinates $x^{*\mu}$: $g_{00} - \eta_{00} = -2a_\mu x^{*\mu}$. The linear term is precisely due to the acceleration of the observer.

Remarkably, the metric 3.129 does not depend on the spacetime curvature (up to $O(x^{*2})$). Indeed, introducing the Fermi coordinates for an accelerated observer in Special Relativity, i.e. $\xi^\alpha \to x^{*\mu}(\xi^\alpha)$, leads to the metric $ds^2 = -(1+2a_\mu x^{*\mu})(dx^{*0})^2 + \delta_{ij} dx^{*i} dx^{*j}$, which differs from Eq. 3.129 by the $O(x^{*2})$ terms only. We conclude that due to the Equivalence Principle, according to which the laws of physics in a LIF take, locally, the form prescribed by Special Relativity for inertial frames, the laws of physics in a Fermi frame take, locally, the form prescribed by Special Relativity for *accelerated* frames.

3.10 NON-COORDINATE BASES

In Boxes 2-G and 2-P we showed that changing from Minkowskian coordinates $\{\xi^{\alpha'}\} \equiv (ct, x, y)$ to polar coordinates $\{x^\alpha\} \equiv (ct, r, \theta)$, the coordinate basis for vectors[3]

$$\{\vec{e}_{(\alpha')}\} = \begin{cases} \vec{e}_{(0')} & \to & (1,0,0) \\ \vec{e}_{(1')} & \to & (0,1,0) \\ \vec{e}_{(2')} & \to & (0,0,1) \end{cases} \tag{3.130}$$

transforms to $\{\vec{e}_{(\alpha)}\}$, where (see Eq. 2.73)

$$\begin{cases} \vec{e}_{(0)} = \vec{e}_{(0')} \\ \vec{e}_{(1)} = \vec{e}_{(r)} = \cos\theta \vec{e}_{(1')} + \sin\theta \vec{e}_{(2')} \\ \vec{e}_{(2)} = \vec{e}_{(\theta)} = -r\sin\theta \vec{e}_{(1')} + r\cos\theta \vec{e}_{(2')}\,. \end{cases} \tag{3.131}$$

These expressions follow from the transformation laws

$$\vec{e}_{(\alpha)} = \Lambda^{\mu'}{}_{\alpha}\; \vec{e}_{(\mu')}\,, \tag{3.132}$$

where $\Lambda^{\mu'}{}_{\alpha} = \frac{\partial x^{\mu'}}{\partial x^\alpha}$ and $\Lambda^{\alpha}{}_{\mu'} = \frac{\partial x^\alpha}{\partial x^{\mu'}}$. We now want to choose a different basis for vectors. For example, while the vectors $\{\vec{e}_{(\alpha)}\}$ are not normalized because

$$\vec{e}_{(\alpha)} \cdot \vec{e}_{(\beta)} = g_{\alpha\beta} = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & r^2 \end{pmatrix} \neq \eta_{\alpha\beta}\,, \tag{3.133}$$

---

[3] Note that, at variance with Boxes 2-G and 2-P, we indicate with a prime the Minkowskian coordinates.

we may choose a basis of normalized vectors given by

$$\begin{cases} \vec{e}_{(\hat{0})} = \vec{e}_{(0)} \\ \vec{e}_{(\hat{r})} = \vec{e}_{(r)} \\ \vec{e}_{(\hat{\theta})} = \frac{1}{r}\vec{e}_{(\theta)}\,, \end{cases} \tag{3.134}$$

such that

$$\vec{e}_{(\hat{\alpha})} \cdot \vec{e}_{(\hat{\beta})} = \eta_{\hat{\alpha}\hat{\beta}}\,. \tag{3.135}$$

In this basis the transformation 3.131 becomes

$$\begin{aligned} \vec{e}_{(\hat{r})} &= \cos\theta\vec{e}_{(1')} + \sin\theta\vec{e}_{(2')} \\ \vec{e}_{(\hat{\theta})} &= -\sin\theta\vec{e}_{(1')} + \cos\theta\vec{e}_{(2')}\,. \end{aligned} \tag{3.136}$$

In the previous sections we have always introduced the basis vectors as the coordinate basis associated to a coordinate frame, but they can also be defined independently of the choice of the coordinate frame, as in Eq. 3.134. In this case, it is natural to ask whether there exists a set of coordinates $\{x^{\hat{\alpha}}\}$ such that

$$e_{(\hat{\alpha})} = \Lambda^{\beta}{}_{\hat{\alpha}}\ \vec{e}_{(\beta)} = \frac{\partial x^{\beta}}{\partial x^{\hat{\alpha}}}\ \vec{e}_{(\beta)}\,, \tag{3.137}$$

so that the basis $\{\vec{e}_{(\hat{\alpha})}\}$ is a coordinate basis. The same question can be formulated for the basis one-forms, i.e. whether there exist coordinates $\{x^{\hat{\alpha}}\}$ such that

$$\tilde{\omega}^{(\hat{\alpha})} = \Lambda^{\hat{\alpha}}{}_{\beta}\ \tilde{\omega}^{(\beta)} = \frac{\partial x^{\hat{\alpha}}}{\partial x^{\beta}}\ \tilde{\omega}^{(\beta)} \tag{3.138}$$

and

$$\Lambda^{\hat{\alpha}}{}_{\beta} = \frac{\partial x^{\hat{\alpha}}}{\partial x^{\beta}}\,. \tag{3.139}$$

For instance, in the considered example

$$\Lambda^{\beta}{}_{\hat{\alpha}} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \frac{1}{r} \end{pmatrix} \qquad \text{and} \qquad \Lambda^{\hat{\alpha}}{}_{\beta} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & r \end{pmatrix}\,. \tag{3.140}$$

If Eq. 3.139 is true, the following condition must be satisfied

$$\frac{\partial}{\partial x^{\gamma}}\Lambda^{\hat{\alpha}}{}_{\beta} = \frac{\partial^2 x^{\hat{\alpha}}}{\partial x^{\gamma}\partial x^{\beta}} = \frac{\partial^2 x^{\hat{\alpha}}}{\partial x^{\beta}\partial x^{\gamma}} = \frac{\partial}{\partial x^{\beta}}\Lambda^{\hat{\alpha}}{}_{\gamma}\,. \tag{3.141}$$

This is an “integrability condition” that all the components of $\Lambda^{\hat{\alpha}}{}_{\gamma}$ must satisfy in order for the coordinates $\{x^{\hat{\alpha}}\}$ to exist. In the considered example Eq. 3.141 gives

$$\frac{\partial}{\partial\theta}\Lambda^{\hat{2}}{}_{1} = \frac{\partial}{\partial r}\Lambda^{\hat{2}}{}_{2} \qquad \to \qquad 0 = 1 \tag{3.142}$$

which is certainly not true. We conclude that the normalized vector basis in Eq. 3.134 and the dual basis for one forms $\{\tilde{\omega}^{(\hat{\alpha})}\}$ *are not* coordinate bases, since we cannot associate a coordinate transformation to them.

CHAPTER 4

The curvature tensor

In this chapter we shall introduce the curvature tensor, showing that it describes the curvature of the spacetime. This derivation is based on the parallel transport of a vector along a closed loop. We shall discuss the main properties of the curvature tensor and show how the latter is related to the equation of geodesic deviation.

4.1 PARALLEL TRANSPORT ALONG A LOOP

Let us consider an infinitesimal closed loop, having as sides the coordinate lines $x^1 = a$, $x^1 = a + \delta a$, $x^2 = b$, $x^2 = b + \delta b$ (see Fig. 4.1).

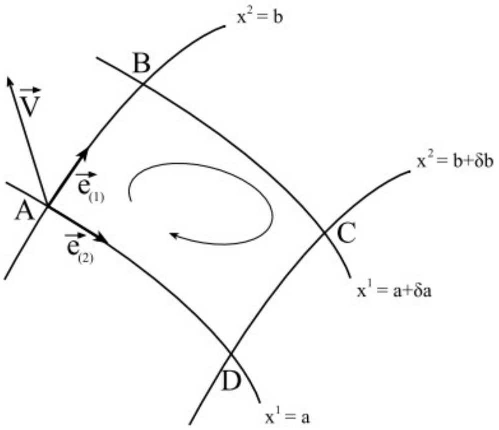

Figure 4.1: A generic vector $\vec{V}$ is parallely transported along an infinitesimal, closed loop whose boundaries are portions of coordinate lines.

We wish to compute how the components of a generic vector $\vec{V}$ change when the vector is parallely transported along the loop. The loop can be divided into four parts, so that the total variation of the vector components is

$$\delta V^\alpha = \delta V^\alpha_{AB} + \delta V^\alpha_{BC} + \delta V^\alpha_{CD} + \delta V^\alpha_{DA} \,. \tag{4.1}$$

The vector tangent to the curves AB and CD and that tangent to the curves BC and DA are, respectively, the basis vectors $\vec{e}_{(1)}$ and $\vec{e}_{(2)}$; since their only non-vanishing components are $e^1_{(1)} = 1$ and $e^2_{(2)} = 1$, the equation of parallel transport, Eq. 3.92, gives

$$\text{on AB and CD :} \qquad \nabla_{\vec{e}_{(1)}}\vec{V} = e^{\mu}_{(1)} V^{\alpha}{}_{;\mu} = 0 \quad \rightarrow \quad \frac{\partial V^{\alpha}}{\partial x^1} + \Gamma^{\alpha}_{\beta 1} V^{\beta} = 0\,, \tag{4.2}$$

$$\text{on BC and DA :} \qquad \nabla_{\vec{e}_{(2)}}\vec{V} = e^{\mu}_{(2)} V^{\alpha}{}_{;\mu} = 0 \quad \rightarrow \quad \frac{\partial V^{\alpha}}{\partial x^2} + \Gamma^{\alpha}_{\beta 2} V^{\beta} = 0\,. \tag{4.3}$$

Eq. 4.2 has to be integrated along the line $x^2 = b$ from A to B, and $x^2 = b + \delta b$ from C to D; Eq. 4.3 has to be integrated along $x^1 = a + \delta a$ from B to C, and on $x^1 = a$ from D to A. The integrals to evaluate thus are

$$\delta V^{\alpha}_{AB} = -\textstyle\int_{A(x^2=b)}^{B} \Gamma^{\alpha}_{\beta 1} V^{\beta} dx^1\,, \qquad \delta V^{\alpha}_{BC} = -\displaystyle\int_{B(x^1=a+\delta a)}^{C} \Gamma^{\alpha}_{\beta 2} V^{\beta} dx^2\,, \tag{4.4}$$

$$\delta V^{\alpha}_{CD} = -\textstyle\int_{C(x^2=b+\delta b)}^{D} \Gamma^{\alpha}_{\beta 1} V^{\beta} dx^1\,, \quad \delta V^{\alpha}_{DA} = -\displaystyle\int_{D(x^1=a)}^{A} \Gamma^{\alpha}_{\beta 2} V^{\beta} dx^2\,. \tag{4.5}$$

The integral in δV^{α}_{BC} is a function of $x^1 = a + \delta a$, with $\delta a \ll a$; therefore it can be Taylor-expanded as

$$\delta V^{\alpha}_{BC} = -\left[\int_{B(x^1=a)}^{C} \Gamma^{\alpha}_{\beta 2} V^{\beta} dx^2 + \frac{\partial}{\partial x^1}\left(\int_{B}^{C} \Gamma^{\alpha}_{\beta 2} V^{\beta} dx^2\right)\bigg|_{(x^1=a)} \delta a\right]. \tag{4.6}$$

The integral in δV^{α}_{CD} can be expanded in a similar way

$$\delta V^{\alpha}_{CD} = -\left[\int_{C(x^2=b)}^{D} \Gamma^{\alpha}_{\beta 1} V^{\beta} dx^1 + \frac{\partial}{\partial x^2}\left(\int_{C}^{D} \Gamma^{\alpha}_{\beta 1} V^{\beta} dx^1\right)\bigg|_{(x^2=b)} \delta b\right]. \tag{4.7}$$

Thus, finally

$$\begin{aligned}\delta V^{\alpha} \simeq & -\int_{A(x^2=b)}^{B} \Gamma^{\alpha}_{\beta 1} V^{\beta} dx^1 - \int_{D(x^1=a)}^{A} \Gamma^{\alpha}_{\beta 2} V^{\beta} dx^2 \\ & -\left[\int_{B(x^1=a)}^{C} \Gamma^{\alpha}_{\beta 2} V^{\beta} dx^2 + \frac{\partial}{\partial x^1}\left(\int_{B}^{C} \Gamma^{\alpha}_{\beta 2} V^{\beta} dx^2\right)\bigg|_{(x^1=a)} \delta a\right] \\ & -\left[\int_{C(x^2=b)}^{D} \Gamma^{\alpha}_{\beta 1} V^{\beta} dx^1 + \frac{\partial}{\partial x^2}\left(\int_{C}^{D} \Gamma^{\alpha}_{\beta 1} V^{\beta} dx^1\right)\bigg|_{(x^2=b)} \delta b\right].\end{aligned} \tag{4.8}$$

If we now replace the coordinates of the points A, B, C, D in the previous equation, i.e.

$$A = (a, b), \quad C = (a + \delta a, b + \delta b), \quad B = (a + \delta a, b), \quad \text{and} \quad D = (a, b + \delta b)\,, \tag{4.9}$$

only two terms survive in Eq. 4.8, and since the operators of integration and differentiation commute, the final expression of δV^{α} can be written as

$$\begin{aligned}\delta V^{\alpha} &\simeq -\delta a \int_{b}^{b+\delta b} \frac{\partial}{\partial x^1}\left(\Gamma^{\alpha}_{\beta 2} V^{\beta}\right) dx^2 + \delta b \int_{a}^{a+\delta a} \frac{\partial}{\partial x^2}\left(\Gamma^{\alpha}_{\beta 1} V^{\beta}\right) dx^1 \\ &\simeq \delta a \delta b \left[-\frac{\partial}{\partial x^1}\left(\Gamma^{\alpha}_{\beta 2} V^{\beta}\right) + \frac{\partial}{\partial x^2}\left(\Gamma^{\alpha}_{\beta 1} V^{\beta}\right)\right].\end{aligned} \tag{4.10}$$

By expanding the derivatives and making use of Eqs. 4.2 and 4.3, Eq. 4.10 can be further simplified to give

$$\begin{aligned}\delta V^\alpha &= \delta a\delta b\left[\frac{\partial\Gamma^\alpha_{\beta 1}}{\partial x^2}V^\beta+\Gamma^\alpha_{\sigma 1}\frac{\partial V^\sigma}{\partial x^2}-\frac{\partial\Gamma^\alpha_{\beta 2}}{\partial x^1}V^\beta-\Gamma^\alpha_{\sigma 2}\frac{\partial V^\sigma}{\partial x^1}\right] \\ &= \delta a\delta b\left[\frac{\partial\Gamma^\alpha_{\beta 1}}{\partial x^2}-\frac{\partial\Gamma^\alpha_{\beta 2}}{\partial x^1}-\Gamma^\alpha_{\sigma 1}\Gamma^\sigma_{\beta 2}+\Gamma^\alpha_{\sigma 2}\Gamma^\sigma_{\beta 1}\right]V^\beta\,.\end{aligned} \tag{4.11}$$

Note that δa and δb are the non-vanishing components of the displacement vectors $\vec{\delta x}_{(1)}$ and $\vec{\delta x}_{(2)}$ along the direction of the basis vectors $\vec{e}_{(1)}$ and $\vec{e}_{(2)}$, i.e.

$$\delta x^\mu_{(1)} = (0,\delta a,0,0)=\delta a\ \delta^\mu_1\ , \tag{4.12}$$

$$\delta x^\mu_{(2)} = (0,0,\delta b,0)=\delta b\ \delta^\mu_2\ ; \tag{4.13}$$

therefore Eq. 4.11 can be written as follows

$$\delta V^\alpha=\delta x^\nu_{(1)}\ \delta x^\mu_{(2)}\ \left[\frac{\partial\Gamma^\alpha_{\beta\nu}}{\partial x^\mu}-\frac{\partial\Gamma^\alpha_{\beta\mu}}{\partial x^\nu}-\Gamma^\alpha_{\sigma\nu}\Gamma^\sigma_{\beta\mu}+\Gamma^\alpha_{\sigma\mu}\Gamma^\sigma_{\beta\nu}\right]V^\beta\,. \tag{4.14}$$

If the loop is defined through different coordinate lines, the same proof leads to the same final expression, Eq. 4.14. A similar, but more involved, calculation shows that Eq. 4.14 also holds when the sides of the loop are not coordinate lines, i.e. when $\vec{\delta x}_{(1)}$ and $\vec{\delta x}_{(2)}$ are general vectors.

We shall now show that the terms in square brackets in Eq. 4.14 are the components of a tensor. According to the definition given in Chapter 2, a $\binom{1}{3}$ tensor **T** is a linear function of one one-form and three vectors which, when applied to these arguments, produces a scalar, i.e.

$$T(\tilde q,\vec A,\vec B,\vec C)=T^\alpha{}_{\beta\rho\delta}\ q_\alpha A^\beta B^\rho C^\delta\,, \tag{4.15}$$

where $T^\alpha{}_{\beta\rho\delta}$ are the components of **T**. To begin with, we note that V^α, δV^α, $\delta x^\mu_{(1)}$, and $\delta x^\mu_{(2)}$ are the components of generic vectors. Let us consider a generic one-form field with components q_α. The quantity $\delta V^\alpha q_\alpha$ is a scalar, because it is the contraction of a vector and a one-form, and

$$\delta V^\alpha q_\alpha=\left[\frac{\partial\Gamma^\alpha_{\beta\nu}}{\partial x^\mu}-\frac{\partial\Gamma^\alpha_{\beta\mu}}{\partial x^\nu}-\Gamma^\alpha_{\sigma\nu}\Gamma^\sigma_{\beta\mu}+\Gamma^\alpha_{\sigma\mu}\Gamma^\sigma_{\beta\nu}\right]q_\alpha V^\beta\delta x^\nu_{(1)}\ \delta x^\mu_{(2)}\,. \tag{4.16}$$

Therefore, the contraction of the components of the vectors $\delta x^\nu_{(1)}$, $\delta x^\mu_{(2)}$, and V^β, and of the one-form q_α with the quantity in brackets is a scalar. In addition, Eq. 4.16 is linear in $\vec V$, $\tilde q$, $\vec{\delta x}_{(1)}$, and $\vec{\delta x}_{(2)}$. Indeed, if we consider for example a displacement $\vec{\delta x}_{(1a)}+\vec{\delta x}_{(1b)}$ along $\vec e_{(1)}$, it is immediate to check that

$$\delta V^\alpha q_\alpha=\delta x^\nu_{(1a)}\delta x^\mu_{(2)}\,[...]\,q_\alpha V^\beta+\delta x^\nu_{(1b)}\delta x^\mu_{(2)}\,[...]\,q_\alpha V^\beta\,, \tag{4.17}$$

and similarly for the other quantities. Thus, we can conclude that the terms in square brackets in Eq. 4.16 are the components of a $\binom{1}{3}$ tensor, the **Riemann tensor**

$$R^\alpha{}_{\beta\mu\nu}\equiv\Gamma^\alpha_{\beta\nu,\mu}-\Gamma^\alpha_{\beta\mu,\nu}-\Gamma^\alpha_{\sigma\nu}\Gamma^\sigma_{\beta\mu}+\Gamma^\alpha_{\sigma\mu}\Gamma^\sigma_{\beta\nu}\,. \tag{4.18}$$

Note that the Riemann tensor is antisymmetric in ν and μ; indeed, if we interchange $\vec{\delta x}_{(1)}$ and $\vec{\delta x}_{(2)}$ in Eq. 4.14, δV^α changes sign, because the loop goes in the opposite direction.

This shows that the sign of Eq. 4.18 can be chosen arbitrarily, and for this reason the definitions of the Riemann tensor given in textbooks may differ for an overall sign.

The Riemann tensor depends on the affine connection and on its first derivatives, i.e. on the first and second derivatives of the metric tensor. If we choose a LIF the $\Gamma^{\alpha}_{\beta\mu}$'s vanish, but their derivatives do not; the Riemann tensor is generically nonzero in a LIF.

We shall call a spacetime *flat* if the parallel transport of any vector field around any loop vanishes, otherwise we shall call it *curved*. Therefore, in a flat spacetime the Riemann tensor vanishes everywhere and (since it is a tensor) in any frame; in a curved spacetime, instead, the Riemann tensor is non-zero at some point of the manifold, and this is also true in any frame. It can be shown (but the rigorous derivation goes beyond the scope of this book) that a global, Minkowskian coordinate system can be defined if and only if the Riemann tensor vanishes on the entire spacetime[1].

In conclusion, *if the spacetime is flat the Riemann tensor is zero, if it is curved the Riemann tensor is non-zero, and this is true in any coordinate frame.* This justifies why the Riemann tensor is also called the **curvature tensor**.

Furthermore, Eq. 4.14 shows that if $R^{\alpha}{}_{\beta\gamma\delta} = 0$, i.e. the spacetime is flat, a vector $\vec{V}$ parallely transported along *any* closed loop does not change, i.e. $\delta V^{\alpha} = 0$. Conversely, if the Riemann tensor does not vanish, i.e. the spacetime is curved, there will exist at least one loop such that $\delta V^{\alpha} \neq 0$.

It should be stressed that

- The Riemann tensor is linear in the second derivatives of $g_{\mu\nu}$, and non-linear in the first derivatives. Note that it has the same differential structure of the Gaussian curvature introduced in Chapter 1, Eq. 1.12.
- In a LIF $\Gamma^{\alpha}_{\nu\sigma} = 0$, therefore the non-linear part of the Riemann tensor vanishes as well.

By contracting the Riemann tensor with the metric we can construct a $\binom{0}{2}$ tensor, called the **Ricci tensor**

$$R_{\mu\nu} = g^{\alpha\beta} R_{\alpha\mu\beta\nu} = R^{\alpha}{}_{\mu\alpha\nu} \,. \tag{4.19}$$

By further contracting the Ricci tensor with the metric, we can also define the **scalar (or Ricci) curvature**

$$R = g^{\alpha\beta} R_{\alpha\beta} = R^{\alpha}{}_{\alpha} \,. \tag{4.20}$$

As the Riemann tensor, both the Ricci tensor and the Ricci scalar are linear in the second derivatives of $g_{\mu\nu}$, and non-linear in the first derivatives.

In a LIF, the components of the Riemann tensor have a very simple form since the non-linear part of the tensor vanishes, i.e.

$$R^{\mu}{}_{\nu\alpha\beta} = \Gamma^{\mu}_{\nu\beta,\alpha} - \Gamma^{\mu}_{\nu\alpha,\beta} \,, \tag{4.21}$$

and by replacing the expression of the Christoffel symbols given in Eq. 3.68, we find

$$R^{\alpha}{}_{\beta\mu\nu} = \frac{1}{2} g^{\alpha\sigma} \left[g_{\sigma\nu,\beta\mu} - g_{\sigma\mu,\beta\nu} + g_{\beta\mu,\sigma\nu} - g_{\beta\nu,\sigma\mu} \right] \,, \tag{4.22}$$

or, lowering the index α,

$$R_{\alpha\beta\mu\nu} = g_{\alpha\lambda} R^{\lambda}{}_{\beta\mu\nu} = \frac{1}{2} \left[g_{\alpha\nu,\beta\mu} - g_{\alpha\mu,\beta\nu} + g_{\beta\mu,\alpha\nu} - g_{\beta\nu,\alpha\mu} \right] \,. \tag{4.23}$$

---

[1] This can be understood by noting that in a LIF $g_{\mu\nu} = \eta_{\mu\nu} + O(x^2)$, and the $O(x^2)$ terms depend on the second derivatives of the metric; it can be shown that the $O(x^2)$ terms can be expressed in terms of the Riemann tensor components. If these terms vanish everywhere, the LIF can be extended to the entire spacetime.

Consequently, in a LIF the components of the Ricci tensor are

$$R_{\beta\nu} = R^{\alpha}{}_{\beta\alpha\nu} = \frac{1}{2} g^{\alpha\sigma} \left[g_{\sigma\nu,\beta\alpha} - g_{\sigma\alpha,\beta\nu} + g_{\beta\alpha,\sigma\nu} - g_{\beta\nu,\sigma\alpha} \right] . \tag{4.24}$$

4.2 SYMMETRIES OF THE RIEMANN TENSOR

Using Eq. 4.23 it is easy to show that the curvature tensor is antisymmetric in the first and in the second pair of indices, i.e.

$$R_{\alpha\beta\mu\nu} = -R_{\beta\alpha\mu\nu} \,, \quad \text{and} \quad R_{\alpha\beta\mu\nu} = -R_{\alpha\beta\nu\mu} \,, \tag{4.25}$$

whereas it is symmetric under exchange of the two pairs of indices

$$R_{\alpha\beta\mu\nu} = R_{\mu\nu\alpha\beta} \,. \tag{4.26}$$

In addition it satisfies the *Ricci identities*

$$R_{\alpha\beta\mu\nu} + R_{\alpha\nu\beta\mu} + R_{\alpha\mu\nu\beta} = 0 \,. \tag{4.27}$$

Since $R_{\alpha\beta\mu\nu}$ is a tensor, these symmetry properties, which can easily be derived in a LIF using Eq. 4.23, hold in any reference frame. The symmetries of the Riemann tensor reduce the number of its independent components from $4^4 = 256$ to only 20.

As a consequence of Eq. 4.26, the Ricci tensor $R_{\mu\nu} = g^{\alpha\beta} R_{\mu\alpha\nu\beta}$ is symmetric under exchange of its indices:

$$R_{\mu\nu} = R_{\nu\mu} \,, \tag{4.28}$$

and therefore it has only 10 independent components.

4.3 THE RIEMANN TENSOR GIVES THE COMMUTATOR OF COVARIANT DERIVATIVES

Let us consider the second covariant derivatives of a vector field $\vec{V}$

$$\nabla_\alpha \nabla_\beta V^\mu = \nabla_\alpha (V^\mu{}_{;\beta}) = (V^\mu{}_{;\beta})_{,\alpha} + \Gamma^\mu_{\sigma\alpha} V^\sigma{}_{;\beta} - \Gamma^\sigma_{\beta\alpha} V^\mu{}_{;\sigma} \,. \tag{4.29}$$

In a LIF $\Gamma^\mu_{\sigma\alpha} = 0$, and Eq. 4.29 becomes

$$\nabla_\alpha \nabla_\beta V^\mu = (V^\mu{}_{;\beta})_{,\alpha} = V^\mu{}_{,\beta,\alpha} + \Gamma^\mu_{\nu\beta,\alpha} V^\nu \,. \tag{4.30}$$

By interchanging α and β

$$\nabla_\beta \nabla_\alpha V^\mu = (V^\mu{}_{;\alpha})_{,\beta} = V^\mu{}_{,\alpha,\beta} + \Gamma^\mu_{\nu\alpha,\beta} V^\nu \,. \tag{4.31}$$

The commutator of the covariant derivatives is then

$$[\nabla_\alpha, \nabla_\beta] \, V^\mu \equiv \nabla_\alpha \nabla_\beta V^\mu - \nabla_\beta \nabla_\alpha V^\mu = \left(\Gamma^\mu_{\nu\beta,\alpha} - \Gamma^\mu_{\nu\alpha,\beta} \right) V^\nu \,. \tag{4.32}$$

The term in round brackets in this equation coincides with the expression of the Riemann tensor in the LIF (see Eq. 4.21), therefore

$$[\nabla_\alpha, \nabla_\beta] \, V^\mu = R^\mu{}_{\nu\alpha\beta} V^\nu \,. \tag{4.33}$$

This is a tensor equation and since it is valid in a given reference frame, it will be valid in *any* frame. Eq. 4.33 shows that *in curved spacetime the covariant derivatives do not commute* and therefore the order in which they appear is important.

4.4 THE BIANCHI IDENTITIES

We shall now derive the *Bianchi identities*, a set of differential equations satisfied by the Riemann tensor. Since in a LIF the expression of the tensor is much simpler, we shall use Eq. 4.23 to prove the identities in this frame, and then generalize them to any frame.

Let us differentiate Eq. 4.23 with respect to x^λ

$$R_{\alpha\beta\mu\nu,\lambda} = \frac{1}{2}\left[g_{\alpha\nu,\beta\mu\lambda} - g_{\alpha\mu,\beta\nu\lambda} + g_{\beta\mu,\alpha\nu\lambda} - g_{\beta\nu,\alpha\mu\lambda}\right] . \tag{4.34}$$

Using Eq. 4.34 and the symmetry of $g_{\alpha\beta}$, it is easy to show that

$$R_{\alpha\beta\mu\nu,\lambda} + R_{\alpha\beta\lambda\mu,\nu} + R_{\alpha\beta\nu\lambda,\mu} = 0 . \tag{4.35}$$

In a LIF ordinary and covariant derivatives coincide, therefore Eq. 4.35 can also be written as

$$R_{\alpha\beta\mu\nu;\lambda} + R_{\alpha\beta\lambda\mu;\nu} + R_{\alpha\beta\nu\lambda;\mu} = 0 . \tag{4.36}$$

These equations have been derived in a LIF, and since they are tensor equations, they will be valid in any frame.

Eqs. 4.36 are the Bianchi identities which, as we shall later see, play an important role in the derivation of Einstein's equations.

4.5 THE EQUATION OF GEODESIC DEVIATION

If the spacetime is curved, the Equivalence Principle establishes that we can always choose a LIF where the affine connection vanishes. In this frame a free particle (i.e. one subjected to no other force than gravity) follows the geodesic equation with zero acceleration.

Conversely, if the spacetime is flat we can always choose a coordinate frame in which the affine connection does not vanish as, for instance, in Minkowski's spacetime when spherical coordinates are chosen. In this case a free particle would follow a geodesic with non-zero acceleration, and we would not be able to establish whether this acceleration is due to a true gravitational field or to the fact that the reference frame is not inertial. In other words, the local curvature of spacetime cannot be measured by observing the motion of a single particle.

We shall now show that the local curvature of spacetime can be measured by comparing the motion of two close particles, i.e. by comparing the behaviour of close geodesics.

Let us consider a two-parameter family of geodesics $x^\mu(\tau, p)$, where τ is the affine parameter and p labels different curves of the family. Along each geodesic $p = const$. We also consider the family of non-geodesic curves which join points of the family $x^\mu(\tau, p)$ having the same τ; these curves are parametrized by p and are indicated with $\tau = const$ in Fig. 4.2.

Two particles move along two infinitely close geodesics $x^\mu(\tau, p)$ and $x^\mu(\tau, p) + \delta x^\mu = x^\mu(\tau, p + \delta p)$. Here $\vec{\delta x}$ is the infinitesimal displacement vector between points having the same τ on the two geodesics. Let $\vec{t}$ be the tangent vector to the geodesics, and $\vec{b}$ the tangent vector to the $p = const$ curves, as indicated in Fig. 4.2, i.e.

$$t^\alpha = \frac{\partial x^\alpha}{\partial \tau} \qquad \text{and} \qquad b^\alpha = \frac{\partial x^\alpha}{\partial p} . \tag{4.37}$$

The displacement vector is $\delta x^\alpha = b^\alpha \delta p$. For simplicity, we choose the parameter p such that the tangent vector b^α and the displacement vector δx^α coincide. With this definition, $\delta x^\alpha = \frac{\partial x^\alpha}{\partial p}$, and

$$\frac{\partial t^\alpha}{\partial p} = \frac{\partial \delta x^\alpha}{\partial \tau} . \tag{4.38}$$

CHAPTER 3

Curvature

3.1 ■ OVERVIEW

We all know what curvature means, at least informally, and in the first two chapters of this book we have felt free to refer on occasion to the concept of curvature without giving it a careful definition. Clearly curvature depends somehow on the metric, which defines the geometry of our manifold; but it is not immediately clear how we should attribute curvature to any given metric (since, as we have seen, even the metric of a flat space can look arbitrarily complicated in a sufficiently extravagant coordinate system). As is often the case in mathematics, we require quite a bit of care to formalize our intuition about a concept into a usable mathematical structure; formalizing what we think of as "curvature" is the subject of this chapter.

The techniques we are about to develop are absolutely crucial to the subject; it is safe to say that there is a higher density of useful formulas per page in this chapter than in any of the others. Let's quickly summarize the most important ones, to provide a roadmap for the formalism to come.

All the ways in which curvature manifests itself rely on something called a "connection," which gives us a way of relating vectors in the tangent spaces of nearby points. There is a unique connection that we can construct from the metric, and it is encapsulated in an object called the *Christoffel symbol*, given by

$$\Gamma^{\lambda}_{\mu\nu} = \tfrac{1}{2} g^{\lambda\sigma}(\partial_\mu g_{\nu\sigma} + \partial_\nu g_{\sigma\mu} - \partial_\sigma g_{\mu\nu}). \tag{3.1}$$

The notation makes $\Gamma^{\lambda}_{\mu\nu}$ look like a tensor, but in fact it is not; this is why we call it an "object" or "symbol." The fundamental use of a connection is to take a *covariant derivative* ∇_μ (a generalization of the partial derivative); the covariant derivative of a vector field V^ν is given by

$$\nabla_\mu V^\nu = \partial_\mu V^\nu + \Gamma^{\nu}_{\mu\sigma} V^\sigma, \tag{3.2}$$

and covariant derivatives of other sorts of tensors are given by similar expressions. The connection also appears in the definition of *geodesics* (a generalization of the notion of a straight line). A parameterized curve $x^\mu(\lambda)$ is a geodesic if it obeys

$$\frac{d^2 x^\mu}{d\lambda^2} + \Gamma^{\mu}_{\rho\sigma} \frac{dx^\rho}{d\lambda} \frac{dx^\sigma}{d\lambda} = 0, \tag{3.3}$$

known as the geodesic equation.

Finally, the technical expression of curvature is contained in the Riemann tensor, a $(1, 3)$ tensor obtained from the connection by

$$R^{\rho}{}_{\sigma\mu\nu} = \partial_{\mu}\Gamma^{\rho}_{\nu\sigma} - \partial_{\nu}\Gamma^{\rho}_{\mu\sigma} + \Gamma^{\rho}_{\mu\lambda}\Gamma^{\lambda}_{\nu\sigma} - \Gamma^{\rho}_{\nu\lambda}\Gamma^{\lambda}_{\mu\sigma}. \tag{3.4}$$

Everything we want to know about the curvature of a manifold is given to us by the Riemann tensor; it will vanish if and only if the metric is perfectly flat. Einstein's equation of general relativity relates certain components of this tensor to the energy-momentum tensor.

These four equations are all of primary importance in the study of curved manifolds. We will now see how they arise from a careful consideration of how familiar notions of geometry in flat space adapt to this more general context.

3.2 ■ COVARIANT DERIVATIVES

In our discussion of manifolds, it became clear that there were various notions we could talk about as soon as the manifold was defined: we could define functions, take their derivatives, consider parameterized paths, set up tensors, and so on. Other concepts, such as the volume of a region or the length of a path, required some additional piece of structure, namely the introduction of a metric. It would be natural to think of the notion of curvature as something that depends exclusively on the metric. In a more careful treatment, however, we find that curvature depends on a connection, and connections may or may not depend on the metric. Nevertheless, we will also show how the existence of a metric implies a certain unique connection, whose curvature may be thought of as that of the metric. This is the connection used in general relativity, so in this particular context it is legitimate to think of curvature as characterizing the metric, without introducing any additional structures.

The connection becomes necessary when we attempt to address the problem of the partial derivative not being a good tensor operator. What we would like is a covariant derivative, that is, an operator that reduces to the partial derivative in flat space with inertial coordinates, but transforms as a tensor on an arbitrary manifold. It is conventional to spend a certain amount of time motivating the introduction of a covariant derivative, but in fact the need is obvious; equations such as $\partial_{\mu}T^{\mu\nu} = 0$ must be generalized to curved space somehow. So let's agree that a covariant derivative would be a good thing to have, and go about setting it up.

In flat space in inertial coordinates, the partial derivative operator ∂_{μ} is a map from (k, l) tensor fields to $(k, l + 1)$ tensor fields, which acts linearly on its arguments and obeys the Leibniz rule on tensor products. All of this continues to be true in the more general situation we would now like to consider, but the map provided by the partial derivative depends on the coordinate system used. We would therefore like to define a **covariant derivative** operator ∇ to perform the functions of the partial derivative, but in a way independent of coordinates. Rather than simply postulating the answer (which would be perfectly acceptable), let's motivate it by thinking carefully about what properties a covariant generalization of the partial derivative *should* have—mathematical structures are, after all, invented by human beings, not found lying on sidewalks. We begin by requiring that ∇ be a map from (k, l) tensor fields, to $(k, l+1)$ tensor fields which has these two properties:

1. linearity: $\nabla(T + S) = \nabla T + \nabla S$;
2. Leibniz (product) rule: $\nabla(T \otimes S) = (\nabla T) \otimes S + T \otimes (\nabla S)$.

If ∇ is going to obey the Leibniz rule, it can always be written as the partial derivative plus some linear transformation. That is, to take the covariant derivative we first take the partial derivative, and then apply a correction to make the result covariant. [We aren't going to prove this reasonable-sounding statement; see Wald (1984) if you are interested.] Let's consider what this means for the covariant derivative of a vector V^ν. It means that, for each direction μ, the covariant derivative ∇_μ will be given by the partial derivative ∂_μ plus a correction specified by a set of n matrices $(\Gamma_\mu)^\rho{}_\sigma$ (one $n \times n$ matrix, where n is the dimensionality of the manifold, for each μ). In fact the parentheses are usually dropped and we write these matrices, known as the **connection coefficients**, with haphazard index placement as $\Gamma^\rho_{\mu\sigma}$. We therefore have

$$\boxed{\nabla_\mu V^\nu = \partial_\mu V^\nu + \Gamma^\nu_{\mu\lambda} V^\lambda.} \tag{3.5}$$

Notice that in the second term the index originally on V has moved to the Γ, and a new index is summed over. If this is the expression for the covariant derivative of a vector in terms of the partial derivative, we should be able to determine the transformation properties of $\Gamma^\nu_{\mu\lambda}$ by demanding that the left-hand side be a (1, 1) tensor. That is, we want the transformation law to be

$$\nabla_{\mu'} V^{\nu'} = \frac{\partial x^\mu}{\partial x^{\mu'}} \frac{\partial x^{\nu'}}{\partial x^\nu} \nabla_\mu V^\nu. \tag{3.6}$$

Let's look at the left side first; we can expand it using (3.5) and then transform the parts that we understand (which is everything except $\Gamma^{\nu'}_{\mu'\lambda'}$):

$$\begin{aligned}\nabla_{\mu'} V^{\nu'} &= \partial_{\mu'} V^{\nu'} + \Gamma^{\nu'}_{\mu'\lambda'} V^{\lambda'} \\ &= \frac{\partial x^\mu}{\partial x^{\mu'}} \frac{\partial x^{\nu'}}{\partial x^\nu} \partial_\mu V^\nu + \frac{\partial x^\mu}{\partial x^{\mu'}} V^\nu \frac{\partial}{\partial x^\mu} \frac{\partial x^{\nu'}}{\partial x^\nu} + \Gamma^{\nu'}_{\mu'\lambda'} \frac{\partial x^{\lambda'}}{\partial x^\lambda} V^\lambda. \end{aligned} \tag{3.7}$$

On the right-hand side we can also expand $\nabla_\mu V^\nu$:

$$\frac{\partial x^\mu}{\partial x^{\mu'}} \frac{\partial x^{\nu'}}{\partial x^\nu} \nabla_\mu V^\nu = \frac{\partial x^\mu}{\partial x^{\mu'}} \frac{\partial x^{\nu'}}{\partial x^\nu} \partial_\mu V^\nu + \frac{\partial x^\mu}{\partial x^{\mu'}} \frac{\partial x^{\nu'}}{\partial x^\nu} \Gamma^\nu_{\mu\lambda} V^\lambda. \tag{3.8}$$

These last two expressions are to be equated; the first terms in each are identical and therefore cancel, so we have

$$\Gamma^{\nu'}_{\mu'\lambda'}\frac{\partial x^{\lambda'}}{\partial x^{\lambda}}V^{\lambda}+\frac{\partial x^{\mu}}{\partial x^{\mu'}}V^{\lambda}\frac{\partial}{\partial x^{\mu}}\frac{\partial x^{\nu'}}{\partial x^{\lambda}}=\frac{\partial x^{\mu}}{\partial x^{\mu'}}\frac{\partial x^{\nu'}}{\partial x^{\nu}}\Gamma^{\nu}_{\mu\lambda}V^{\lambda}, \tag{3.9}$$

where we have changed a dummy index from ν to λ. This equation must be true for any vector V^{λ}, so we can eliminate that on both sides. Then the connection coefficients in the primed coordinates may be isolated by multiplying by $\partial x^{\lambda}/\partial x^{\sigma'}$ and relabeling $\sigma' \to \lambda'$. The result is

$$\Gamma^{\nu'}_{\mu'\lambda'}=\frac{\partial x^{\mu}}{\partial x^{\mu'}}\frac{\partial x^{\lambda}}{\partial x^{\lambda'}}\frac{\partial x^{\nu'}}{\partial x^{\nu}}\Gamma^{\nu}_{\mu\lambda}-\frac{\partial x^{\mu}}{\partial x^{\mu'}}\frac{\partial x^{\lambda}}{\partial x^{\lambda'}}\frac{\partial^2 x^{\nu'}}{\partial x^{\mu}\partial x^{\lambda}}. \tag{3.10}$$

This is not, of course, the tensor transformation law; the second term on the right spoils it. That's okay, because *the connection coefficients are not the components of a tensor*. They are purposefully constructed to be nontensorial, but in such a way that the combination (3.5) transforms as a tensor—the extra terms in the transformation of the partials and the Γ's exactly cancel. This is why we are not so careful about index placement on the connection coefficients; they are not a tensor, and therefore you should try not to raise and lower their indices.

What about the covariant derivatives of other sorts of tensors? By similar reasoning to that used for vectors, the covariant derivative of a one-form can also be expressed as a partial derivative plus some linear transformation. But there is no reason as yet that the matrices representing this transformation should be related to the coefficients $\Gamma^{\nu}_{\mu\lambda}$. In general we could write something like

$$\nabla_{\mu}\omega_{\nu}=\partial_{\mu}\omega_{\nu}+\widetilde{\Gamma}^{\lambda}_{\mu\nu}\omega_{\lambda}, \tag{3.11}$$

where $\widetilde{\Gamma}^{\lambda}_{\mu\nu}$ is a new set of matrices for each μ. Pay attention to where all of the various indices go. It is straightforward to derive that the transformation properties of $\widetilde{\Gamma}$ must be the same as those of Γ, since otherwise $\nabla_{\mu}\omega_{\nu}$ wouldn't transform as a tensor, but otherwise no relationship has been established. To do so, we need to introduce two new properties that we would like our covariant derivative to have, in addition to the two above:

3. commutes with contractions: $\nabla_{\mu}(T^{\lambda}{}_{\lambda\rho})=(\nabla T)_{\mu}{}^{\lambda}{}_{\lambda\rho}$,
4. reduces to the partial derivative on scalars: $\nabla_{\mu}\phi=\partial_{\mu}\phi$.

There is no way to "derive" these properties; we are simply demanding that they be true as part of the definition of a covariant derivative. Note that property 3 is equivalent to saying that the Kronecker delta (the identity map) is covariantly constant, $\nabla_{\mu}\delta^{\lambda}_{\sigma}=0$; this is certainly a reasonable thing to ask.

Let's see what these new properties imply. Given some one-form field ω_{μ} and vector field V^{μ}, we can take the covariant derivative of the scalar defined by $\omega_{\lambda}V^{\lambda}$ to get

$$\begin{aligned}\nabla_\mu(\omega_\lambda V^\lambda) &= (\nabla_\mu\omega_\lambda)V^\lambda + \omega_\lambda(\nabla_\mu V^\lambda)\\ &= (\partial_\mu\omega_\lambda)V^\lambda + \widetilde{\Gamma}^\sigma_{\mu\lambda}\omega_\sigma V^\lambda + \omega_\lambda(\partial_\mu V^\lambda) + \omega_\lambda\Gamma^\lambda_{\mu\rho}V^\rho.\end{aligned} \tag{3.12}$$

But since $\omega_\lambda V^\lambda$ is a scalar, this must also be given by the partial derivative:

$$\begin{aligned}\nabla_\mu(\omega_\lambda V^\lambda) &= \partial_\mu(\omega_\lambda V^\lambda)\\ &= (\partial_\mu\omega_\lambda)V^\lambda + \omega_\lambda(\partial_\mu V^\lambda).\end{aligned} \tag{3.13}$$

This can only be true if the terms in (3.12) with connection coefficients cancel each other; that is, rearranging dummy indices, we must have

$$0 = \widetilde{\Gamma}^\sigma_{\mu\lambda}\omega_\sigma V^\lambda + \Gamma^\sigma_{\mu\lambda}\omega_\sigma V^\lambda. \tag{3.14}$$

But both ω_σ and V^λ are completely arbitrary, so

$$\widetilde{\Gamma}^\sigma_{\mu\lambda} = -\Gamma^\sigma_{\mu\lambda}. \tag{3.15}$$

The two extra conditions we have imposed therefore allow us to express the covariant derivative of a one-form using the same connection coefficients as were used for the vector, but now with a minus sign (and indices matched up somewhat differently):

$$\boxed{\nabla_\mu\omega_\nu = \partial_\mu\omega_\nu - \Gamma^\lambda_{\mu\nu}\omega_\lambda.} \tag{3.16}$$

It should come as no surprise that the connection coefficients encode all the information necessary to take the covariant derivative of a tensor of arbitrary rank. The formula is quite straightforward; for each upper index you introduce a term with a single $+\Gamma$, and for each lower index a term with a single $-\Gamma$:

$$\begin{aligned}\nabla_\sigma T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} &= \partial_\sigma T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l}\\ &\quad + \Gamma^{\mu_1}_{\sigma\lambda}T^{\lambda\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} + \Gamma^{\mu_2}_{\sigma\lambda}T^{\mu_1\lambda\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} + \cdots\\ &\quad - \Gamma^\lambda_{\sigma\nu_1}T^{\mu_1\mu_2\cdots\mu_k}{}_{\lambda\nu_2\cdots\nu_l} - \Gamma^\lambda_{\sigma\nu_2}T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\lambda\cdots\nu_l} - \cdots.\end{aligned} \tag{3.17}$$

This is the general expression for the covariant derivative. You can check it yourself; it comes from the set of axioms we have established, and the usual requirements that tensors of various sorts be coordinate-independent entities. Sometimes an alternative notation is used; just as commas are used for partial derivatives, semicolons are used for covariant ones:

$$\nabla_\sigma T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} \equiv T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l;\sigma}. \tag{3.18}$$

Once again, in this book we will stick to "∇_σ."

To define a covariant derivative, then, we need to put a connection on our manifold, which is specified in some coordinate system by a set of coefficients $\Gamma^{\lambda}_{\mu\nu}$ ($n^3 = 64$ independent components in $n = 4$ dimensions) that transform according to (3.10). (The name *connection* comes from the fact that it is used to transport vectors from one tangent space to another, as we will soon see; it is sometimes used to refer to the operator ∇, and sometimes to the coefficients $\Gamma^{\lambda}_{\mu\nu}$.) Evidently, we could define a large number of connections on any manifold, and each of them implies a distinct notion of covariant differentiation. In general relativity this freedom is not a big concern, because it turns out that every metric defines a unique connection, which is the one used in GR. Let's see how that works.

The first thing to notice is that the difference of two connections is a tensor. Imagine we have defined two different kinds of covariant derivative, ∇_μ and $\widehat{\nabla}_\mu$, with associated connection coefficients $\Gamma^{\lambda}_{\mu\nu}$ and $\widehat{\Gamma}^{\lambda}_{\mu\nu}$. Then the difference

$$S^{\lambda}{}_{\mu\nu} = \Gamma^{\lambda}_{\mu\nu} - \widehat{\Gamma}^{\lambda}_{\mu\nu} \tag{3.19}$$

is a $(1, 2)$ tensor. (Notice that we had to choose a convention for index placement.) We could show this by brute force, plugging in the transformation laws for the connection coefficients, but let's be a little more slick. Given an arbitrary vector field V^λ, we know that both $\nabla_\mu V^\lambda$ and $\widehat{\nabla}_\mu V^\lambda$ are tensors, so their difference must also be. This difference is simply

$$\begin{aligned}\nabla_\mu V^\lambda - \widehat{\nabla}_\mu V^\lambda &= \partial_\mu V^\lambda + \Gamma^{\lambda}_{\mu\nu} V^\lambda - \partial_\mu V^\lambda - \widehat{\Gamma}^{\lambda}_{\mu\nu} V^\lambda \\ &= S^{\lambda}{}_{\mu\nu} V^\nu.\end{aligned} \tag{3.20}$$

Since V^λ was arbitrary, and the left-hand side is a tensor, $S^{\lambda}{}_{\mu\nu}$ must be a tensor. As a trivial consequence, we learn that any set of connection coefficients can be expressed as some fiducial connection plus a tensorial correction,

$$\Gamma^{\lambda}_{\mu\nu} = \widehat{\Gamma}^{\lambda}_{\mu\nu} + S^{\lambda}{}_{\mu\nu}. \tag{3.21}$$

Next notice that, given a connection specified by $\Gamma^{\lambda}_{\mu\nu}$, we can immediately form another connection simply by permuting the lower indices. That is, the set of coefficients $\Gamma^{\lambda}_{\nu\mu}$ will also transform according to (3.10) (since the partial derivatives appearing in the last term can be commuted), so they determine a distinct connection. There is thus a tensor we can associate with any given connection, known as the **torsion tensor**, defined by

$$T^{\lambda}{}_{\mu\nu} = \Gamma^{\lambda}_{\mu\nu} - \Gamma^{\lambda}_{\nu\mu} = 2\Gamma^{\lambda}_{[\mu\nu]}. \tag{3.22}$$

It is clear that the torsion is antisymmetric in its lower indices, and a connection that is symmetric in its lower indices is known as "torsion-free."

We can now define a unique connection on a manifold with a metric $g_{\mu\nu}$ by introducing two additional properties:

- torsion-free: $\Gamma^{\lambda}_{\mu\nu} = \Gamma^{\lambda}_{(\mu\nu)}$.
- metric compatibility: $\nabla_\rho g_{\mu\nu} = 0$.

A connection is **metric compatible** if the covariant derivative of the metric with respect to that connection is everywhere zero. This implies a couple of nice properties. First, it's easy to show that both the Levi–Civita tensor and the inverse metric also have zero covariant derivative,

$$\begin{aligned} \nabla_\lambda \epsilon_{\mu\nu\rho\sigma} &= 0 \\ \nabla_\rho g^{\mu\nu} &= 0. \end{aligned} \tag{3.23}$$

Second, a metric-compatible covariant derivative commutes with raising and lowering of indices. Thus, for some vector field V^λ,

$$g_{\mu\lambda}\nabla_\rho V^\lambda = \nabla_\rho(g_{\mu\lambda}V^\lambda) = \nabla_\rho V_\mu. \tag{3.24}$$

With non-metric-compatible connections we would have to be very careful about index placement when taking a covariant derivative.

Our claim is therefore that there is exactly one torsion-free connection on a given manifold that is compatible with some given metric on that manifold. We do not want to make these two requirements part of the definition of a covariant derivative; they simply single out one of the many possible ones.

We can demonstrate both existence and uniqueness by deriving a manifestly unique expression for the connection coefficients in terms of the metric. To accomplish this, we expand out the equation of metric compatibility for three different permutations of the indices:

$$\begin{aligned} \nabla_\rho g_{\mu\nu} &= \partial_\rho g_{\mu\nu} - \Gamma^{\lambda}_{\rho\mu} g_{\lambda\nu} - \Gamma^{\lambda}_{\rho\nu} g_{\mu\lambda} = 0 \\ \nabla_\mu g_{\nu\rho} &= \partial_\mu g_{\nu\rho} - \Gamma^{\lambda}_{\mu\nu} g_{\lambda\rho} - \Gamma^{\lambda}_{\mu\rho} g_{\nu\lambda} = 0 \\ \nabla_\nu g_{\rho\mu} &= \partial_\nu g_{\rho\mu} - \Gamma^{\lambda}_{\nu\rho} g_{\lambda\mu} - \Gamma^{\lambda}_{\nu\mu} g_{\rho\lambda} = 0. \end{aligned} \tag{3.25}$$

We subtract the second and third of these from the first, and use the symmetry of the connection to obtain

$$\partial_\rho g_{\mu\nu} - \partial_\mu g_{\nu\rho} - \partial_\nu g_{\rho\mu} + 2\Gamma^{\lambda}_{\mu\nu} g_{\lambda\rho} = 0. \tag{3.26}$$

It is straightforward to solve this for the connection by multiplying by $g^{\sigma\rho}$. The result is

$$\boxed{\Gamma^{\sigma}_{\mu\nu} = \tfrac{1}{2} g^{\sigma\rho}(\partial_\mu g_{\nu\rho} + \partial_\nu g_{\rho\mu} - \partial_\rho g_{\mu\nu}).} \tag{3.27}$$

This formula is one of the most important in this subject; commit it to memory. Of course, we have only proved that if a metric-compatible and torsion-free connection exists, it must be of the form (3.27); you can check for yourself that the right-hand side of (3.27) transforms like a connection.

This connection we have derived from the metric is the one on which conventional general relativity is based. It is known by different names: sometimes the **Christoffel** connection, sometimes the **Levi–Civita** connection, sometimes the **Riemannian** connection. The associated connection coefficients are sometimes called **Christoffel symbols** and written as $\left\{ {\sigma \atop \mu\nu} \right\}$; we will sometimes call them Christoffel symbols, but we won't use the funny notation. The study of manifolds with metrics and their associated connections is called Riemannian geometry, or sometimes pseudo-Riemannian when the metric has a Lorentzian signature.

Before putting our covariant derivatives to work, we should mention some miscellaneous properties. First, note that in ordinary flat space there is an implicit connection we use all the time—the Christoffel connection constructed from the flat metric. The coefficients of the Christoffel connection in flat space vanish in Cartesian coordinates, but not in curvilinear coordinate systems. Consider for example the plane in polar coordinates, with metric

$$ds^2 = \mathrm{d}r^2 + r^2 \mathrm{d}\theta^2. \tag{3.28}$$

The nonzero components of the inverse metric are readily found to be $g^{rr} = 1$ and $g^{\theta\theta} = r^{-2}$. Notice that we use r and θ as indices in an obvious notation. We can compute a typical connection coefficient:

$$\begin{aligned}
\Gamma^r_{rr} &= \tfrac{1}{2} g^{r\rho}(\partial_r g_{r\rho} + \partial_r g_{\rho r} - \partial_\rho g_{rr}) \\
&= \tfrac{1}{2} g^{rr}(\partial_r g_{rr} + \partial_r g_{rr} - \partial_r g_{rr}) \\
&\quad + \tfrac{1}{2} g^{r\theta}(\partial_r g_{r\theta} + \partial_r g_{\theta r} - \partial_\theta g_{rr}) \\
&= \tfrac{1}{2}(1)(0+0-0) + \tfrac{1}{2}(0)(0+0-0) \\
&= 0.
\end{aligned} \tag{3.29}$$

Sadly, it vanishes. But not all of them do:

$$\begin{aligned}
\Gamma^r_{\theta\theta} &= \tfrac{1}{2} g^{r\rho}(\partial_\theta g_{\theta\rho} + \partial_\theta g_{\rho\theta} - \partial_\rho g_{\theta\theta}) \\
&= \tfrac{1}{2} g^{rr}(\partial_\theta g_{\theta r} + \partial_\theta g_{r\theta} - \partial_r g_{\theta\theta}) \\
&= \tfrac{1}{2}(1)(0+0-2r) \\
&= -r.
\end{aligned} \tag{3.30}$$

Continuing to turn the crank, we eventually find

$$\begin{aligned}
\Gamma^r_{\theta r} &= \Gamma^r_{r\theta} = 0 \\
\Gamma^\theta_{rr} &= 0 \\
\Gamma^\theta_{r\theta} &= \Gamma^\theta_{\theta r} = \frac{1}{r} \\
\Gamma^\theta_{\theta\theta} &= 0.
\end{aligned} \tag{3.31}$$

From these and similar expressions, we can derive formulas for the divergence, gradient, and curl in curvilinear coordinate systems.

Contrariwise, even in a curved space it is still possible to make the Christoffel symbols vanish at any one point. This is because, as we argued in the last chapter, we can always make the first derivative of the metric vanish at a point; so by (3.27) the connection coefficients derived from this metric will also vanish. Of course this can only be established at a point, not in some neighborhood of the point. We will discuss this more fully in Section 3.4.

Another useful property is that the formula for the divergence of a vector (with respect to the Christoffel connection) has a simplified form. The covariant divergence of V^μ is given by

$$\nabla_\mu V^\mu = \partial_\mu V^\mu + \Gamma^\mu_{\mu\lambda} V^\lambda. \tag{3.32}$$

It is straightforward to show that the Christoffel connection satisfies

$$\Gamma^\mu_{\mu\lambda} = \frac{1}{\sqrt{|g|}} \partial_\lambda \sqrt{|g|}, \tag{3.33}$$

and we therefore obtain

$$\nabla_\mu V^\mu = \frac{1}{\sqrt{|g|}} \partial_\mu (\sqrt{|g|} V^\mu). \tag{3.34}$$

There are also formulas for the divergences of higher-rank tensors, but they are generally not such a great simplification.

We use the Christoffel covariant derivative in the curved-space version of Stokes's theorem (see Appendix E). If V^μ is a vector field over a region Σ with boundary $\partial\Sigma$, Stokes's theorem is

$$\boxed{\int_\Sigma \nabla_\mu V^\mu \sqrt{|g|}\, d^n x = \int_{\partial\Sigma} n_\mu V^\mu \sqrt{|\gamma|}\, d^{n-1} x,} \tag{3.35}$$

where n_μ is normal to $\partial\Sigma$, and γ_{ij} is the induced metric on $\partial\Sigma$. If the connection weren't metric-compatible or torsion-free, there would be additional terms in this equation.

The last thing we need to mention is that converting partial derivatives into covariant derivatives is not always necessary in order to construct well-defined tensors; in particular, the exterior derivative and the vector-field commutator are both well-defined in terms of partials, essentially because both involve an antisymmetrization that cancels the nontensorial piece of the partial derivative transformation law. The same feature implies that they could, on the other hand, be equally well-defined in terms of (torsion-free) covariant derivatives; the antisymmetrization causes the connection coefficient terms to vanish. Thus, if ∇ is the Christoffel connection, ω_μ is a one-form, and X^μ and Y^μ are vector fields, we can write

$$(\mathrm{d}\omega)_{\mu\nu} = \partial_{[\mu}\omega_{\nu]} = \nabla_{[\mu}\omega_{\nu]} \tag{3.36}$$

and

$$[X, Y]^{\mu} = X^{\lambda}\partial_{\lambda}Y^{\mu} - Y^{\lambda}\partial_{\lambda}X^{\mu} = X^{\lambda}\nabla_{\lambda}Y^{\mu} - Y^{\lambda}\nabla_{\lambda}X^{\mu}. \tag{3.37}$$

If the connection is not torsion-free, the last equalities in these expressions are no longer true; the more fundamental definitions of the exterior derivative and the commutator are those in terms of the partial derivative.

Before moving on, let's review the process by which we have been adding structures to our mathematical constructs. We started with the basic notion of a set, which you were presumed to be familiar with (informally, if not rigorously). We introduced the concept of open subsets of our set; this is equivalent to introducing a topology, and promoted the set to a topological space. Then by demanding that each open set look like a region of $\mathbf{R}^n$ (with n the same for each set) and that the coordinate charts be smoothly sewn together, the topological space became a manifold. A manifold is simultaneously a very flexible and powerful structure, and comes equipped naturally with a tangent bundle, tensor bundles of various ranks, the ability to take exterior derivatives, and so forth. We then proceeded to put a metric on the manifold, resulting in a manifold with metric (sometimes Riemannian manifold). Independently of the metric we found we could introduce a connection, allowing us to take covariant derivatives. Once we have a metric, however, there is automatically a unique torsion-free metric-compatible connection. Likewise we could introduce an independent volume form, although one is automatically determined by the metric. In principle there is nothing to stop us from introducing more than one connection, or volume form, or metric, on any given manifold. In general relativity we do have a physical metric, which determines volumes and the covariant derivative, and the independence of these notions is not a crucial feature.

3.3 ■ PARALLEL TRANSPORT AND GEODESICS

Now that we know how to take covariant derivatives, let's step back and put this in the context of differentiation more generally. We think of a derivative as a way of quantifying how fast something is changing. In the case of tensors, the crucial issue is "changing with respect to what?" An ordinary function defines a number at each point in spacetime, and it is straightforward to compare two different numbers, so we shouldn't be surprised that the partial derivative of functions remained valid on arbitrary manifolds. But a tensor is a map from vectors and dual vectors to the real numbers, and it's not clear how to compare such maps at different points in spacetime. Since we have successfully constructed a covariant derivative, can we think of it as somehow measuring the rate of change of tensors? The answer turns out to be yes: the covariant derivative quantifies the instantaneous rate of

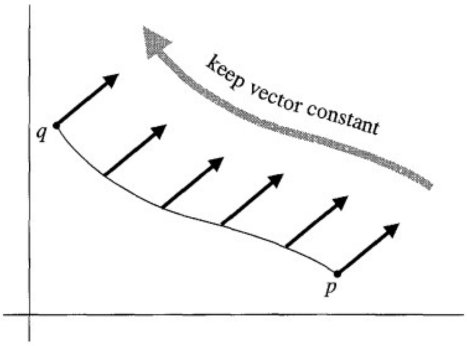

FIGURE 3.1 In flat space, we can parallel transport a vector by simply keeping its Cartesian components constant.

change of a tensor field in comparison to what the tensor would be if it were "parallel transported." In other words, a connection defines a specific way of keeping a tensor constant (along some path), on the basis of which we can compare nearby tensors.

It turns out that the concept of parallel transport is interesting in its own right, and worth spending some time thinking about. Recall that in flat space it is unnecessary to be very careful about the fact that vectors are elements of tangent spaces defined at individual points; it is actually very natural to compare vectors at different points (where by "compare" we mean add, subtract, take the dot product, and so on). The reason why it is natural is because it makes sense, in flat space, to move a vector from one point to another while keeping it constant, as illustrated in Figure 3.1. Then, once we get the vector from one point to another, we can do the usual operations allowed in a vector space.

This concept of moving a vector along a path, keeping constant all the while, is known as *parallel transport*. Parallel transport requires a connection to be well-defined; the intuitive manipulation of vectors in flat space makes implicit use of the Christoffel connection on this space. The crucial difference between flat and curved spaces is that, in a curved space, *the result of parallel transporting a vector from one point to another will depend on the path taken between the points.* Without yet assembling the complete mechanism of parallel transport, we can use our intuition about the two-sphere to see that this is the case. Start with a vector on the equator, pointing along a line of constant longitude. Parallel transport it up to the north pole along a line of longitude in the obvious way. Then take the original vector, parallel transport it along the equator by an angle θ, and then move it up to the north pole as before. As shown in Figure 3.2, it should be clear that the vector, parallel transported along two paths, arrived at the same destination with two different values (rotated by θ).

It therefore appears as if there is no natural way to uniquely move a vector from one tangent space to another; we can always parallel-transport it, but the result depends on the path, and there is no natural choice of which path to take.

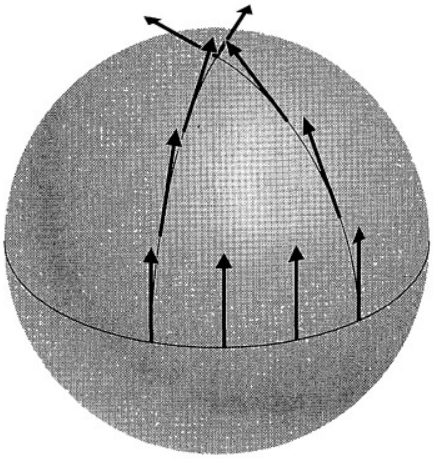

FIGURE 3.2 Parallel transport on a two-sphere. On a curved manifold, the result of parallel transport can depend on the path taken.

Unlike some of the problems we have encountered, *there is no solution to this one*—we simply must learn to live with the fact that two vectors can only be compared in a natural way if they are elements of the same tangent space. For example, two particles passing by each other have a well-defined relative velocity, which cannot be greater than the speed of light. But two particles at different points on a curved manifold do not have any well-defined notion of relative velocity—the concept simply makes no sense. Of course, in certain special situations it is still useful to talk as if it did make sense, but occasional usefulness is not a substitute for rigorous definition. In cosmology, for example, the light from distant galaxies is redshifted with respect to the frequencies we would observe from a nearby stationary source. Since this phenomenon bears such a close resemblance to the conventional Doppler effect due to relative motion, we are very tempted to say that the galaxies are "receding away from us" at a speed defined by their redshift. At a rigorous level this is nonsense, what Wittgenstein would call a "grammatical mistake"—the galaxies are not receding, since the notion of their velocity with respect to us is not well-defined. What is actually happening is that the metric of spacetime between us and the galaxies has changed (the universe has expanded) along the path of the photon from here to there, leading to an increase in the wavelength of the light. As an example of how you can go wrong, naive application of the Doppler formula to the redshift of galaxies implies that some of them are receding faster than light, in apparent contradiction with relativity. The resolution of this apparent paradox is simply that the very notion of their recession should not be taken literally.

Enough about what we cannot do; let's see what we can. Parallel transport is supposed to be the curved-space generalization of the concept of "keeping the vector constant" as we move it along a path; similarly for a tensor of arbitrary rank.

Given a curve $x^\mu(\lambda)$, the requirement of constancy of a tensor $T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l}$ along this curve in flat space is simply that the components be constant:

$$\frac{d}{d\lambda}T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} = \frac{dx^\mu}{d\lambda}\frac{\partial}{\partial x^\mu}T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} = 0.$$

To make this properly tensorial we simply replace this partial derivative by a covariant one, and define the **directional covariant derivative** to be

$$\frac{D}{d\lambda} = \frac{dx^\mu}{d\lambda}\nabla_\mu. \tag{3.38}$$

This is a map, defined only along the path, from (k, l) tensors to (k, l) tensors. We then define **parallel transport** of the tensor T along the path $x^\mu(\lambda)$ to be the requirement that the covariant derivative of T along the path vanishes:

$$\left(\frac{D}{d\lambda}T\right)^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} \equiv \frac{dx^\sigma}{d\lambda}\nabla_\sigma T^{\mu_1\mu_2\cdots\mu_k}{}_{\nu_1\nu_2\cdots\nu_l} = 0. \tag{3.39}$$

This is a well-defined tensor equation (since both the tangent vector $dx^\mu/d\lambda$ and the covariant derivative ∇T are tensors), known as the **equation of parallel transport**. For a vector it takes the form

$$\frac{d}{d\lambda}V^\mu + \Gamma^\mu_{\sigma\rho}\frac{dx^\sigma}{d\lambda}V^\rho = 0. \tag{3.40}$$

We can look at the parallel transport equation as a first-order differential equation defining an initial-value problem: given a tensor at some point along the path, there will be a unique continuation of the tensor to other points along the path such that the continuation solves (3.39). We say that such a tensor is parallel-transported.

The notion of parallel transport is obviously dependent on the connection, and different connections lead to different answers. If the connection is metric-compatible, the metric is always parallel transported with respect to it:

$$\frac{D}{d\lambda}g_{\mu\nu} = \frac{dx^\sigma}{d\lambda}\nabla_\sigma g_{\mu\nu} = 0. \tag{3.41}$$

It follows that the inner product of two parallel-transported vectors is preserved. That is, if V^μ and W^ν are parallel-transported along a curve $x^\sigma(\lambda)$, we have

$$\begin{aligned}\frac{D}{d\lambda}(g_{\mu\nu}V^\mu W^\nu) &= \left(\frac{D}{d\lambda}g_{\mu\nu}\right)V^\mu W^\nu + g_{\mu\nu}\left(\frac{D}{d\lambda}V^\mu\right)W^\nu + g_{\mu\nu}V^\mu\left(\frac{D}{d\lambda}W^\nu\right)\\ &= 0.\end{aligned} \tag{3.42}$$

This means that parallel transport with respect to a metric-compatible connection preserves the norm of vectors, the sense of orthogonality, and so on.

With parallel transport defined, the next logical step is to discuss geodesics. A geodesic is the curved-space generalization of the notion of a straight line in Euclidean space. We all know what a straight line is: it's the path of shortest distance between two points. But there is an equally good definition—a straight line is a path that parallel-transports its own tangent vector. It will turn out that these two concepts coincide if and only if the connection is the Christoffel connection.

We'll start with the second definition (a geodesic is a curve along which the tangent vector is parallel-transported), since it is computationally much more straightforward. The tangent vector to a path $x^\mu(\lambda)$ is $dx^\mu/d\lambda$. The condition that it be parallel transported is thus

$$\frac{D}{d\lambda}\frac{dx^\mu}{d\lambda} = 0, \tag{3.43}$$

or alternatively

$$\boxed{\frac{d^2x^\mu}{d\lambda^2} + \Gamma^\mu_{\rho\sigma}\frac{dx^\rho}{d\lambda}\frac{dx^\sigma}{d\lambda} = 0.} \tag{3.44}$$

This is the **geodesic equation**, another one you should memorize. We can easily see that it reproduces the usual notion of straight lines if the connection coefficients are the Christoffel symbols in Euclidean space; in that case we can choose Cartesian coordinates in which $\Gamma^\mu_{\rho\sigma} = 0$, and the geodesic equation is just $d^2x^\mu/d\lambda^2 = 0$, which is the equation for a straight line.

That was embarrassingly simple; let's turn to the more nontrivial case of the shortest-distance definition. As we know, various subtleties are involved in the definition of distance in a Lorentzian spacetime; for null paths the distance is zero, for timelike paths it's more convenient to use the proper time. So in the name of simplicity let's do the calculation just for a timelike path—the resulting equation will turn out to be good for any path, so we are not losing any generality. We therefore consider the proper time functional,

$$\tau = \int \left(-g_{\mu\nu}\frac{dx^\mu}{d\lambda}\frac{dx^\nu}{d\lambda}\right)^{1/2} d\lambda, \tag{3.45}$$

where the integral is over the path. To search for shortest-distance paths, we could do the usual calculus-of-variations treatment to seek critical points of this functional. They will turn out to be curves of *maximum* proper time, consistent with our discussion of the twin paradox in Chapter 1. However, we can simplify the algebra by means of a trick. The integral (3.45) is of the form $\tau = \int \sqrt{-f}\, d\lambda$, where $f = g_{\mu\nu}(dx^\mu/d\lambda)(dx^\nu/d\lambda)$. The variation looks like

$$\begin{aligned}\delta\tau &= \int \delta\sqrt{-f}\, d\lambda \\ &= -\int \frac{1}{2}(-f)^{-1/2}\,\delta f\, d\lambda.\end{aligned} \tag{3.46}$$

It makes things easier if we now specify that our parameter is the proper time τ itself, rather than the arbitrary parameter λ, so that the tangent vector is the four-velocity U^μ. This fixes the value of f,

$$f = g_{\mu\nu}\frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau} = g_{\mu\nu}U^\mu U^\nu = -1. \tag{3.47}$$

From (3.46) we then have

$$\delta\tau = -\frac{1}{2}\int \delta f\, d\tau. \tag{3.48}$$

Stationary points of (3.45)—paths for which $\delta\tau = 0$—are therefore equivalent to stationary points (with fixed parameterization) of the simpler integral

$$I = \frac{1}{2}\int f\, d\tau = \frac{1}{2}\int g_{\mu\nu}\frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau}\, d\tau. \tag{3.49}$$

(The $\frac{1}{2}$ is by no means necessary, but will make things nicer later on.) Taking variations of this expression is thus a shortcut to finding shortest-distance paths, one that we will wisely follow.

Stationary points of I will of course obey the Euler–Lagrange equations (1.128), but evaluating them involves repeated application of the chain rule, and it is just as simple to directly consider the change in the integral under infinitesimal variations of the path,

$$\begin{aligned} x^\mu &\rightarrow x^\mu + \delta x^\mu \\ g_{\mu\nu} &\rightarrow g_{\mu\nu} + (\partial_\sigma g_{\mu\nu})\delta x^\sigma. \end{aligned} \tag{3.50}$$

The second line comes from Taylor expansion in curved spacetime, which as you can see, uses the partial derivative, not the covariant derivative. This is because we are simply thinking of the components $g_{\mu\nu}$ as functions on spacetime in some specific coordinate system. Plugging this into (3.49) and keeping only terms first-order in δx^μ, we get

$$\delta I = \frac{1}{2}\int\left[\partial_\sigma g_{\mu\nu}\frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau}\delta x^\sigma + g_{\mu\nu}\frac{d(\delta x^\mu)}{d\tau}\frac{dx^\nu}{d\tau} + g_{\mu\nu}\frac{dx^\mu}{d\tau}\frac{d(\delta x^\nu)}{d\tau}\right] d\tau. \tag{3.51}$$

The last two terms can be integrated by parts; for example,

$$\begin{aligned} \frac{1}{2}\int\left[g_{\mu\nu}\frac{dx^\mu}{d\tau}\frac{d(\delta x^\nu)}{d\tau}\right] d\tau &= -\frac{1}{2}\int\left[g_{\mu\nu}\frac{d^2x^\mu}{d\tau^2} + \frac{dg_{\mu\nu}}{d\tau}\frac{dx^\mu}{d\tau}\right]\delta x^\nu\, d\tau \\ &= -\frac{1}{2}\int\left[g_{\mu\nu}\frac{d^2x^\mu}{d\tau^2} + \partial_\sigma g_{\mu\nu}\frac{dx^\sigma}{d\tau}\frac{dx^\mu}{d\tau}\right]\delta x^\nu\, d\tau, \end{aligned} \tag{3.52}$$

where we have neglected boundary terms, which vanish because we take our variation δx^μ to vanish at the endpoints of the path. In the second line we have used the chain rule on the derivative of $g_{\mu\nu}$. The variation (3.51) then becomes, after rearranging some dummy indices,

$$\delta I = -\int \left[g_{\mu\sigma} \frac{d^2x^\mu}{d\tau^2} + \frac{1}{2}\left(\partial_\mu g_{\nu\sigma} + \partial_\nu g_{\sigma\mu} - \partial_\sigma g_{\mu\nu}\right) \frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau} \right] \delta x^\sigma \, d\tau. \tag{3.53}$$

Since we are searching for stationary points, we want δI to vanish for any variation δx^σ; this implies

$$g_{\mu\sigma} \frac{d^2x^\mu}{d\tau^2} + \frac{1}{2}\left(\partial_\mu g_{\nu\sigma} + \partial_\nu g_{\sigma\mu} - \partial_\sigma g_{\mu\nu}\right) \frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau} = 0, \tag{3.54}$$

and multiplying by the inverse metric $g^{\rho\sigma}$ finally leads to

$$\frac{d^2x^\rho}{d\tau^2} + \frac{1}{2} g^{\rho\sigma}\left(\partial_\mu g_{\nu\sigma} + \partial_\nu g_{\sigma\mu} - \partial_\sigma g_{\mu\nu}\right) \frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau} = 0. \tag{3.55}$$

We see that this is precisely the geodesic equation (3.40), but with the specific choice of Christoffel connection (3.27). Thus, on a manifold with metric, extremals of the length functional are curves that parallel transport their tangent vector with respect to the Christoffel connection associated with that metric. It doesn't matter if any other connection is defined on the same manifold. Of course, in GR the Christoffel connection is the only one used, so the two notions are the same.

The variational principle provides a convenient way to actually calculate the Christoffel symbols for a given metric. Rather than simply plugging into (3.27), it is often less work to explicitly vary the integral (3.49), with the metric of interest substituted in for $g_{\mu\nu}$. An example of this procedure is shown in Section 3.5.

3.4 ■ PROPERTIES OF GEODESICS

The primary usefulness of geodesics in general relativity is that they are the paths followed by unaccelerated test particles. A **test particle** is a body that does not itself influence the geometry through which it moves—never perfectly true, but often an excellent approximation. This concept allows us to explore, for example, the properties of the gravitational field around the Sun, without worrying about the field of the planet whose motion we are considering. The geodesic equation can be thought of as the generalization of Newton's law $\mathbf{f} = m\mathbf{a}$, for the case $\mathbf{f} = 0$, to curved spacetime. It is also possible to introduce forces by adding terms to the right-hand side; in fact, looking back to the expression (1.105)

$$\frac{d^2x^\mu}{d\tau^2} + \Gamma^\mu_{\rho\sigma} \frac{dx^\rho}{d\tau}\frac{dx^\sigma}{d\tau} = \frac{q}{m} F^\mu{}_\nu \frac{dx^\nu}{d\tau}. \tag{3.56}$$

We will talk about this more later, but in fact your guess would be correct.

We should say some more careful words about the parameterization of a geodesic path. When we presented the geodesic equation as the requirement that the tangent vector be parallel-transported, (3.44), we parameterized our path with some parameter λ, whereas when we found the formula (3.55) for the extremal of the spacetime interval, we wound up with a very specific parameterization, the proper time. Of course from the form of (3.55) it is clear that a transformation,

$$\tau \to \lambda = a\tau + b, \tag{3.57}$$

for some constants a and b, leaves the equation invariant. Any parameter related to the proper time in this way is called an **affine parameter**, and is just as good as the proper time for parameterizing a geodesic. What was hidden in our derivation of (3.44) was that *the demand that the tangent vector be parallel-transported actually constrains the parameterization of the curve*, specifically to one related to the proper time by (3.57). In other words, if you start at some point and with some initial direction, and then construct a curve by beginning to walk in that direction and keeping your tangent vector parallel transported, you will not only define a path in the manifold but also (up to linear transformations) define the parameter along the path.

Of course, there is nothing to stop you from using any other parameterization you like, but then (3.44) will not be satisfied. More generally you will satisfy an equation of the form

$$\frac{d^2x^\mu}{d\alpha^2} + \Gamma^\mu_{\rho\sigma}\frac{dx^\rho}{d\alpha}\frac{dx^\sigma}{d\alpha} = f(\alpha)\frac{dx^\mu}{d\alpha}, \tag{3.58}$$

for some parameter $\alpha(\lambda)$, where $f(\alpha)$ is related to the affine parameter by

$$f(\alpha) = -\left(\frac{d^2\alpha}{d\lambda^2}\right)\left(\frac{d\alpha}{d\lambda}\right)^{-2}. \tag{3.59}$$

Conversely, if (3.58) is satisfied along a curve you can always find an affine parameter $\lambda(\alpha)$ for which the geodesic equation (3.44) will be satisfied.

For timelike paths, we can write the geodesic equation in terms of the four-velocity $U^\mu = dx^\mu/d\tau$ as

$$U^\lambda \nabla_\lambda U^\mu = 0. \tag{3.60}$$

Similarly, in terms of the four-momentum $p^\mu = mU^\mu$, the geodesic equation is simply

$$p^\lambda \nabla_\lambda p^\mu = 0. \tag{3.61}$$

This relation expresses the idea that freely-falling particles keep moving in the direction in which their momenta are pointing.

For null paths, the proper time vanishes and τ is not an appropriate affine parameter. Nevertheless, it is still perfectly well-defined to ask whether a parameterized path $x^\mu(\lambda)$ satisfies the geodesic equation (3.44). If a null path is a geodesic for some parameter λ, it will also be a geodesic for any other affine parameter of the form $a\lambda + b$. However, there is no preferred choice among these parameters like the proper time is for timelike paths. Once we choose a parameter at some point along the path, of course, there is a unique continuation to the rest of the path if we want to solve the geodesic equation. It is often convenient to choose the normalization of the affine parameter λ along a null geodesic such that $dx^\mu/d\lambda$ is equal to the momentum four-vector:

$$p^\mu = \frac{dx^\mu}{d\lambda}. \tag{3.62}$$

This is in contrast to timelike paths, where $dx^\mu/d\tau$ is the momentum per unit mass. Then an observer with four-velocity U^μ measures the energy of the particle (or equivalently the frequency, since we are setting $\hbar = 1$) to be

$$E = -p_\mu U^\mu. \tag{3.63}$$

This expression always tells us the energy of a particle with momentum p^μ as measured by an observer with four-velocity U^μ, whether p^μ is null or timelike; you can check it by going to locally inertial coordinates. (A caveat: this expression for E does not include potential energy, only the intrinsic energy from motion and inertia. In a general spacetime there will not be a well-defined notion of gravitational potential energy, although in special cases it does exist.)

An important property of geodesics in a spacetime with Lorentzian metric is that the character (timelike/null/spacelike) of the geodesic, relative to a metric-compatible connection, never changes. This is simply because parallel transport preserves inner products, and the character is determined by the inner product of the tangent vector with itself. This is why we were consistent to consider purely timelike paths when we derived (3.55); for spacelike paths we would have derived the same equation, since the only difference is an overall minus sign in the final answer.

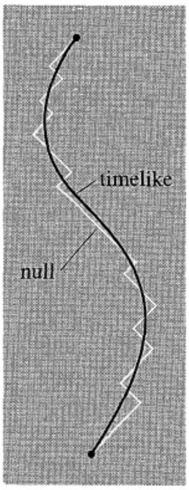

FIGURE 3.3 We can always approximate a timelike path by a sequence of null paths with a total path length of zero. Hence, timelike geodesics must be maxima of the proper time rather than minima.

Let's now explain the earlier remark that timelike geodesics are maxima of the proper time. The reason we know this is true is that, given any timelike curve (geodesic or not), we can approximate it to arbitrary accuracy by a null curve. To do this all we have to do is to consider "jagged" null curves that follow the timelike one, as portrayed in Figure 3.3. As we increase the number of sharp corners, the null curve comes closer and closer to the timelike curve while still having zero path length. Timelike geodesics cannot therefore be curves of minimum proper time, since they are always infinitesimally close to curves of less proper time (zero, in fact); actually they maximize the proper time. This is how you can remember which twin in the twin paradox ages more—the one who stays home is basically on a geodesic, and therefore experiences more proper time. Of course even this is being a little cavalier; actually every time we say "maximize" or "minimize" we should add the modifier "locally." Often the case is that between two points on a manifold there is more than one geodesic. For instance, on S^2 we can draw a great circle through any two points, and imagine traveling between them either the short way or the long way around. One of these is obviously longer than the other, although both are stationary points of the length functional.

Geodesics provide a convenient a way of mapping the tangent space T_p of a point p to a region of the manifold that contains p, called the **exponential map**. This map in turn defines a set of coordinates for this region that are automatically the locally inertial coordinates discussed in Section 2.5 [coordinates $x^{\hat{\mu}}$ around a point p such that $g_{\hat{\mu}\hat{\nu}}(p) = \eta_{\hat{\mu}\hat{\nu}}$ and $\partial_{\hat{\sigma}} g_{\hat{\mu}\hat{\nu}}(p) = 0$]. We begin by noticing that any vector $k \in T_p$ defines a unique geodesic passing through it, for which k is the tangent vector at p, and $\lambda(p) = 0$:

$$\frac{dx^\mu}{d\lambda}(\lambda = 0) = k^\mu. \tag{3.64}$$

Uniqueness follows from the fact that the geodesic equation is a second-order differential equation, and specifying initial data in the form $x^\mu(p)$ and $k^\mu = (dx^\mu/d\lambda)(p)$ completely determines a solution. On this geodesic there will be a unique point in M for which $\lambda = 1$. The exponential map at p, $\exp_p : T_p \to M$, is then defined as

$$\exp_p(k) = x^\nu(\lambda = 1), \tag{3.65}$$

where $x^\nu(\lambda)$ solves the geodesic equation subject to (3.64), as shown in Figure 3.4.

For some set of tangent vectors k^μ near the zero vector, this map will be well-defined, and in fact invertible. Depending on the geometry, however, different geodesics emanating from a single point may eventually cross, at which point $\exp_p : T_p \to M$ is no longer one-to-one. Furthermore, the range of the exponential map is not necessarily the whole manifold, and the domain is not necessarily the whole tangent space. The range can fail to be all of M simply because there can be two points that are not connected by any geodesic. An example is given by anti-de Sitter space, discussed in Chapter 8. The domain can fail to be all of T_p because a geodesic may run into a singularity, which we think of as "the edge of the manifold." Manifolds that have such singularities are known as **geodesically incomplete**. In a more careful discussion it would actually be the

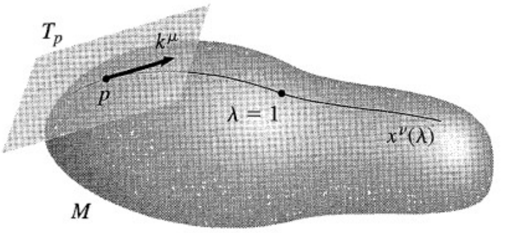

FIGURE 3.4 The exponential map takes a vector in T_p to a point in M that lies at unit affine parameter along the geodesic to which the vector is tangent.

other way around: the best way we have of defining a singularity is as a place where geodesics appear to "end," after we remove trivial cases in which a part of the manifold is artificially excluded by hand. See Wald (1984) or Hawking and Ellis (1973). This problem is not merely technical; the singularity theorems of Hawking and Penrose state that, for certain matter content, spacetimes in general relativity are almost guaranteed to be geodesically incomplete. As examples, two of the most useful spacetimes in GR—the Schwarzschild solution describing black holes and the Friedmann–Robertson–Walker solutions describing homogeneous, isotropic cosmologies—both feature important singularities; these will be discussed in later chapters.

We now use the exponential map to construct locally inertial coordinates. The easy part is to find basis vectors $\{\hat{e}_{(\hat{\mu})}\}$ for T_p such that the components of the metric are those of the canonical form:

$$g_{\hat{\mu}\hat{\nu}} = g(\hat{e}_{(\hat{\mu})}, \hat{e}_{(\hat{\nu})}) = \eta_{\hat{\mu}\hat{\nu}}. \tag{3.66}$$

Here $g(\ ,\ )$ denotes the metric, thought of as a multilinear map from $T_p \times T_p$ to **R**. And the hats have different meanings: over e they remind us that it's a basis vector, and over the indices they remind us that we are in locally inertial coordinates (as we shall see). This is easy because it's just linear algebra, not yet referring to coordinates; starting with any set of components for $g_{\mu\nu}$, we can always diagonalize this matrix and then rescale our basis vectors to satisfy (3.66). The hard part, we would expect, is finding a coordinate system $x^{\hat{\mu}}$ for which the basis vectors $\{\hat{e}_{(\hat{\mu})}\}$ comprise the coordinate basis, $\hat{e}_{(\hat{\mu})} = \partial_{\hat{\mu}}$, and such that the first partial derivatives of $g_{\hat{\mu}\hat{\nu}}$ vanish. In fact, however, the exponential map achieves this automatically. For any point q sufficiently close to p, there is a unique geodesic path connecting p to q, and a unique parameterization λ such that $\lambda(p) = 0$ and $\lambda(q) = 1$. At p the tangent vector k to this geodesic can be written as a linear combination of our basis vectors, $k = k^{\hat{\mu}}\hat{e}_{(\hat{\mu})}$. We define the sought-after coordinates x^{μ} simply to be these components: $x^{\hat{\mu}}(q) = k^{\hat{\mu}}$. In other words, we have defined the coordinates $x^{\hat{\mu}}(q)$ to be the components (with respect to our normalized basis $\{\hat{e}_{(\hat{\mu})}\}$) of the tangent vector k that gets mapped to q by $\exp_p$. Coordinates constructed in this way are known as **Riemann normal coordinates** at p.

We still need to verify that these Riemann normal coordinates satisfy $\partial_{\hat{\sigma}} g_{\hat{\mu}\hat{\nu}}(p) = 0$. Note that a ray in the tangent space (a parameterized set of vectors of the form $\lambda k^{\hat{\mu}}$, for some fixed vector $k^{\hat{\mu}}$) gets mapped to a geodesic by the exponential map. Therefore, in Riemann normal coordinates, a curve $x^{\hat{\mu}}(\lambda)$ of the form

$$x^{\hat{\mu}}(\lambda) = \lambda k^{\hat{\mu}} \tag{3.67}$$

will solve the geodesic equation. Indeed, *any* geodesic through p may be expressed this way, for some appropriate vector $k^{\hat{\mu}}$. We therefore have

$$\frac{d^2 x^{\hat{\mu}}}{d\lambda^2} = 0 \tag{3.68}$$

along any geodesic through p in this coordinate system. But, by the geodesic equation, we also have

$$\frac{d^2x^{\hat{\mu}}}{d\lambda^2}(p) = -\Gamma^{\hat{\mu}}_{\hat{\rho}\hat{\sigma}}(p)k^{\hat{\rho}}k^{\hat{\sigma}}, \tag{3.69}$$

where $k^{\hat{\rho}} = (dx^{\hat{\rho}}/d\lambda)(p)$. Since this holds for arbitrary $k^{\hat{\rho}}$, we conclude that

$$\Gamma^{\hat{\mu}}_{\hat{\rho}\hat{\sigma}}(p) = 0. \tag{3.70}$$

Now apply metric compatibility:

$$\begin{aligned} 0 &= \nabla_{\hat{\sigma}} g_{\hat{\mu}\hat{\nu}} \\ &= \partial_{\hat{\sigma}} g_{\hat{\mu}\hat{\nu}} - \Gamma^{\hat{\lambda}}_{\hat{\sigma}\hat{\mu}} g_{\hat{\lambda}\hat{\nu}} - \Gamma^{\hat{\lambda}}_{\hat{\sigma}\hat{\nu}} g_{\hat{\mu}\hat{\lambda}} \\ &= \partial_{\hat{\sigma}} g_{\hat{\mu}\hat{\nu}}, \end{aligned} \tag{3.71}$$

where all quantities are evaluated at p. We see that Riemann normal coordinates provide a realization of the locally inertial coordinates discussed in Section 2.5. They are not unique; there are an infinite number of non-Riemann-normal coordinate systems in which $g_{\hat{\mu}\hat{\nu}}(p) = \eta_{\hat{\mu}\hat{\nu}}$ and $\partial_{\hat{\sigma}} g_{\hat{\mu}\hat{\nu}}(p) = 0$, but in an expansion around p they will differ from the Riemann normal coordinates only at third order in $x^{\hat{\mu}}$.

3.5 ■ THE EXPANDING UNIVERSE REVISITED

Let's put some of the technology we have developed to work in understanding a simple metric. Recall the expanding-universe metric we studied in Chapter 2,

$$\begin{aligned} ds^2 &= -\mathrm{d}t^2 + a^2(t)[\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2] \\ &= -\mathrm{d}t^2 + a^2(t)\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j. \end{aligned} \tag{3.72}$$

This metric describes a universe consisting of flat spatial sections expanding as a function of time, with the relative distance between particles at fixed spatial coordinates growing proportionally to the scale factor $a(t)$.

Faced with a metric, the first thing we do is to calculate the Christoffel symbols. As mentioned at the end of Section 3.3, the easiest technique for doing so is actually to vary explicitly an integral of the form (3.49). Plugging in the metric under consideration, we have

$$I = \frac{1}{2}\int \left[-\left(\frac{dt}{d\tau}\right)^2 + a^2(t)\delta_{ij}\frac{dx^i}{d\tau}\frac{dx^j}{d\tau} \right] d\tau. \tag{3.73}$$

The technique is to consider variations $x^\mu \to x^\mu + \delta x^\mu$ and demand that δI vanish. We get n equations on an n-dimensional manifold (in this case $n = 4$), one for each μ; each equation corresponds to a component of the geodesic equation

(3.44). In the equation derived by varying with respect to x^μ, the coefficient of $(dx^\rho/d\tau)(dx^\sigma/d\tau)$ will be $\Gamma^\mu_{\rho\sigma}$.

For the metric (3.72), we need to consider separately variations with respect to $x^0 = t$ and one of the x^i's (it doesn't matter which one, since the results for each spacelike direction will be equivalent). Let's start with $t \to t + \delta t$. The nontrivial time dependence comes from the scale factor, for which, to first order,

$$a(t + \delta t) = a(t) + \dot{a}\delta t, \tag{3.74}$$

where $\dot{a} = da/dt$. We therefore have

$$\begin{aligned}\delta I &= \frac{1}{2}\int\left[-2\frac{dt}{d\tau}\frac{d(\delta t)}{d\tau} + 2a\dot{a}\delta_{ij}\frac{dx^i}{d\tau}\frac{dx^j}{d\tau}\delta t\right]d\tau \\ &= \int\left[\frac{d^2t}{d\tau^2} + a\dot{a}\delta_{ij}\frac{dx^i}{d\tau}\frac{dx^j}{d\tau}\right]\delta t\, d\tau,\end{aligned} \tag{3.75}$$

where we have dropped a boundary term after integrating by parts (as always). Setting the coefficient of δt equal to zero implies

$$\frac{d^2t}{d\tau^2} + a\dot{a}\delta_{ij}\frac{dx^i}{d\tau}\frac{dx^j}{d\tau} = 0, \tag{3.76}$$

which is supposed to be equivalent to the geodesic equation (with $\mu = 0$)

$$\frac{d^2x^0}{d\tau^2} + \Gamma^0_{\rho\sigma}\frac{dx^\rho}{d\tau}\frac{dx^\sigma}{d\tau} = 0. \tag{3.77}$$

Comparison of these two equations implies

$$\begin{aligned}\Gamma^0_{00} &= 0, \\ \Gamma^0_{i0} = \Gamma^0_{0i} &= 0, \\ \Gamma^0_{ij} &= a\dot{a}\,\delta_{ij}.\end{aligned} \tag{3.78}$$

We can repeat this procedure for a spatial coordinate, $x^i \to x^i + \delta x^i$. The variation is then

$$\begin{aligned}\delta I &= \frac{1}{2}\int a^2\left(2\delta_{ij}\frac{dx^i}{d\tau}\frac{d(\delta x^j)}{d\tau}\right)d\tau \\ &= -\int\left(a^2\frac{d^2x^i}{d\tau^2} + 2a\frac{da}{d\tau}\frac{dx^i}{d\tau}\right)\delta_{ij}\delta x^j\, d\tau.\end{aligned} \tag{3.79}$$

We can express $da/d\tau$ in terms of $\dot{a}$ by using the chain rule,

$$\frac{da}{d\tau} = \dot{a}\frac{dt}{d\tau}. \tag{3.80}$$

Then setting the coefficient of δx^j equal to zero in (3.79) implies

$$\frac{d^2x^i}{d\tau^2}+2\frac{\dot{a}}{a}\frac{dt}{d\tau}\frac{dx^i}{d\tau}=0. \tag{3.81}$$

Comparing to the geodesic equation, we find that the Christoffel symbols must satisfy

$$\Gamma^i_{\rho\sigma}\frac{dx^\rho}{d\tau}\frac{dx^\sigma}{d\tau}=2\frac{\dot{a}}{a}\frac{dt}{d\tau}\frac{dx^i}{d\tau}. \tag{3.82}$$

The Christoffel symbols are therefore given by

$$\begin{aligned}\Gamma^i_{00}&=0\\ \Gamma^i_{j0}=\Gamma^i_{0j}&=\frac{\dot{a}}{a}\delta^i_j\\ \Gamma^i_{jk}&=0.\end{aligned} \tag{3.83}$$

Together, (3.78) and (3.83) are all of the connection coefficients for the metric (3.72). These are, of course, necessary both for studying geodesics of the spacetime and for taking covariant derivatives; in fact, (3.76) and (3.81) together *are* the geodesic equation. Let's put this to work by solving for null geodesics, those followed by massless particles such as photons, for which we have to use λ rather than τ as a parameter. Without loss of generality we can consider paths along the x-direction, for which $x^\mu(\lambda)=\{t(\lambda),x(\lambda),0,0\}$. It is trivial to solve for null paths of this sort, using $ds^2=0$. We have

$$0=-\mathrm{d}t^2+a^2(t)\mathrm{d}x^2, \tag{3.84}$$

which implies

$$\frac{dx}{d\lambda}=\frac{1}{a}\frac{dt}{d\lambda}. \tag{3.85}$$

In Section 2.6 we solved this for $a=t^q$, but here we will remain more general. Also, we have chosen to consider paths moving in the positive x-direction, which determines the sign of $dx/d\lambda$. We must distinguish, however, between "null paths" and "null geodesics": the latter are a much more restrictive class, and to show that these paths are geodesics, we need to solve for the coordinates t and x in terms of the parameter λ.

Let's solve for $dt/d\lambda$, which will turn out to be the quantity in which we are most interested. Plugging the null condition (3.85) into the $\mu=0$ component of the geodesic equation (3.76), and remembering to replace $\tau\to\lambda$, we get

$$\frac{d^2t}{d\lambda^2}+\frac{\dot{a}}{a}\left(\frac{dt}{d\lambda}\right)^2=0. \tag{3.86}$$

It is straightforward to verify that this is solved by

$$\frac{dt}{d\lambda} = \frac{\omega_0}{a}, \tag{3.87}$$

where ω_0 is a constant. For a given $a(t)$, this could be instantly integrated to yield $t(\lambda)$. But more interesting is to consider the energy E of the photon as it would be measured by a comoving observer (one at fixed spatial coordinates), who would have four-velocity

$$U^\mu = (1, 0, 0, 0). \tag{3.88}$$

Don't get tricked into thinking that the timelike component of the four-velocity of a particle at rest will always equal unity; we need to satisfy the normalization condition $g_{\mu\nu}U^\mu U^\nu = -1$, which in the rest frame ($U^i = 0$) implies $U^0 = \sqrt{-g_{00}}$. According to (3.63), and using $p^\mu = dx^\mu/d\lambda$, we have

$$\begin{aligned} E &= -p_\mu U^\mu \\ &= -g_{00}\frac{dx^0}{d\lambda}U^0 \\ &= \frac{\omega_0}{a}. \end{aligned} \tag{3.89}$$

We see why the notation ω_0 was chosen for the constant of proportionality in (3.87): ω_0 is simply the frequency of the photon when $a = 1$. Recall that $E = \hbar\omega$, and we are using units in which $\hbar = 1$.

We have uncovered a profound phenomenon: the **cosmological redshift**. A photon emitted with energy E_1 at scale factor a_1 and observed with energy E_2 at scale factor a_2 will have

$$\frac{E_2}{E_1} = \frac{a_1}{a_2}. \tag{3.90}$$

This is called a "redshift" because the wavelength of the photon is inversely proportional to the frequency, and in an expanding universe the wavelength therefore grows with time. As a practical matter this provides an easy way to measure the change in the scale factor between us and distant galaxies, and also serves as a proxy for the distance: since the universe has been monotonically expanding, a greater redshift implies a greater distance. In conventional notation, the amount of redshift is denoted by

$$z = \frac{\omega_1 - \omega_2}{\omega_2} = \frac{a_2}{a_1} - 1, \tag{3.91}$$

so that z vanishes if there has been no expansion, for instance, if the emitter and observer are so close that there hasn't been enough time for the universe to appreciably expand.

As mentioned in Section 3.3, the cosmological redshift is *not* a Doppler shift (despite the understandable temptation to refer to the "velocity" of receding galaxies). Now we can understand this statement quantitatively. You might imagine that, as far as the behavior of emitted photons is concerned, there is little difference between two galaxies physically moving apart in a flat spacetime and two galaxies at fixed comoving coordinates in an expanding spacetime. But let's consider a specific (unrealistic, but educational) example. Start with flat spacetime, and imagine that our two galaxies are initially not moving apart, but are at rest in some globally inertial coordinate system. One emits a photon toward the other; while the photon is traveling, we quickly move the two galaxies apart until they are twice their original separation, then leave them stationary at that distance; and then the photon is absorbed by the second galaxy. Clearly there will be no Doppler shift, since the galaxies were at rest both at emission and absorption. Now consider the analogous phenomenon in an expanding spacetime, with the galaxies stuck at fixed comoving coordinates. We begin with the scale factor constant (the universe is not expanding). One galaxy emits a photon, and we imagine that during the photon's journey the universe starts expanding until the scale factor is twice its original size, and then stops expanding before the photon is absorbed. In this case there certainly will be a redshift, despite the fact that there was no "relative motion" (an ill-defined concept in any case) at either absorption or emission; the photon's wavelength will have doubled as the scale factor doubled, so we observe a redshift $z = 1$. This demonstrates the conceptual distinction between the cosmological redshift and the conventional Doppler effect.

Beyond the geodesic equation, covariant derivatives will play a role in generalizing laws of physics from the flat spacetime of special relativity to the curved geometry of general relativity. As we will discuss in more detail in the next chapter, a simple rule of thumb is simply to replace all partial derivatives by covariant derivatives, and all appearances of the flat spacetime metric $\eta_{\mu\nu}$ by the curved metric $g_{\mu\nu}$. For example, the energy-momentum conservation equation of special relativity, $\partial_\mu T^{\mu\nu} = 0$, where $T^{\mu\nu}$ is the energy-momentum tensor, becomes

$$\nabla_\mu T^{\mu\nu} = 0. \tag{3.92}$$

In cosmology, we typically model the matter filling the universe as a perfect fluid; the corresponding energy-momentum tensor comes from generalizing (1.114) to curved spacetime,

$$T^{\mu\nu} = (\rho + p)U^\mu U^\nu + p g^{\mu\nu}. \tag{3.93}$$

Recall that ρ is the energy density, p is the pressure, and U^μ is the four-velocity of the fluid. For the metric (3.72) the components of the inverse metric are

$$g^{\mu\nu} = \begin{pmatrix} -1 & & & \\ & a^{-2} & & \\ & & a^{-2} & \\ & & & a^{-2} \end{pmatrix}. \tag{3.94}$$

We can take the fluid to be in its rest frame in these coordinates, so that the components of the four-velocity are $U^\mu = (1, 0, 0, 0)$. In fact the fluid would have to be in its rest frame for this particular metric to solve Einstein's equation, as we will later see. The energy-momentum tensor therefore takes the form

$$T^{\mu\nu} = \begin{pmatrix} \rho & & & \\ & a^{-2}p & & \\ & & a^{-2}p & \\ & & & a^{-2}p \end{pmatrix}. \tag{3.95}$$

Note that these components are specific to the metric (3.72), and will generally look different for other metrics.

Let's see what the energy-momentum conservation equation $\nabla_\mu T^{\mu\nu} = 0$ implies for a perfect fluid in an expanding universe. The rule for covariant derivatives (3.17) implies

$$\nabla_\mu T^{\mu\nu} = \partial_\mu T^{\mu\nu} + \Gamma^\mu_{\mu\lambda} T^{\lambda\nu} + \Gamma^\nu_{\mu\lambda} T^{\mu\lambda} = 0. \tag{3.96}$$

This equation has four components, one for each μ, although the three $\mu = i \in \{1, 2, 3\}$ are equivalent. Let's first look at the $\nu = 0$ component, piece by piece. The first term is straightforward,

$$\partial_\mu T^{\mu 0} = \partial_0 T^{00} = \dot{\rho}. \tag{3.97}$$

The second term is

$$\Gamma^\mu_{\mu\lambda} T^{\lambda 0} = \Gamma^\mu_{\mu 0} T^{00} = 3\frac{\dot{a}}{a}\rho, \tag{3.98}$$

and the third term is

$$\Gamma^0_{\mu\lambda} T^{\mu\lambda} = \Gamma^0_{00} T^{00} + \Gamma^0_{11} T^{11} + \Gamma^0_{22} T^{22} + \Gamma^0_{33} T^{33} = 3\frac{\dot{a}}{a}p. \tag{3.99}$$

In each of these sets of equations, we have first invoked the fact that $T^{\mu\nu}$ is diagonal, and then used the explicit formulae for the energy-momentum tensor and the connection coefficients in this metric. All together, then, we find

$$\dot{\rho} = -3\frac{\dot{a}}{a}(\rho + p). \tag{3.100}$$

Now let's look at one of the spatial components, choosing $\nu = 1$ for definiteness. Once again working piece by piece, we have for the first term in (3.96),

$$\partial_\mu T^{\mu 1} = \partial_1 T^{11} = a^{-2}\partial_x p. \tag{3.101}$$

The second and third terms are

$$\Gamma^\mu_{\mu\lambda} T^{\lambda 1} = \Gamma^\mu_{\mu 1} T^{11} = 0, \tag{3.102}$$

and

$$\Gamma^1_{\mu\lambda}T^{\mu\lambda} = \Gamma^1_{00}T^{00} + \Gamma^1_{11}T^{11} + \Gamma^1_{22}T^{22} + \Gamma^1_{33}T^{33} = 0. \tag{3.103}$$

Equivalent results will hold for $\nu = 2$ and $\nu = 3$. So the spatial components of the energy-momentum conservation equation simply amount to

$$\partial_i p = 0. \tag{3.104}$$

It is illuminating to compare these results to those we would obtain in Minkowski spacetime, which can be found by simply setting $a = 1$, $\dot{a} = 0$. The pressure-gradient equation (3.104) is unaffected, so there is no effect of curvature on the spatial components: for a fluid that is motionless as measured by a comoving observer, the pressure must be constant throughout space. For the timelike component, on the other hand, the expansion of the universe introduces a nonzero right-hand side to (3.100). To understand the consequences of this new feature, let us consider equations of state of the form

$$p = w\rho, \tag{3.105}$$

where w is some constant. Then (3.100) becomes

$$\frac{\dot{\rho}}{\rho} = -3(1+w)\frac{\dot{a}}{a}, \tag{3.106}$$

which can be solved to yield

$$\rho \propto a^{-3(1+w)}. \tag{3.107}$$

In Chapter 1 we mentioned three kinds of perfect fluid with equations of state of the form (3.105): dust, with $w = 0$; radiation, with $w = \frac{1}{3}$; and vacuum, with $w = -1$. A set of nonrelativistic, noninteracting particles behaves like dust; a set of photons or other massless particles behaves like radiation; and a nonzero constant energy density throughout spacetime acts like vacuum. From (3.107) we see that the equation of state determines how the energy density evolves as the universe expands:

$$\begin{array}{rll} \text{matter} & p = 0 & \rho \propto a^{-3} \\ \text{radiation} & p = \frac{1}{3}\rho & \rho \propto a^{-4} \\ \text{vacuum} & p = -\rho & \rho = \text{constant}. \end{array} \tag{3.108}$$

We will explore these behaviors more thoroughly in Chapter 8; for right now let's simply note that they make sense. For dust, the energy density comes from the rest mass of each particle; if all the particles have mass m, the energy density is simply $\rho = nm$, where n is the number density. Since the number density goes down as a^{-3} (the physical volume of a comoving region goes up, while the total number of particles stays constant), while the masses remain unchanged, we expect that the energy density obeys $\rho \propto a^{-3}$. For radiation, meanwhile, the energy of each particle (such as a photon) redshifts away as a^{-1} as the universe expands; since the number density still obeys $n \propto a^{-3}$, we expect that $\rho \propto a^{-4}$. Finally, the vacuum energy density is an intrinsic and unchanging amount of energy in any physical volume; it doesn't redshift at all as the universe expands, so we get $\rho =$ constant.

This example brings to life the differences between flat and curved spacetimes. For example, consider what we might be tempted to call the "energy," the integral over space of the energy density: $E = \int \rho a^3\, d^3x$, where the boundaries are at fixed comoving coordinates, so the region expands along with the universe, and the factor of a^3 comes from the square root of the determinant of the spatial metric $a^2\delta_{ij}$. This number is clearly not conserved in general. For dust, since $\rho \propto a^{-3}$, E remains constant as the universe expands; but for radiation it decreases, and for vacuum energy it increases. This is upsetting, since conservation of energy is one of the more cherished principles of physics. What has happened? One way of thinking about this is from the viewpoint of Noether's theorem, which states that every symmetry implies a conserved quantity. Energy is the conserved quantity that derives from invariance under time translations. Clearly, in an expanding universe, the energy-momentum tensor is defined on a background that is changing with time; therefore there is no reason to believe that the energy should be conserved. ("There is no timelike Killing vector," in the language to be introduced in Section 3.8.) Nevertheless, we continue to refer to $\nabla_\mu T^{\mu\nu} = 0$ as the energy-momentum conservation equation. It conveys the idea that there is a definite law obeyed by the energy-momentum tensor, even if there is no integral corresponding to a conserved energy. The transition from flat to curved spacetime induces the additional Christoffel-symbol terms in (3.96); these terms serve, roughly speaking, to allow transfer of energy between the matter fields (comprising $T^{\mu\nu}$) and the gravitational field. This notion is not very formal, however, and you shouldn't push it too far—it turns out to be difficult to associate a local energy density to the gravitational field, although it is possible in certain circumstances.

Of course there is also a notion of time-translation invariance that refers not to the background spacetime, but to the theory itself (that is, to the equations that define the theory rather than a specific solution to them). We haven't yet developed the dynamical equations of general relativity, but they will turn out to be invariant under time translations, as well as under any other sort of coordinate transformations, as indeed they must be. This general coordinate invariance leads to a set of constraints on allowed configurations of the theory, and generally requires a more subtle analysis.

In the end, you should come to accept that there is a profound difference between flat and curved spacetimes, and some of our favorite notions from flat-spacetime physics will be seriously modified in this more general context. This is not a sign of any flaw in general relativity, but a natural consequence of discarding the rigid spacetime geometry we learn to take for granted.

3.6 ■ THE RIEMANN CURVATURE TENSOR

Having set up the machinery of covariant derivatives and parallel transport, we are at last prepared to discuss curvature proper. The curvature is quantified by the Riemann tensor, which is derived from the connection. The idea behind this measure of curvature is that we know what we mean by "flatness" of a connection—the conventional (and usually implicit) Christoffel connection associated with a Euclidean or Minkowskian metric has a number of properties that can be thought of as different manifestations of flatness. These include the fact that parallel transport around a closed loop leaves a vector unchanged, that covariant derivatives of tensors commute, and that initially parallel geodesics remain parallel. As we shall see, the Riemann tensor arises when we study how any of these properties are altered in more general contexts.

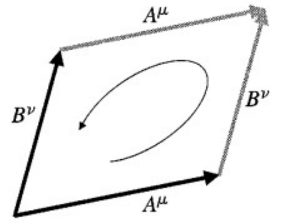

FIGURE 3.5 An infinitesimal loop defined by two vectors A^μ and B^ν.

We have already argued, using the two-sphere as an example, that parallel transport of a vector around a closed loop in a curved space will lead to a transformation of the vector. The resulting transformation depends on the total curvature enclosed by the loop; it would be more useful to have a local description of the curvature at each point, which is what the Riemann tensor is supposed to provide. One conventional way to introduce the Riemann tensor, therefore, is to consider parallel transport around an infinitesimal loop. We are not going to do that here, but take a more direct route. Nevertheless, even without working through the details, it is possible to see what form the answer should take. Since spacetime looks flat in sufficiently small regions, our loop will be specified by two (infinitesimal) vectors A^μ and B^ν. We imagine parallel transporting a vector V^μ by first moving it in the direction of A^μ, then along B^ν, then backward along A^μ and B^ν to return to the starting point, as shown in Figure 3.5. We know the action of parallel transport is independent of coordinates, so there should be some tensor that tells us how the vector changes when it comes back to its starting point; it will be a linear transformation on a vector, and therefore involve one upper and one lower index. But it will also depend on the two vectors A and B that define the loop; therefore there should be two additional lower indices to contract with A^μ and B^ν. Furthermore, the tensor should be antisymmetric in these two indices, since interchanging the vectors corresponds to traversing the loop in the opposite direction, and should give the inverse of the original answer. This is consistent with the fact that the transformation should vanish if A and B are the same vector. We therefore expect that the expression for the change δV^ρ experienced by this vector when parallel transported around the loop should be of the form

$$\delta V^\rho = R^\rho{}_{\sigma\mu\nu} V^\sigma A^\mu B^\nu, \tag{3.109}$$

where $R^\rho{}_{\sigma\mu\nu}$ is a $(1, 3)$ tensor known as the **Riemann tensor** (or simply curvature tensor). It is antisymmetric in the last two indices:

$$R^\rho{}_{\sigma\mu\nu} = -R^\rho{}_{\sigma\nu\mu}. \tag{3.110}$$

Of course, if (3.109) is taken as a definition of the Riemann tensor, a convention needs to be chosen for the ordering of the indices. There is no agreement at all on what this convention should be, so be careful.

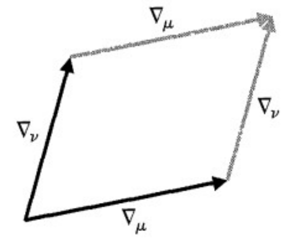

FIGURE 3.6 The commutator of two covariant derivatives.

Knowing what we do about parallel transport, we could very carefully perform the necessary manipulations to see what happens to the vector under this operation, and the result would be a formula for the curvature tensor in terms of the connection coefficients. It is much quicker, however, to consider a related operation, the commutator of two covariant derivatives. The relationship between this and parallel transport around a loop should be evident; the covariant derivative of a tensor in a certain direction measures how much the tensor changes relative to what it would have been if it had been parallel transported, since the covariant derivative of a tensor in a direction along which it is parallel transported is zero. The commutator of two covariant derivatives, then, measures the difference between parallel transporting the tensor first one way and then the other, versus the opposite ordering, as shown in Figure 3.6.

The actual computation is very straightforward. Considering a vector field V^ρ, we take

$$\begin{aligned}
[\nabla_\mu, \nabla_\nu]V^\rho &= \nabla_\mu\nabla_\nu V^\rho - \nabla_\nu\nabla_\mu V^\rho \\
&= \partial_\mu(\nabla_\nu V^\rho) - \Gamma^\lambda_{\mu\nu}\nabla_\lambda V^\rho + \Gamma^\rho_{\mu\sigma}\nabla_\nu V^\sigma - (\mu \leftrightarrow \nu) \\
&= \partial_\mu\partial_\nu V^\rho + (\partial_\mu\Gamma^\rho_{\nu\sigma})V^\sigma + \Gamma^\rho_{\nu\sigma}\partial_\mu V^\sigma - \Gamma^\lambda_{\mu\nu}\partial_\lambda V^\rho - \Gamma^\lambda_{\mu\nu}\Gamma^\rho_{\lambda\sigma}V^\sigma \\
&\quad + \Gamma^\rho_{\mu\sigma}\partial_\nu V^\sigma + \Gamma^\rho_{\mu\sigma}\Gamma^\sigma_{\nu\lambda}V^\lambda - (\mu \leftrightarrow \nu) \\
&= (\partial_\mu\Gamma^\rho_{\nu\sigma} - \partial_\nu\Gamma^\rho_{\mu\sigma} + \Gamma^\rho_{\mu\lambda}\Gamma^\lambda_{\nu\sigma} - \Gamma^\rho_{\nu\lambda}\Gamma^\lambda_{\mu\sigma})V^\sigma - 2\Gamma^\lambda_{[\mu\nu]}\nabla_\lambda V^\rho.
\end{aligned} \tag{3.111}$$

In the last step we have relabeled some dummy indices and eliminated some terms that cancel when antisymmetrized. We recognize that the last term is simply the torsion tensor, and that the left hand side is manifestly a tensor; therefore the expression in parentheses must be a tensor itself. We write

$$[\nabla_\mu, \nabla_\nu]V^\rho = R^\rho{}_{\sigma\mu\nu}V^\sigma - T^\lambda{}_{\mu\nu}\nabla_\lambda V^\rho, \tag{3.112}$$

where the Riemann tensor is identified as

$$\boxed{R^\rho{}_{\sigma\mu\nu} = \partial_\mu\Gamma^\rho_{\nu\sigma} - \partial_\nu\Gamma^\rho_{\mu\sigma} + \Gamma^\rho_{\mu\lambda}\Gamma^\lambda_{\nu\sigma} - \Gamma^\rho_{\nu\lambda}\Gamma^\lambda_{\mu\sigma}.} \tag{3.113}$$

Notice a number of things about the derivation of this expression:

- Of course we have not demonstrated that (3.113) is actually the same tensor that appeared in (3.109), but in fact it's true. You are asked to show this in the Exercises.
- It is perhaps surprising that the commutator $[\nabla_\mu, \nabla_\nu]$, which appears to be a differential operator, has an action on vector fields that (in the absence of

torsion, at any rate) is a simple multiplicative transformation. The Riemann tensor measures that part of the commutator of covariant derivatives that is proportional to the vector field, while the torsion tensor measures the part that is proportional to the covariant derivative of the vector field; the second derivative doesn't enter at all.

- Notice that the expression (3.113) is constructed from nontensorial elements; you can check that the transformation laws all work out to make this particular combination a legitimate tensor.
- The antisymmetry of $R^\rho{}_{\sigma\mu\nu}$ in its last two indices is immediate from this formula and its derivation.
- We constructed the curvature tensor completely from the connection (no mention of the metric was made). We were sufficiently careful that the above expression is true for any connection, whether or not it is metric compatible or torsion free.
- Using what are by now our usual methods, the action of $[\nabla_\rho, \nabla_\sigma]$ can be computed on a tensor of arbitrary rank. The answer is

$$\begin{aligned}
[\nabla_\rho, \nabla_\sigma] & X^{\mu_1\cdots\mu_k}{}_{\nu_1\cdots\nu_l} \\
&= -T^\lambda{}_{\rho\sigma}\nabla_\lambda X^{\mu_1\cdots\mu_k}{}_{\nu_1\cdots\nu_l} \\
&\quad + R^{\mu_1}{}_{\lambda\rho\sigma} X^{\lambda\mu_2\cdots\mu_k}{}_{\nu_1\cdots\nu_l} + R^{\mu_2}{}_{\lambda\rho\sigma} X^{\mu_1\lambda\cdots\mu_k}{}_{\nu_1\cdots\nu_l} + \cdots \\
&\quad - R^\lambda{}_{\nu_1\rho\sigma} X^{\mu_1\cdots\mu_k}{}_{\lambda\nu_2\cdots\nu_l} - R^\lambda{}_{\nu_2\rho\sigma} X^{\mu_1\cdots\mu_k}{}_{\nu_1\lambda\cdots\nu_l} - \cdots. \qquad (3.114)
\end{aligned}$$

Both the torsion tensor and the Riemann tensor, thought of as multilinear maps, have elegant expressions in terms of the vector-field commutator. Thinking of the torsion as a map from two vector fields to a third vector field, we have

$$T(X, Y) = \nabla_X Y - \nabla_Y X - [X, Y], \qquad (3.115)$$

and thinking of the Riemann tensor as a map from three vector fields to a fourth one, we have (in funny-looking but standard notation)

$$R(X, Y)Z = \nabla_X \nabla_Y Z - \nabla_Y \nabla_X Z - \nabla_{[X,Y]} Z. \qquad (3.116)$$

In these expressions, the notation ∇_X refers to the covariant derivative along the vector field X; in components, $\nabla_X = X^\mu \nabla_\mu$. So, for example, (3.116) is equivalent to

$$\begin{aligned}
R^\rho{}_{\sigma\mu\nu} X^\mu Y^\nu Z^\sigma &= X^\lambda \nabla_\lambda (Y^\eta \nabla_\eta Z^\rho) - Y^\lambda \nabla_\lambda (X^\eta \nabla_\eta Z^\rho) \\
&\quad - (X^\lambda \partial_\lambda Y^\eta - Y^\lambda \partial_\lambda X^\eta) \nabla_\eta Z^\rho, \qquad (3.117)
\end{aligned}$$

which you can check is equivalent to (3.113). Note that the two vectors X and Y in (3.116) correspond to the last two indices in the component form of the Riemann tensor. The last term in (3.116), involving the commutator $[X, Y]$, vanishes when X and Y are taken to be the coordinate basis vector fields (since $[\partial_\mu, \partial_\nu] = 0$), which is why this term did not arise when we originally took the commutator of two covariant derivatives. We will not use this notation extensively, but you might see it in the literature, so you should be able to decode it.

Having defined the curvature tensor as something that characterizes the connection, let us now admit that in GR we are most concerned with the Christoffel connection. In this case the connection is derived from the metric, and the associated curvature may be thought of as that of the metric itself. This identification allows us to finally make sense of our informal notion that spaces for which the metric looks Euclidean or Minkowskian are flat. In fact it works both ways:

- If a coordinate system exists in which the components of the metric are constant, the Riemann tensor will vanish.
- If the Riemann tensor vanishes, we can always construct a coordinate system in which the metric components are constant.

Technically, these statements should be restricted to a region of the manifold that is simply-connected (all loops in the region can be smoothly deformed to a point without leaving the region); we will implicitly assume this condition below.

The first of these is easy to show. If we are in some coordinate system such that $\partial_\sigma g_{\mu\nu} = 0$ everywhere, not just at a point, then $\Gamma^\rho_{\mu\nu} = 0$ and $\partial_\sigma \Gamma^\rho_{\mu\nu} = 0$; thus $R^\rho{}_{\sigma\mu\nu} = 0$ by (3.113). But this is a tensor equation, and if it is true in one coordinate system it must be true in any coordinate system. Therefore, the statement that the Riemann tensor vanishes is a necessary condition for it to be possible to find coordinates in which the components of $g_{\mu\nu}$ are constant everywhere.

The second claim, that $R^\rho{}_{\sigma\mu\nu} = 0$ everywhere implies we can find a coordinate system in which the metric components are constant everywhere, is harder to prove (but not very hard). Consider as a warm-up a one-form $\omega = \omega_\mu \mathrm{d}x^\mu$, defined at some point p. For any path $x^\mu(\lambda)$ that includes p, we can construct a unique one-form field along the path by demanding that ω_μ be parallel-transported:

$$\frac{dx^\mu}{d\lambda}\nabla_\mu \omega_\nu = 0. \tag{3.118}$$

In general, if we performed this procedure for distinct paths that started at p and passed through some other point q, the value of ω_μ at q would depend on the path. However, if the Riemann tensor vanishes everywhere, the parallel-transport will be path-independent, and we can define a unique one-form field throughout the manifold. Therefore (3.118) must be true for arbitrary $dx^\mu/d\lambda$; this can only be true if ω_μ is covariantly constant:

$$\nabla_\mu \omega_\nu = 0. \tag{3.119}$$

On an arbitrary manifold there will be no solutions to this equation; it is only possible here because we are assuming that the curvature vanishes. We can take the antisymmetric part of (3.119), and from (3.36) we know that this is just the exterior derivative:

$$\nabla_{[\mu}\omega_{\nu]} = \partial_{[\mu}\omega_{\nu]} = 0, \tag{3.120}$$

or, in index-free notation,

$$\mathrm{d}\omega = 0. \tag{3.121}$$

In other words, ω is closed. It is also exact (there exists a scalar function α such that $\omega = \mathrm{d}\alpha$), since we have restricted the topology of the region in which we are working. In components we have

$$\omega_\mu = \partial_\mu \alpha. \tag{3.122}$$

There is nothing special about the one-form ω, so we can repeat this procedure with a set of one-forms $\hat{\theta}^{(a)}$, where $a \in \{1 \dots n\}$ on an n-dimensional manifold. We may choose our one-forms to comprise a normalized basis for the dual space T^*_p, such that the components of the metric with respect to this basis are those of the canonical form; in other words,

$$ds^2(p) = \eta_{ab}\, \hat{\theta}^{(a)} \otimes \hat{\theta}^{(b)}. \tag{3.123}$$

Here we use η_{ab} in a generalized sense, as a matrix with either $+1$ or -1 for each diagonal element and zeroes elsewhere. The actual arrangement of the $+1$'s and -1's depends on the canonical form of the metric, but is irrelevant for the present argument. Now let us parallel transport the entire set of basis forms all over the manifold; the vanishing of the Riemann tensor ensures that the result will be independent of the path taken. Since the metric is always automatically parallel-transported with respect to a metric-compatible connection, the metric components will remain unchanged,

$$ds^2(\text{anywhere}) = \eta_{ab}\, \hat{\theta}^{(a)} \otimes \hat{\theta}^{(b)}. \tag{3.124}$$

We therefore have specified a set of one-form fields, which everywhere define a basis in which the metric components are constant. This is completely unimpressive; it can be done on any manifold, regardless of what the curvature is. What we would like to show is that this is a *coordinate* basis (which will only be possible if the curvature vanishes). However, by the same arguments that led to (3.122), we know that all of the $\hat{\theta}^{(a)}$'s are exact forms, so that there exists a set of functions y^a such that the one-form fields are their gradients,

$$\hat{\theta}^{(a)} = \mathrm{d}y^a. \tag{3.125}$$

These n functions are precisely the sought-after coordinates; all over the manifold the metric takes the form

$$ds^2 = \eta_{ab}\, \mathrm{d}y^a \mathrm{d}y^b. \tag{3.126}$$

At this point you are welcome to switch from using a, b as indices to μ, ν if you prefer.

We have thus verified that the Riemann tensor provides us with an answer to the question of whether some horrible-looking metric is secretly that of flat space in a perverse coordinate system. If we calculate the Riemann tensor of such a metric and find that it vanishes, we know that the metric is flat; if it doesn't vanish, there is curvature.

3.7 ■ PROPERTIES OF THE RIEMANN TENSOR

The Riemann tensor, with four indices, naively has n^4 independent components in an n-dimensional space. In fact the antisymmetry property (3.110) means that there are only $n(n-1)/2$ independent values these last two indices can take on, leaving us with $n^3(n-1)/2$ independent components. When we consider the Christoffel connection, however, a number of other symmetries reduce the independent components further. Let's consider these now.

The simplest way to derive these additional symmetries is to examine the Riemann tensor with all lower indices,

$$R_{\rho\sigma\mu\nu} = g_{\rho\lambda} R^{\lambda}{}_{\sigma\mu\nu}. \tag{3.127}$$

Let us further consider the components of this tensor in locally inertial coordinates $x^{\hat{\mu}}$ established at a point p. Then the Christoffel symbols themselves will vanish, although their derivatives will not. We therefore have

$$\begin{aligned} R_{\hat{\rho}\hat{\sigma}\hat{\mu}\hat{\nu}}(p) &= g_{\hat{\rho}\hat{\lambda}}(\partial_{\hat{\mu}}\Gamma^{\hat{\lambda}}_{\hat{\nu}\hat{\sigma}} - \partial_{\hat{\nu}}\Gamma^{\hat{\lambda}}_{\hat{\mu}\hat{\sigma}}) \\ &= \tfrac{1}{2} g_{\hat{\rho}\hat{\lambda}} g^{\hat{\lambda}\hat{\tau}}(\partial_{\hat{\mu}}\partial_{\hat{\nu}} g_{\hat{\sigma}\hat{\tau}} + \partial_{\hat{\mu}}\partial_{\hat{\sigma}} g_{\hat{\tau}\hat{\nu}} - \partial_{\hat{\mu}}\partial_{\hat{\tau}} g_{\hat{\nu}\hat{\sigma}} - \partial_{\hat{\nu}}\partial_{\hat{\mu}} g_{\hat{\sigma}\hat{\tau}} \\ &\qquad - \partial_{\hat{\nu}}\partial_{\hat{\sigma}} g_{\hat{\tau}\hat{\mu}} + \partial_{\hat{\nu}}\partial_{\hat{\tau}} g_{\hat{\mu}\hat{\sigma}}) \\ &= \tfrac{1}{2}(\partial_{\hat{\mu}}\partial_{\hat{\sigma}} g_{\hat{\rho}\hat{\nu}} - \partial_{\hat{\mu}}\partial_{\hat{\rho}} g_{\hat{\nu}\hat{\sigma}} - \partial_{\hat{\nu}}\partial_{\hat{\sigma}} g_{\hat{\rho}\hat{\mu}} + \partial_{\hat{\nu}}\partial_{\hat{\rho}} g_{\hat{\mu}\hat{\sigma}}). \end{aligned} \tag{3.128}$$

In the first line we have used $\Gamma^{\hat{\tau}}_{\hat{\mu}\hat{\nu}}(p) = 0$, in the second line we have used $\partial_{\hat{\mu}} g^{\hat{\lambda}\hat{\tau}} = 0$ in Riemann normal coordinates, and the fact that partials commute in the third line. From this expression we can notice immediately three properties of $R_{\rho\sigma\mu\nu}$: it is antisymmetric in its first two indices,

$$\boxed{R_{\rho\sigma\mu\nu} = -R_{\sigma\rho\mu\nu},} \tag{3.129}$$

it is antisymmetric in its last two indices [which we already knew from (3.110)],

$$\boxed{R_{\rho\sigma\mu\nu} = -R_{\rho\sigma\nu\mu},} \tag{3.130}$$

and it is invariant under interchange of the first pair of indices with the second:

$$\boxed{R_{\rho\sigma\mu\nu} = R_{\mu\nu\rho\sigma}.} \tag{3.131}$$

With a little more work, which is left to your imagination, we can see that the sum of cyclic permutations of the last three indices vanishes:

$$\boxed{R_{\rho\sigma\mu\nu} + R_{\rho\mu\nu\sigma} + R_{\rho\nu\sigma\mu} = 0.} \tag{3.132}$$

Given (3.130), it's easy to see that this last property is equivalent to the vanishing of the antisymmetric part of the last three indices:

$$\boxed{R_{\rho[\sigma\mu\nu]} = 0.} \tag{3.133}$$

All of these properties have been derived in a special coordinate system, but they are all tensor equations; therefore they will be true in any coordinates (so we haven't bothered with hats on the indices). Not all of them are independent; with some effort, you can show that (3.129), (3.130), and (3.133) together imply (3.131). The logical interdependence of the equations is usually less important than the fact that they are true.

Given these relationships between the different components of the Riemann tensor, how many independent quantities remain? Let's begin with the facts that $R_{\rho\sigma\mu\nu}$ is antisymmetric in the first two indices, antisymmetric in the last two indices, and symmetric under interchange of these two pairs. This means that we can think of it as a symmetric matrix $R_{[\rho\sigma][\mu\nu]}$, where the pairs $\rho\sigma$ and $\mu\nu$ are thought of as individual indices. An $m \times m$ symmetric matrix has $m(m+1)/2$ independent components, while an $n \times n$ antisymmetric matrix has $n(n-1)/2$ independent components. We therefore have

$$\frac{1}{2}\left[\frac{1}{2}n(n-1)\right]\left[\frac{1}{2}n(n-1)+1\right] = \frac{1}{8}(n^4 - 2n^3 + 3n^2 - 2n) \tag{3.134}$$

independent components. We still have to deal with the additional symmetry (3.133). An immediate consequence of (3.133) is that the totally antisymmetric part of the Riemann tensor vanishes,

$$R_{[\rho\sigma\mu\nu]} = 0. \tag{3.135}$$

In fact, this equation plus the other symmetries (3.129), (3.130), and (3.131), are enough to imply (3.133), as can be easily shown by expanding (3.135) and manipulating the resulting terms. Therefore imposing the additional constraint of (3.135) is equivalent to imposing (3.133), once the other symmetries have been accounted for. How many independent restrictions does this represent? Let us imagine decomposing

$$R_{\rho\sigma\mu\nu} = X_{\rho\sigma\mu\nu} + R_{[\rho\sigma\mu\nu]}. \tag{3.136}$$

It is easy to see that any totally antisymmetric 4-index tensor is automatically antisymmetric in its first and last indices, and symmetric under interchange of the two pairs. Therefore these properties are independent restrictions on $X_{\rho\sigma\mu\nu}$, unrelated to the requirement (3.135). Now a totally antisymmetric 4-index tensor has $n(n-1)(n-2)(n-3)/4!$ terms, and therefore (3.135) reduces the number of independent components by this amount. We are left with

$$\tfrac{1}{8}(n^4 - 2n^3 + 3n^2 - 2n) - \tfrac{1}{24}n(n-1)(n-2)(n-3) = \tfrac{1}{12}n^2(n^2-1) \tag{3.137}$$

independent components of the Riemann tensor.

In four dimensions, therefore, the Riemann tensor has 20 independent components. (In one dimension it has none.) These twenty functions are precisely the 20 degrees of freedom in the second derivatives of the metric that we could not set to zero by a clever choice of coordinates when we first discussed locally inertial coordinates in Chapter 2. This should reinforce your confidence that the Riemann tensor is an appropriate measure of curvature.

In addition to the algebraic symmetries of the Riemann tensor (which constrain the number of independent components at any point), it obeys a differential identity, which constrains its relative values at different points. Consider the covariant derivative of the Riemann tensor, evaluated in locally inertial coordinates:

$$\begin{aligned}\nabla_{\hat\lambda} R_{\hat\rho\hat\sigma\hat\mu\hat\nu} &= \partial_{\hat\lambda} R_{\hat\rho\hat\sigma\hat\mu\hat\nu} \\ &= \tfrac{1}{2}\partial_{\hat\lambda}(\partial_{\hat\mu}\partial_{\hat\sigma} g_{\hat\rho\hat\nu} - \partial_{\hat\mu}\partial_{\hat\rho} g_{\hat\nu\hat\sigma} - \partial_{\hat\nu}\partial_{\hat\sigma} g_{\hat\rho\hat\mu} + \partial_{\hat\nu}\partial_{\hat\rho} g_{\hat\mu\hat\sigma}).\end{aligned} \tag{3.138}$$

It may seem illegitimate to take the derivative of an expression that is only true at a point, but the terms we are neglecting are all proportional to $\partial_{\hat\sigma} g_{\hat\mu\hat\nu}$, and therefore vanish. We would like to consider the sum of cyclic permutations of the first three indices:

$$\begin{aligned}&\nabla_{\hat\lambda} R_{\hat\rho\hat\sigma\hat\mu\hat\nu} + \nabla_{\hat\rho} R_{\hat\sigma\hat\lambda\hat\mu\hat\nu} + \nabla_{\hat\sigma} R_{\hat\lambda\hat\rho\hat\mu\hat\nu} \\ &\quad = \tfrac{1}{2}(\partial_{\hat\lambda}\partial_{\hat\mu}\partial_{\hat\sigma} g_{\hat\rho\hat\nu} - \partial_{\hat\lambda}\partial_{\hat\mu}\partial_{\hat\rho} g_{\hat\nu\hat\sigma} - \partial_{\hat\lambda}\partial_{\hat\nu}\partial_{\sigma} g_{\hat\rho\hat\mu} + \partial_{\hat\lambda}\partial_{\hat\nu}\partial_{\hat\rho} g_{\hat\mu\hat\sigma} \\ &\qquad + \partial_{\hat\rho}\partial_{\hat\mu}\partial_{\hat\lambda} g_{\hat\sigma\hat\nu} - \partial_{\hat\rho}\partial_{\hat\mu}\partial_{\hat\sigma} g_{\hat\nu\hat\lambda} - \partial_{\hat\rho}\partial_{\hat\nu}\partial_{\hat\lambda} g_{\hat\sigma\hat\mu} + \partial_{\hat\rho}\partial_{\hat\nu}\partial_{\hat\sigma} g_{\hat\mu\hat\lambda} \\ &\qquad + \partial_{\hat\sigma}\partial_{\hat\mu}\partial_{\hat\rho} g_{\hat\lambda\hat\nu} - \partial_{\hat\sigma}\partial_{\hat\mu}\partial_{\hat\lambda} g_{\hat\nu\hat\rho} - \partial_{\hat\sigma}\partial_{\hat\nu}\partial_{\hat\rho} g_{\hat\lambda\hat\mu} + \partial_{\hat\sigma}\partial_{\hat\nu}\partial_{\hat\lambda} g_{\hat\mu\hat\rho}) \\ &\quad = 0.\end{aligned} \tag{3.139}$$

Once again, since this is an equation between tensors it is true in any coordinate system, even though we derived it in a particular one. We recognize by now that the antisymmetry $R_{\rho\sigma\mu\nu} = -R_{\sigma\rho\mu\nu}$ allows us to write this result as

$$\nabla_{[\lambda} R_{\rho\sigma]\mu\nu} = 0. \tag{3.140}$$

This is known as the **Bianchi identity**. For a general connection there would be additional terms involving the torsion tensor. It is closely related to the Jacobi identity, since (recalling the definition of the Riemann tensor in terms of the commutator of covariant derivatives) it expresses

$$[[\nabla_\lambda, \nabla_\rho], \nabla_\sigma] + [[\nabla_\rho, \nabla_\sigma], \nabla_\lambda] + [[\nabla_\sigma, \nabla_\lambda], \nabla_\rho] = 0. \tag{3.141}$$

The Riemann tensor has four indices. At times it is useful to express a tensor as a sum of various pieces that are individually easier to handle and may have direct physical interpretations. The trick is to do this in a coordinate-invariant way. For example, we could decompose the Riemann tensor into $R^\rho{}_{\sigma ij}$ and $R^\rho{}_{\sigma i0}$, from which we could reconstruct the entire tensor (since $R^\rho{}_{\sigma 00}$ vanishes). But clearly this decomposition is not invariant under change of basis; we want to find a decomposition that is preserved when we change coordinates. What we are really doing is considering representations of the Lorentz group. We have two fundamental tricks at our disposal: taking contractions, and taking symmetric/antisymmetric parts. For example, given an arbitrary $(0, 2)$ tensor $X_{\mu\nu}$, we can decompose it into its symmetric and antisymmetric pieces,

$$X_{\mu\nu} = X_{(\mu\nu)} + X_{[\mu\nu]}, \tag{3.142}$$

and the symmetric part can be further decomposed into its trace $X = g^{\mu\nu} X_{(\mu\nu)}$ and a trace-free part $\widehat{X}_{\mu\nu} = X_{(\mu\nu)} - \frac{1}{n} X g_{\mu\nu}$, so that

$$X_{\mu\nu} = \frac{1}{n} X g_{\mu\nu} + \widehat{X}_{\mu\nu} + X_{[\mu\nu]}. \tag{3.143}$$

(Note that $X_{[\mu\nu]}$ is automatically traceless.) When we change coordinates, the different pieces $X g_{\mu\nu}$, $\widehat{X}_{\mu\nu}$, and $X_{[\mu\nu]}$ are rotated into themselves, not into each other; we say that they define "invariant subspaces" of the space of $(0, 2)$ tensors. For more complicated tensors the equivalent decomposition might not be so simple.

For the Riemann tensor, our first step is to take a contraction to form the **Ricci tensor**:

$$\boxed{R_{\mu\nu} = R^\lambda{}_{\mu\lambda\nu}.} \tag{3.144}$$

For the curvature tensor formed from an arbitrary (not necessarily Christoffel) connection, there are a number of independent contractions to take. Our primary concern is with the Christoffel connection, for which (3.144) is the only independent contraction; all others either vanish, or are related to this one. The Ricci tensor associated with the Christoffel connection is automatically symmetric,

$$\boxed{R_{\mu\nu} = R_{\nu\mu},} \tag{3.145}$$

as a consequence of the symmetries of the Riemann tensor. The trace of the Ricci tensor is the **Ricci scalar** (or **curvature scalar**):

$$\boxed{R = R^\mu{}_\mu = g^{\mu\nu} R_{\mu\nu}.} \tag{3.146}$$

We could also form the trace-free part $\widehat{R}_{\mu\nu} = R_{\mu\nu} - \frac{1}{n} R g_{\mu\nu}$, but this turns out not to be especially useful; it is more common to express things in terms of $R_{\mu\nu}$ and R.

The Ricci tensor and scalar contain all of the information about traces of the Riemann tensor, leaving us the trace-free parts. These are captured by the **Weyl tensor**, which is basically the Riemann tensor with all of its contractions removed. It is given in n dimensions by

$$\begin{aligned} C_{\rho\sigma\mu\nu} &= R_{\rho\sigma\mu\nu} - \frac{2}{(n-2)} \left(g_{\rho[\mu} R_{\nu]\sigma} - g_{\sigma[\mu} R_{\nu]\rho} \right) \\ &\quad + \frac{2}{(n-1)(n-2)} g_{\rho[\mu} g_{\nu]\sigma} R \end{aligned} \tag{3.147}$$

This messy formula is designed so that all possible contractions of $C_{\rho\sigma\mu\nu}$ vanish, while it retains the symmetries of the Riemann tensor:

$$\begin{aligned} C_{\rho\sigma\mu\nu} &= C_{[\rho\sigma][\mu\nu]}, \\ C_{\rho\sigma\mu\nu} &= C_{\mu\nu\rho\sigma}, \\ C_{\rho[\sigma\mu\nu]} &= 0. \end{aligned} \tag{3.148}$$

The Weyl tensor is only defined in three or more dimensions, and in three dimensions it vanishes identically. One of the most important properties of the Weyl tensor is that it is invariant under conformal transformations (discussed in the Appendices). This means that if you compute $C^\rho{}_{\sigma\mu\nu}$ (note that the first index is upstairs) for some metric $g_{\mu\nu}$, and then compute it again for a metric given by $\omega^2(x) g_{\mu\nu}$, where $\omega(x)$ is an arbitrary nonvanishing function of spacetime, you get the same answer. For this reason it is often known as the *conformal tensor*.

An especially useful form of the Bianchi identity comes from contracting twice on (3.139):

$$\begin{aligned} 0 &= g^{\nu\sigma} g^{\mu\lambda} (\nabla_\lambda R_{\rho\sigma\mu\nu} + \nabla_\rho R_{\sigma\lambda\mu\nu} + \nabla_\sigma R_{\lambda\rho\mu\nu}) \\ &= \nabla^\mu R_{\rho\mu} - \nabla_\rho R + \nabla^\nu R_{\rho\nu}, \end{aligned} \tag{3.149}$$

or

$$\nabla^\mu R_{\rho\mu} = \tfrac{1}{2} \nabla_\rho R. \tag{3.150}$$

Notice that, unlike the partial derivative, it makes sense to raise an index on the covariant derivative, due to metric compatibility. We define the **Einstein tensor** as

$$\boxed{G_{\mu\nu} = R_{\mu\nu} - \tfrac{1}{2} R g_{\mu\nu}.} \tag{3.151}$$

In four dimensions the Einstein tensor can be thought of as a trace-reversed version of the Ricci tensor. We then see that the twice-contracted Bianchi identity (3.150) is equivalent to

$$\boxed{\nabla^\mu G_{\mu\nu} = 0.} \tag{3.152}$$

The Einstein tensor, which is symmetric due to the symmetry of the Ricci tensor and the metric, will be of great importance in general relativity.

We should pause at this point to contrast the formalism we have developed with our intuitive notion of curvature. Our intuition is unfortunately contaminated by the fact that we are used to thinking about one- and two-dimensional spaces embedded in the (almost) Euclidean space in which we live. We think, for example, of a straight line as having no curvature, while a circle (S^1) is curved. However, according to (3.137), in one, two, three, and four dimensions there are 0, 1, 6 and 20 independent components of the Riemann tensor, respectively. (Everything we say about the curvature in these examples refers to the curvature associated with the Christoffel connection, and therefore the metric.) Therefore it is impossible for a one-dimensional space such as S^1 to have any curvature as we have defined it. The apparent contradiction stems from the fact that our intuitive notion of curvature depends on the extrinsic geometry of the manifold, which characterizes how a space is embedded in some larger space, while the Riemann curvature is a property of the intrinsic geometry of a space, which could be measured by observers confined to the manifold. Beings that lived on a circle and had no access to the larger world would necessarily think that they lived in a flat geometry—for example, there is no possibility of a nondegenerate infinitesimal loop around which we could parallel-transport a vector and have it come back rotated from its original position. Extrinsic curvature, discussed in Appendix D, is occasionally useful in GR when we wish to describe submanifolds of spacetime; but most often we are interested in the intrinsic geometry of spacetime itself, which does not rely on any embeddings.

We can illustrate the intrinsic/extrinsic difference further with an example from two dimensions, where the curvature has one independent component. In fact, all of the information about the curvature is contained in the single component of the Ricci scalar. Consider a torus, portrayed in Figure 3.7, which can be thought of as a square region of the plane with opposite sides identified (topologically, $S^1 \times S^1$). Although a torus embedded in three dimensions looks curved from our point of view, it should be clear that we can put a metric on the torus whose components are constant in an appropriate coordinate system—simply unroll it and use the Euclidean metric of the plane, $ds^2 = dx^2 + dy^2$. In this metric, the torus is flat.

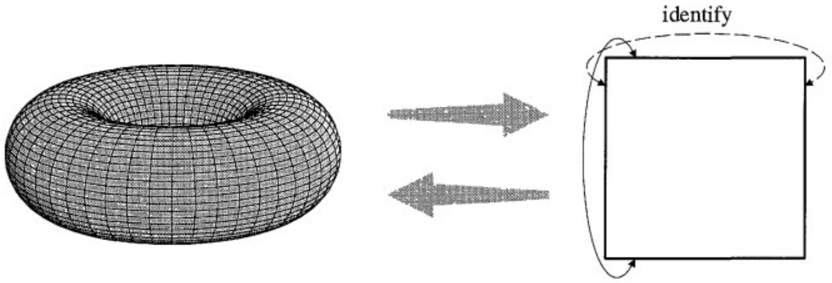

FIGURE 3.7 A torus thought of as a square in flat space with opposite sides identified.

There is also nothing to stop us from introducing a different metric in which the torus is not flat, but the point we are trying to emphasize is that it can be made flat in some metric. Every time we embed a manifold in a larger space, the manifold inherits an "induced metric" from the background in which it is embedded, as discussed in the Appendix A. Our point here is that a torus embedded in a flat three-dimensional Euclidean space will have an induced metric that is curved, but we can nevertheless choose to put a different metric on it so that the intrinsic geometry is flat.

Let's turn to a simple example where the curvature does not vanish. We have already talked about the two-sphere S^2, with metric

$$ds^2 = a^2(d\theta^2 + \sin^2\theta\, d\phi^2), \tag{3.153}$$

where a is the radius of the sphere. It will actually be the radius if our sphere is embedded in $\mathbf{R}^3$, but we can call it the radius even in the absence of any embedding. Two-dimensional people living on the sphere could calculate a by measuring the area of the sphere, dividing by 4π, and taking the square root; using the word "radius" to refer to this quantity is merely a convenience. We should also point out that the notion of a sphere is sometimes used in the weaker topological sense, without any particular metric being assumed; the metric we are using is called the *round metric*. Without going through the details, the nonzero connection coefficients for (3.153) are

$$\begin{aligned} \Gamma^\theta_{\phi\phi} &= -\sin\theta\cos\theta \\ \Gamma^\phi_{\theta\phi} = \Gamma^\phi_{\phi\theta} &= \cot\theta. \end{aligned} \tag{3.154}$$

Let's compute a promising component of the Riemann tensor:

$$\begin{aligned} R^\theta{}_{\phi\theta\phi} &= \partial_\theta\Gamma^\theta_{\phi\phi} - \partial_\phi\Gamma^\theta_{\theta\phi} + \Gamma^\theta_{\theta\lambda}\Gamma^\lambda_{\phi\phi} - \Gamma^\theta_{\phi\lambda}\Gamma^\lambda_{\theta\phi} \\ &= (\sin^2\theta - \cos^2\theta) - (0) + (0) - (-\sin\theta\cos\theta)(\cot\theta) \\ &= \sin^2\theta. \end{aligned} \tag{3.155}$$

The notation is obviously imperfect, since the Greek letter λ is a dummy index that is summed over, while the Greek letters θ and ϕ represent specific coordinates. Lowering an index, we have

$$\begin{aligned} R_{\theta\phi\theta\phi} &= g_{\theta\lambda} R^{\lambda}{}_{\phi\theta\phi} \\ &= g_{\theta\theta} R^{\theta}{}_{\phi\theta\phi} \\ &= a^2 \sin^2\theta . \end{aligned} \tag{3.156}$$

It is easy to check that all of the components of the Riemann tensor either vanish or are related to this one by symmetry. We can go on to compute the Ricci tensor via $R_{\mu\nu} = g^{\alpha\beta} R_{\alpha\mu\beta\nu}$. We obtain

$$\begin{aligned} R_{\theta\theta} &= g^{\phi\phi} R_{\phi\theta\phi\theta} = 1 \\ R_{\theta\phi} &= R_{\phi\theta} = 0 \\ R_{\phi\phi} &= g^{\theta\theta} R_{\theta\phi\theta\phi} = \sin^2\theta . \end{aligned} \tag{3.157}$$

The Ricci scalar is similarly straightforward:

$$R = g^{\theta\theta} R_{\theta\theta} + g^{\phi\phi} R_{\phi\phi} = \frac{2}{a^2}. \tag{3.158}$$

Therefore the Ricci scalar, which for a two-dimensional manifold completely characterizes the curvature, is a constant over the two-sphere. If we had perturbed the metric (corresponding physically to bumps on the sphere), this would no longer have been the case. Note that the scalar curvature decreases as the radius of the sphere increases. Even in more general contexts, we will sometimes refer to the "radius of curvature" of a manifold as providing a length scale over which the curvature varies; the larger the radius of curvature, the smaller the curvature itself.

3.8 ■ SYMMETRIES AND KILLING VECTORS

The real world is a messy place, and we have no hope of finding a metric that describes our actual universe, or even any small part thereof, with perfect precision. Instead, we model spacetime via various approximations appropriate to the physical situation being studied. For example, the geometry outside a star or planet may be approximated, to some order of precision, as being spherically symmetric, even if the real situation includes small deviations from this symmetry—these may be added in later as perturbations.

General relativity is no different from other fields of physics, then, in being especially interested in solutions with symmetry. In fact, such properties may be even more crucial in GR than in, say, electromagnetism, since the nonlinear nature of Einstein's equation (discussed in the next chapter) makes it hard to find any exact solutions at all. In the context of curved spacetime, however, we need to be more careful than usual about what exactly is meant by "symmetry." In this section we develop some useful tools for studying symmetry; a deeper investigation can be found in Appendix B.

We think of a manifold M as possessing a symmetry if the geometry is invariant under a certain transformation that maps M to itself; that is, if the metric is the same, in some sense, from one point to another. In fact different tensor fields may possess different symmetries; symmetries of the metric are called **isometries**. Sometimes the existence of isometries is obvious; consider, for example, four-dimensional Minkowski space,

$$ds^2 = \eta_{\mu\nu} dx^\mu dx^\nu = -dt^2 + dx^2 + dy^2 + dz^2. \tag{3.159}$$

We know of several isometries of this space; these include translations ($x^\mu \to x^\mu + a^\mu$, with a^μ fixed) and Lorentz transformations ($x^\mu \to \Lambda^\mu{}_\nu x^\nu$, with $\Lambda^\mu{}_\nu$ a Lorentz-transformation matrix). The fact that the metric is invariant under translations is made immediately apparent by the simple fact that the metric coefficients $\eta_{\mu\nu}$ are independent of the individual coordinate functions x^μ. Indeed, whenever $\partial_{\sigma_*} g_{\mu\nu} = 0$ for some fixed σ_* (but for all μ and ν), there will be a symmetry under translations along x^{σ_*}:

$$\partial_{\sigma_*} g_{\mu\nu} = 0 \quad \Rightarrow \quad x^{\sigma_*} \to x^{\sigma_*} + a^{\sigma_*} \text{ is a symmetry.} \tag{3.160}$$

The careful reader will have noticed that we still haven't precisely defined what we mean by symmetry; roughly we imagine that the metric is invariant under some transformation, but the precise meaning is only developed in Appendix B. Also, the implication arrow in (3.160) only goes one way, and it would be nice to have a clean criterion for deciding when a given transformation counts as a symmetry; this will come soon.

Isometries of the form (3.160) have immediate consequences for the motion of test particles as described by the geodesic equation. Recall from (3.61) that the geodesic equation can be written in terms of the four-momentum $p^\mu = mU^\mu$ (valid for timelike paths, at least) as

$$p^\lambda \nabla_\lambda p^\mu = 0. \tag{3.161}$$

By metric compatibility we are free to lower the index μ, and then we may expand the covariant derivative to obtain

$$p^\lambda \partial_\lambda p_\mu - \Gamma^\sigma_{\lambda\mu} p^\lambda p_\sigma = 0. \tag{3.162}$$

The first term tells us how the momentum components change along the path,

$$p^\lambda \partial_\lambda p_\mu = m \frac{dx^\lambda}{d\tau} \partial_\lambda p_\mu = m \frac{dp_\mu}{d\tau}, \tag{3.163}$$

while the second term is

$$\Gamma^{\sigma}_{\lambda\mu} p^{\lambda} p_{\sigma} = \tfrac{1}{2} g^{\sigma\nu} (\partial_{\lambda} g_{\mu\nu} + \partial_{\mu} g_{\nu\lambda} - \partial_{\nu} g_{\lambda\mu}) p^{\lambda} p_{\sigma} \tag{3.164}$$

$$= \tfrac{1}{2} (\partial_{\lambda} g_{\mu\nu} + \partial_{\mu} g_{\nu\lambda} - \partial_{\nu} g_{\lambda\mu}) p^{\lambda} p^{\nu} \tag{3.165}$$

$$= \tfrac{1}{2} (\partial_{\mu} g_{\nu\lambda}) p^{\lambda} p^{\nu}, \tag{3.166}$$

where we have used the symmetry of $p^{\lambda} p^{\nu}$ to go from the second line to the third. So, without yet making any assumptions about symmetry, we see that the geodesic equation can be written as

$$m \frac{dp_{\mu}}{d\tau} = \frac{1}{2} (\partial_{\mu} g_{\nu\lambda}) p^{\lambda} p^{\nu}. \tag{3.167}$$

Therefore, if all of the metric coefficients are independent of the coordinate x^{σ_*}, we find that this isometry implies that the momentum component p_{σ_*} is a conserved quantity of the motion:

$$\partial_{\sigma_*} g_{\mu\nu} = 0 \quad \Rightarrow \quad \frac{dp_{\sigma_*}}{d\tau} = 0. \tag{3.168}$$

This will hold along any geodesic, even though we only derived it for timelike ones. The conserved quantities implied by isometries are extremely useful in studying the motion of test particles in curved backgrounds.

Of course, even though independence of the metric components on one or more coordinates implies the existence of isometries, the converse does not necessarily hold. Symmetry under Lorentz transformations, for example, is not manifest as independence of $\eta_{\mu\nu}$ on any coordinates; indeed, in four dimensions, there are four types of translations and six types of Lorentz transformations, for a total of ten, which is obviously larger than the number of dimensions the metric could possibly be independent of. What is more, it would be simple enough to transform to a complicated coordinate system where not even the translational symmetries were obvious. Such a coordinate transformation would change the metric components, but not the underlying geometry, which is what the symmetry is really characterizing. Clearly a more systematic procedure is called for.

We can develop such a procedure by casting the right-hand equation of (3.168), expressing constancy of one of the components of the momentum, in a more manifestly covariant form. If x^{σ_*} is the coordinate which $g_{\mu\nu}$ is independent of, let us consider the vector ∂_{σ_*}, which we label as K:

$$K = \partial_{\sigma_*}, \tag{3.169}$$

which is equivalent in component notation to

$$K^{\mu} = (\partial_{\sigma_*})^{\mu} = \delta^{\mu}_{\sigma_*}. \tag{3.170}$$

We say that the vector K^{μ} generates the isometry; this means that the transformation under which the geometry is invariant is expressed infinitesimally as a motion in the direction of K^μ. Again, the notion is developed more fully in Appendix B. In terms of this vector, the noncovariant-looking quantity p_{σ_*} is simply

$$p_{\sigma_*} = K^\nu p_\nu = K_\nu p^\nu. \tag{3.171}$$

Meanwhile, the constancy of this (scalar) quantity along the path is equivalent to the statement that its directional derivative along the geodesic vanishes:

$$\frac{dp_{\sigma_*}}{d\tau} = 0 \quad \leftrightarrow \quad p^\mu \nabla_\mu (K_\nu p^\nu) = 0. \tag{3.172}$$

Expanding the expression on the right, we obtain

$$\begin{aligned} p^\mu \nabla_\mu (K_\nu p^\nu) &= p^\mu K_\nu \nabla_\mu p^\nu + p^\mu p^\nu \nabla_\mu K_\nu \\ &= p^\mu p^\nu \nabla_\mu K_\nu \\ &= p^\mu p^\nu \nabla_{(\mu} K_{\nu)}, \end{aligned} \tag{3.173}$$

where in the second line we have invoked the geodesic equation ($p^\mu \nabla_\mu p^\nu = 0$). In the third line we have used the fact that $p^\mu p^\nu$ is automatically symmetric in μ and ν, so only the symmetric part of $\nabla_\mu K_\nu$ could possibly contribute. We therefore conclude that any vector K_μ that satisfies $\nabla_{(\mu} K_{\nu)} = 0$ implies that $K_\nu p^\nu$ is conserved along a geodesic trajectory:

$$\boxed{\nabla_{(\mu} K_{\nu)} = 0 \quad \Rightarrow \quad p^\mu \nabla_\mu (K_\nu p^\nu) = 0.} \tag{3.174}$$

The equation on the left is known as **Killing's equation**, and vector fields that satisfy it are known as **Killing vector fields** (or simply Killing vectors). You can verify for yourself that, if the metric is independent of some coordinate x^{σ_*}, the vector ∂_{σ_*} will satisfy Killing's equation. In fact, if a vector K^μ satisfies Killing's equation, it will always be possible to find a coordinate system in which $K = \partial_{\sigma_*}$; but in general we cannot find coordinates in which all the Killing vectors are simultaneously of this form, nor is this form necessary for the vector to satisfy Killing's equation.

As we investigate in Appendix B, Killing vector fields on a manifold are in one-to-one correspondence with continuous symmetries of the metric on that manifold. Every Killing vector implies the existence of conserved quantities associated with geodesic motion. This can be understood physically: by definition the metric is unchanging along the direction of the Killing vector. Loosely speaking, therefore, a free particle will not feel any forces in this direction, and the component of its momentum in that direction will consequently be conserved. In fact, using the same kind of logic by which we showed that $K_\nu p^\nu$ is conserved along a geodesic if $\nabla_{(\mu} K_{\nu)} = 0$ generalizes to additional indices, a **Killing tensor** is a symmetric l-index tensor $K_{\nu_1 \cdots \nu_l}$ that satisfies the obvious generalization of Killing's equation, and correspondingly leads to conserved quantities by contracting with l copies of the momentum:

$$\nabla_{(\mu} K_{\nu_1 \cdots \nu_l)} = 0 \quad \Rightarrow \quad p^\mu \nabla_\mu (K_{\nu_1 \cdots \nu_l} p^{\nu_1} \cdots p^{\nu_l}) = 0. \tag{3.175}$$

Simple examples of Killing tensors are the metric itself, and symmetrized tensor products of Killing vectors. Killing tensors are not related in a simple way to symmetries of the spacetime, but they will simplify our analysis of rotating black holes and expanding universes.

Derivatives of Killing vectors can be related to the Riemann tensor by

$$\nabla_\mu \nabla_\sigma K^\rho = R^\rho{}_{\sigma\mu\nu} K^\nu, \tag{3.176}$$

as you are asked to prove in the exercises. Contracting this expression yields

$$\nabla_\mu \nabla_\sigma K^\mu = R_{\sigma\nu} K^\nu. \tag{3.177}$$

These relations, along with the Bianchi identity and Killing's equation, suffice to show that the directional derivative of the Ricci scalar along a Killing vector field will vanish,

$$K^\lambda \nabla_\lambda R = 0. \tag{3.178}$$

This last fact is another reflection of the idea that the geometry is not changing along a Killing vector field.

Besides leading to conserved quantities for the motion of individual particles, the existence of a timelike Killing vector allows us to define a conserved energy for the entire spacetime. Given a Killing vector K_ν and a conserved energy-momentum tensor $T_{\mu\nu}$, we can construct a current

$$J_T^\mu = K_\nu T^{\mu\nu} \tag{3.179}$$

that is automatically conserved,

$$\begin{aligned} \nabla_\mu J_T^\mu &= (\nabla_\mu K_\nu) T^{\mu\nu} + K_\nu (\nabla_\mu T^{\mu\nu}) \\ &= 0. \end{aligned} \tag{3.180}$$

The first term vanishes by virtue of Killing's equation (since the symmetry of the upper indices serves to automatically symmetrize the lower indices), and the second term vanishes by conservation of $T_{\mu\nu}$. If K_ν is timelike, we can integrate over a spacelike hypersurface Σ to define the total energy,

$$E_T = \int_\Sigma J_T^\mu n_\mu \sqrt{\gamma}\, d^3x, \tag{3.181}$$

where γ_{ij} is the induced metric on Σ and n_μ is the normal vector to Σ. In Appendix E we discuss integration over hypersurfaces, and in particular Stokes's theorem; as explained there, E_T will be the same when integrated over any spacelike hypersurface, and is therefore conserved. This result fits nicely with our discussion in Section 3.5, where we found that the total energy is not typically conserved in an expanding universe; expansion means that the metric is changing with time, so there is no isometry in this direction. When there is a timelike Killing vector, we can write the metric in a form where it is independent of the timelike coordinate, and Noether's theorem implies a conserved energy. Similarly, spacelike Killing vectors may be used to construct conserved momenta (or angular momenta).

Although it may or may not be simple to actually solve Killing's equation in any given spacetime, it is frequently possible to write down some Killing vectors by inspection. (Of course a generic metric has no Killing vectors at all, but to keep things simple we often deal with metrics with high degrees of symmetry.) For example, in $\mathbf{R}^3$ with metric $ds^2 = \mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2$, independence of the metric components with respect to x, y, and z immediately yields three Killing vectors:

$$\begin{aligned} X^\mu &= (1, 0, 0) \\ Y^\mu &= (0, 1, 0) \\ Z^\mu &= (0, 0, 1). \end{aligned} \tag{3.182}$$

These clearly represent the three translations. There are also three rotational symmetries in $\mathbf{R}^3$, which are not quite as simple. To find them, imagine first going to polar coordinates,

$$\begin{aligned} x &= r \sin\theta \cos\phi \\ y &= r \sin\theta \sin\phi \\ z &= r \cos\theta, \end{aligned} \tag{3.183}$$

where the metric takes the form

$$ds^2 = \mathrm{d}r^2 + r^2 \mathrm{d}\theta^2 + r^2 \sin^2\theta \, \mathrm{d}\phi^2. \tag{3.184}$$

Now the metric (the *same* metric, just in a different coordinate system) is manifestly independent of ϕ. We therefore know that $R = \partial_\phi$ is a Killing vector. Transforming back to Cartesian coordinates, this becomes

$$R = -y\partial_x + x\partial_y. \tag{3.185}$$

The Cartesian components R^μ are therefore $(-y, x, 0)$. Since this represents a rotation about the z-axis, it is straightforward to guess the components of all three rotational Killing vectors:

$$\begin{aligned} R^\mu &= (-y,\ \ x,\ \ 0) \\ S^\mu &= (\ \ z,\ \ 0, -x) \\ T^\mu &= (\ \ 0, -z,\ \ y), \end{aligned} \tag{3.186}$$

representing rotations about the z, y, and x-axes, respectively. You can check for yourself that these actually do solve Killing's equation. The overall signs don't matter, since minus a Killing vector is still a Killing vector.

This exercise leads directly to the Killing vectors for the two-sphere S^2 with metric

$$ds^2 = d\theta^2 + \sin^2\theta\, d\phi^2. \tag{3.187}$$

Since this sphere can be thought of as the locus of points at unit distance from the origin in $\mathbf{R}^3$, and the rotational Killing vectors all rotate such a sphere into itself, they also represent symmetries of S^2. To get explicit coordinate-basis representations for these vectors, we first transform the three-dimensional vectors (3.186) to polar coordinates $x^{\mu'} = (r, \theta, \phi)$. A straightforward calculation reveals

$$\begin{aligned} R &= \partial_\phi \\ S &= \cos\phi\, \partial_\theta - \cot\theta \sin\phi\, \partial_\phi \\ T &= -\sin\phi\, \partial_\theta - \cot\theta \cos\phi\, \partial_\phi . \end{aligned} \tag{3.188}$$

Notice that there are no components along ∂_r, which makes sense for a rotational isometry. Therefore the expressions (3.188) for the three rotational Killing vectors in $\mathbf{R}^3$ are exactly the same as those of S^2 in spherical polar coordinates.

In $n \geq 2$ dimensions, there can be more Killing vectors than dimensions. This is because a set of Killing vector fields can be linearly independent, even though at any one point on the manifold the vectors at that point are linearly dependent. It is trivial to show (so you should do it yourself) that a linear combination of Killing vectors with *constant* coefficients is still a Killing vector (in which case the linear combination does not count as an independent Killing vector), but this is not generally true with coefficients that vary over the manifold. You can also show that the commutator of two Killing vector fields is a Killing vector field; this is very useful to know, but it may be the case that the commutator gives you a vector field that is not linearly independent (or it may simply vanish). The problem of finding all of the Killing vectors of a metric is therefore somewhat tricky, as it is not always clear when to stop looking.

3.9 ■ MAXIMALLY SYMMETRIC SPACES

How symmetric can a space possibly be? An example of a space with the highest possible degree of symmetry is $\mathbf{R}^n$ with the flat Euclidean metric. Consider the isometries of this space, which we know to be translations and rotations in n dimensions, from the perspective of what they do in the neighborhood of some fixed point p. The translations are those transformations that move the point; there are n independent axes along which it can be moved, and hence n total translations. The rotations, centered at p, are those transformations that leave p invariant; they can be thought of as moving one of the axes through p into one of the others. There are n axes, and for each axis there are $n-1$ other axes into which it can be rotated, but we shouldn't count a rotation of y into x as separate from a rotation of x into y, so the total number of independent rotations is $\frac{1}{2}n(n-1)$. We therefore have

$$n + \tfrac{1}{2}n(n-1) = \tfrac{1}{2}n(n+1) \tag{3.189}$$

independent symmetries of $\mathbf{R}^n$. But our counting argument only referred to the behavior of the symmetry in a neighborhood of p, not globally all over the manifold; so even in the presence of curvature the counting should be the same. If the metric signature is not Euclidean, some of the rotations will actually be boosts, but again the counting will be the same. The number of isometries is, of course, the number of linearly independent Killing vector fields. We therefore refer to an n-dimensional manifold with $\frac{1}{2}n(n+1)$ Killing vectors as a **maximally symmetric space**. The most familiar examples of maximally symmetric spaces are n-dimensional Euclidean spaces $\mathbf{R}^n$ and the n-dimensional spheres S^n. For an n-dimensional sphere we usually think of the isometries as consisting of $\frac{1}{2}n(n+1)$ independent rotations, rather than as some collection of both rotations and translations. However, if we consider the action of these rotations on some fixed point p, a moment's thought convinces us that the entire set can be decomposed into $\frac{1}{2}n(n-1)$ rotations around the point (keeping p fixed), and another n that move p along each direction, just as in $\mathbf{R}^n$.

If a manifold is maximally symmetric, the curvature is the same everywhere (as expressed by translation-like isometries) and the same in every direction (as expressed by rotation-like isometries). Hence, if we know the curvature of a maximally symmetric space at one point, we know it everywhere. Indeed, there are only a small number of possible maximally symmetric spaces; they are classified by the curvature scalar R (which will be constant everywhere), the dimensionality n, the metric signature, and perhaps some discrete pieces of information relating to the global topology (distinguishing, for example, an n-torus from $\mathbf{R}^n$, and tori of different sizes from each other). It follows that we should be able to reconstruct the entire Riemann tensor of such a space from the Ricci scalar R; let's see how this works.

The basic idea is simply that, since the geometry looks the same in all directions, the curvature tensor should look the same in all directions. What might this mean? First choose locally inertial coordinates at some point p, so that $g_{\hat{\mu}\hat{\nu}} = \eta_{\hat{\mu}\hat{\nu}}$. Of course, locally inertial coordinates are not unique; for example, we can perform a Lorentz transformation at p and the metric components will remain those of $\eta_{\hat{\mu}\hat{\nu}}$. (By "doing a Lorentz transformation" we really are referring to a change of basis vectors in T_p; in a curved spacetime, this only makes sense at a single point, not over a region.) Since the geometry is maximally symmetric, we want the same to be true of the Riemann tensor; that is, the components of $R_{\hat{\rho}\hat{\sigma}\hat{\mu}\hat{\nu}}$ should not change under a Lorentz transformation either, since there is no preferred direction in spacetime. But there are unique tensors that do not change their components under Lorentz transformations—the metric, the Kronecker delta, and the Levi–Civita tensor. This means that, in these coordinates and at this point, the components of $R_{\hat{\rho}\hat{\sigma}\hat{\mu}\hat{\nu}}$ will be proportional to a tensor constructed from these invariant tensors. Attempting to match the symmetries of the Riemann tensor reveals that there is a unique possibility:

$$R_{\hat{\rho}\hat{\sigma}\hat{\mu}\hat{\nu}} \propto g_{\hat{\rho}\hat{\mu}}g_{\hat{\sigma}\hat{\nu}} - g_{\hat{\rho}\hat{\nu}}g_{\hat{\sigma}\hat{\mu}}. \tag{3.190}$$

But this is a completely tensorial relation, so it must be true in any coordinate system. We have argued in favor of this relation at a single point p, but in a maximally symmetric space all points are created equal, so it must also be true at any other point as well. The proportionality constant is easily fixed by contracting both sides twice [the left-hand side becomes R, and the right-hand side is $n(n-1)$]. We end up with an equation true in any maximally symmetric space, at any point, in any coordinate system:

$$R_{\rho\sigma\mu\nu} = \frac{R}{n(n-1)}(g_{\rho\mu}g_{\sigma\nu} - g_{\rho\nu}g_{\sigma\mu}). \tag{3.191}$$

Likewise, if the Riemann tensor satisfies this condition (with R a constant over the manifold), the metric will be maximally symmetric. In two dimensions, finding that R is a constant is sufficient to prove that a space is maximally symmetric, since there is only one independent component of the curvature. In higher dimensions you have to work harder.

Locally, then (ignoring questions of global topology), a maximally symmetric space of given dimension and signature is fully specified by R. The basic classification of such spaces is simply whether R is positive, zero, or negative, since the magnitude of R represents an overall scaling of the size of the space. For Euclidean signatures, the flat maximally symmetric spaces are planes or appropriate higher-dimensional generalizations, while the positively curved ones are spheres. Maximally symmetric Euclidean spaces of negative curvature are hyperboloids, denoted H^n. These are less familiar because even a two-dimensional hyperboloid cannot be isometrically embedded in $\mathbf{R}^3$. Let's examine this two-dimensional hyperboloid briefly.

There are a number of ways of representing H^2, which has the same topology as $\mathbf{R}^2$. One simple way is as the **Poincaré half-plane**, which is the region $y > 0$ of a two-dimensional region with coordinates $\{x, y\}$ and metric

$$ds^2 = \frac{a^2}{y^2}(dx^2 + dy^2). \tag{3.192}$$

The geometry of the Poincaré half-plane is of course different from that of the upper half of $\mathbf{R}^2$, despite the use of similar coordinates. For example, we can compute the length of a line segment stretching vertically ($x =$ constant) from y_1 to y_2:

$$\begin{aligned}\Delta s &= \int_{y_1}^{y_2} \sqrt{g_{\mu\nu}\frac{dx^\mu}{dy}\frac{dx^\nu}{dy}}\,dy \\ &= a\int_{y_1}^{y_2}\frac{dy}{y} \\ &= a\ln\left(\frac{y_2}{y_1}\right).\end{aligned} \tag{3.193}$$

This is not at all the result $\Delta s = y_2 - y_1$ we would expect in Euclidean space. In particular, notice that the path length becomes infinite for paths that approach the boundary $y = 0$. In other words, it's not really a boundary at all; it's infinitely far away, as far as anyone living on the hyperboloid is concerned.

The nonvanishing Christoffel symbols for (3.192) are

$$\begin{aligned}\Gamma^x_{xy} = \Gamma^x_{yx} &= -y^{-1} \\ \Gamma^y_{xx} &= y^{-1} \\ \Gamma^y_{yy} &= -y^{-1}.\end{aligned} \tag{3.194}$$

From these it is straightforward to show that geodesics satisfy

$$(x - x_0)^2 + y^2 = l^2, \tag{3.195}$$

for some constants x_0 and l. Curves of this form are semicircles with centers located on the x-axis, as shown in Figure 3.8. In the limit as $x_0 \to \infty$ and $l \to \infty$ with $l - x_0$ fixed, we get a straight vertical line. Following our discussion of S^2 at the end of Section 3.7, we calculate a representative component of the Riemann tensor to be

$$R^x{}_{yxy} = -y^{-2}. \tag{3.196}$$

As with the two-sphere, all other components are either vanishing or related to this by symmetries. This is simply a reflection of the fact that we are in two di-

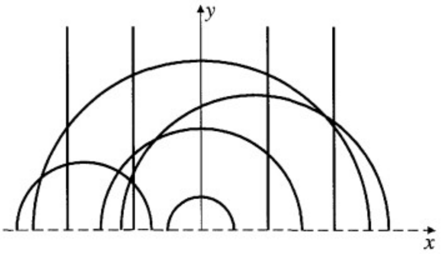

FIGURE 3.8 The upper half plane with a negatively curved metric. Geodesics are semicircles and straight lines that intersect the x-axis vertically.

mensions, with only one independent component of curvature. Turning the crank yields the Ricci tensor,

$$\begin{aligned} R_{xx} &= -y^{-2} \\ R_{xy} &= 0 \\ R_{yy} &= -y^{-2}, \end{aligned} \tag{3.197}$$

and the curvature scalar,

$$R = -\frac{2}{a^2}. \tag{3.198}$$

We see that it matches that of S^2 with the opposite sign, and in particular that it is a constant. Since we are in two dimensions, this is enough to ensure that our metric really is maximally symmetric. Of course there are coordinates in which H^2 looks very different; one is introduced in the Exercises.

Locally, then, a maximally symmetric space of Euclidean signature is either a plane, a sphere, or a hyperboloid, depending on the sign of R. Globally, any maximally symmetric space (of Euclidean signature) can be constructed by taking a carefully chosen region of one of these three spaces and identifying different sides, as the flat torus can be constructed from $\mathbf{R}^2$. As an aside, let's briefly mention a connection between local geometry and global topology, encompassed by the Gauss–Bonnet theorem. For a two-dimensional compact boundaryless orientable manifold, this reads

$$\chi(M) = \frac{1}{4\pi}\int_M R\sqrt{|g|}\, d^n x, \tag{3.199}$$

where $\chi(M)$ is a topological invariant of the space, known as the Euler characteristic. In general it can be calculated from the cohomology spaces mentioned in Chapter 2; in two dimensions, however, it is simply given by

$$\chi(M) = 2(1-g), \tag{3.200}$$

where g is the genus of the surface (zero for a sphere, and equal to the number of handles of a torus or Riemann surface). The Gauss–Bonnet theorem holds whether or not the curvature R is a constant; when it is, however, we see that all Riemann surfaces of genus $g \geq 2$ must have negative curvature, just as a sphere must be positively curved and a torus must ~~be~~ flat.

Continuing our aside, think for the moment about string theory, which claims that the fundamental objects comprising the universe are small one-dimensional loops of string. Such strings have two-dimensional "world-sheets" rather than one-dimensional worldlines. Doing perturbation theory in string theory (the equivalent of calculating Feynman diagrams in quantum field theory) involves summing over all world-sheet geometries (generally, for technical reasons, Euclidean geometries). This sounds like a lot of geometries, but in two dimensions any metric can be written as some fiducial metric times a conformal factor. This should be plausible, since there is only one curvature component; you are asked to prove it in the Exercises. The fiducial metric can be chosen differently for each world-sheet topology, and we can make our lives easier by choosing it to be (locally) a metric of maximal symmetry—the round sphere for genus zero, the plane for genus one, and the hyperboloid for higher genera. Even more fortunately, the string theories of greatest physical interest are the so-called critical string theories, for which the conformal factor itself doesn't matter. This is one of the things that makes doing calculations in perturbative string theory possible; we only have to sum over a discrete set of topologies, with a finite number of modular parameters for each topology (such as the parameters telling us the sizes of the different directions in a torus).

We close this section with one last point. We have explored the maximally symmetric spaces of Euclidean signatures; there are, of course, corresponding spacetimes with Lorentzian signatures. We know that the maximally symmetric spacetime with $R = 0$ is simply Minkowski space. The positively curved maximally symmetric spacetime is called de Sitter space, while that with negative curvature is imaginatively labeled anti-de Sitter space. These spacetimes will be more thoroughly discussed in Chapter 8.

It should be clear by now that the Appendices flesh out these ideas in important ways. Impatient readers may skip over them, but it would be a shame to do so.

3.10 ■ GEODESIC DEVIATION

The Riemann tensor shows up as a consequence of curvature in one more way: geodesic deviation. You have undoubtedly heard that the defining property of Euclidean (flat) geometry is the parallel postulate: initially parallel lines remain parallel forever. Of course in a curved space this is not true; on a sphere, certainly, initially parallel geodesics will eventually cross. We would like to quantify this behavior for an arbitrary curved space.

The problem is that the notion of "parallel" does not extend naturally from flat to curved spaces. The best we can do is to consider geodesic curves that might be initially parallel, and see how they behave as we travel down the geodesics. To this end we consider a one-parameter family of geodesics, $\gamma_s(t)$. That is, for each $s \in \mathbf{R}$, γ_s is a geodesic parameterized by the affine parameter t. The collection of these curves defines a smooth two-dimensional surface (embedded in a manifold M of arbitrary dimensionality). The coordinates on this surface may be chosen to be s and t, provided we have chosen a family of geodesics that do not cross. The entire surface is the set of points $x^\mu(s,t) \in M$. We have two natural vector fields: the tangent vectors to the geodesics,

$$T^\mu = \frac{\partial x^\mu}{\partial t}, \tag{3.201}$$

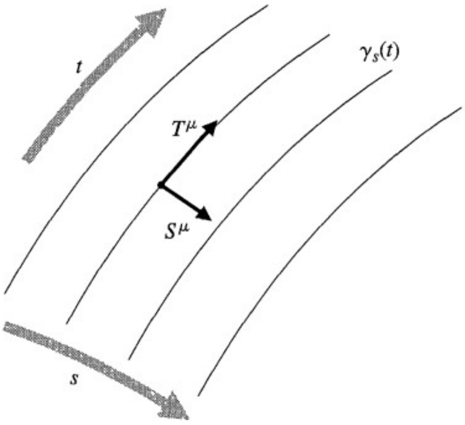

FIGURE 3.9 A set of geodesics $\gamma_s(t)$, with tangent vectors T^μ. The vector field S^μ measures the deviation between nearby geodesics.

and the deviation vectors

$$S^\mu = \frac{\partial x^\mu}{\partial s}. \tag{3.202}$$

This name derives from the informal notion that S^μ points from one geodesic toward the neighboring ones.

The idea that S^μ points from one geodesic to the next inspires us to define the "relative velocity of geodesics,"

$$V^\mu = (\nabla_T S)^\mu = T^\rho \nabla_\rho S^\mu, \tag{3.203}$$

and the "relative acceleration of geodesics,"

$$A^\mu = (\nabla_T V)^\mu = T^\rho \nabla_\rho V^\mu. \tag{3.204}$$

You should take the names with a grain of salt, but these vectors are certainly well-defined. This notion of *relative* acceleration between geodesics should be distinguished from the acceleration of a path away from being a geodesic, which would be given by $a^\mu = T^\sigma \nabla_\sigma T^\mu$.

Since S and T are basis vectors adapted to a coordinate system, their commutator vanishes:

$$[S, T] = 0. \tag{3.205}$$

From (3.37) we then have

$$S^\rho \nabla_\rho T^\mu = T^\rho \nabla_\rho S^\mu. \tag{3.206}$$

With this in mind, let's compute the acceleration:

$$\begin{aligned}
A^\mu &= T^\rho \nabla_\rho (T^\sigma \nabla_\sigma S^\mu) \\
&= T^\rho \nabla_\rho (S^\sigma \nabla_\sigma T^\mu) \\
&= (T^\rho \nabla_\rho S^\sigma)(\nabla_\sigma T^\mu) + T^\rho S^\sigma \nabla_\rho \nabla_\sigma T^\mu \\
&= (S^\rho \nabla_\rho T^\sigma)(\nabla_\sigma T^\mu) + T^\rho S^\sigma (\nabla_\sigma \nabla_\rho T^\mu + R^\mu{}_{\nu\rho\sigma} T^\nu) \\
&= (S^\rho \nabla_\rho T^\sigma)(\nabla_\sigma T^\mu) + S^\sigma \nabla_\sigma (T^\rho \nabla_\rho T^\mu) - (S^\sigma \nabla_\sigma T^\rho)\nabla_\rho T^\mu \\
&\quad + R^\mu{}_{\nu\rho\sigma} T^\nu T^\rho S^\sigma \\
&= R^\mu{}_{\nu\rho\sigma} T^\nu T^\rho S^\sigma .
\end{aligned} \tag{3.207}$$

Let's think about this line by line. The first line is the definition of A^μ, and the second line comes directly from (3.206). The third line is simply the Leibniz rule. The fourth line replaces a double covariant derivative by the derivatives in the opposite order plus the Riemann tensor. In the fifth line we use Leibniz again (in the opposite order from usual), and then we cancel two identical terms and notice that the term involving $T^\rho \nabla_\rho T^\mu$ vanishes because T^μ is the tangent vector to a geodesic. The result,

$$\boxed{A^\mu = \frac{D^2}{dt^2} S^\mu = R^\mu{}_{\nu\rho\sigma} T^\nu T^\rho S^\sigma ,} \tag{3.208}$$

is the **geodesic deviation equation**. It expresses something that we might have expected: the relative acceleration between two neighboring geodesics is proportional to the curvature.

The geodesic deviation equation characterizes the behavior of a one-parameter family of neighboring geodesics. We will sometimes be interested in keeping track of the behavior of a multi-dimensional set of neighboring geodesics, perhaps representing a bundle of photons or a distribution of massive test particles. Such a set of geodesics forms a congruence; in Appendix F we derive equations that describe the evolution of such congruences.

Physically, of course, the acceleration of neighboring geodesics is interpreted as a manifestation of gravitational tidal forces. In the next chapter we explore in more detail how properties of curved spacetime are reflected by physics in a gravitational field.

3.11 ■ EXERCISES

1. Verify these consequences of metric compatibility ($\nabla_\sigma g_{\mu\nu} = 0$):

$$\begin{aligned}
\nabla_\sigma g^{\mu\nu} &= 0 \\
\nabla_\lambda \epsilon_{\mu\nu\rho\sigma} &= 0.
\end{aligned} \tag{3.209}$$

2. You are familiar with the operations of gradient ($\nabla\phi$), divergence ($\nabla\cdot\mathbf{V}$) and curl ($\nabla\times\mathbf{V}$) in ordinary vector analysis in three-dimensional Euclidean space. Using covariant derivatives, derive formulae for these operations in spherical polar coordinates $\{r, \theta, \phi\}$ defined by

$$x = r\sin\theta\cos\phi \tag{3.210}$$

$$y = r\sin\theta\sin\phi \tag{3.211}$$

$$z = r\cos\theta. \tag{3.212}$$

Compare your results to those in Jackson (1999) or an equivalent text. Are they identical? Should they be?

3. Imagine we have a *diagonal* metric $g_{\mu\nu}$. Show that the Christoffel symbols are given by

$$\Gamma^{\lambda}_{\mu\nu} = 0 \tag{3.213}$$

$$\Gamma^{\lambda}_{\mu\mu} = -\tfrac{1}{2}(g_{\lambda\lambda})^{-1}\partial_\lambda g_{\mu\mu} \tag{3.214}$$

$$\Gamma^{\lambda}_{\mu\lambda} = \partial_\mu\left(\ln\sqrt{|g_{\lambda\lambda}|}\right) \tag{3.215}$$

$$\Gamma^{\lambda}_{\lambda\lambda} = \partial_\lambda\left(\ln\sqrt{|g_{\lambda\lambda}|}\right) \tag{3.216}$$

In these expressions, $\mu \neq \nu \neq \lambda$, and repeated indices are *not* summed over.

4. In Euclidean three-space, we can define paraboloidal coordinates (u, v, ϕ) via

$$x = uv\cos\phi \quad y = uv\sin\phi \quad z = \tfrac{1}{2}(u^2 - v^2).$$

- **(a)** Find the coordinate transformation matrix between paraboloidal and Cartesian coordinates $\partial x^{\alpha}/\partial x^{\beta'}$ and the inverse transformation. Are there any singular points in the map?
- **(b)** Find the basis vectors and basis one-forms in terms of Cartesian basis vectors and forms.
- **(c)** Find the metric and inverse metric in paraboloidal coordinates.
- **(d)** Calculate the Christoffel symbols.
- **(e)** Calculate the divergence $\nabla_\mu V^\mu$ and Laplacian $\nabla_\mu\nabla^\mu f$.

5. Consider a 2-sphere with coordinates (θ, ϕ) and metric

$$ds^2 = d\theta^2 + \sin^2\theta\, d\phi^2. \tag{3.217}$$

- **(a)** Show that lines of constant longitude (ϕ = constant) are geodesics, and that the only line of constant latitude (θ = constant) that is a geodesic is the equator ($\theta = \pi/2$).
- **(b)** Take a vector with components $V^\mu = (1, 0)$ and parallel-transport it once around a circle of constant latitude. What are the components of the resulting vector, as a function of θ?

6. A good approximation to the metric outside the surface of the Earth is provided by

$$ds^2 = -(1 + 2\Phi)dt^2 + (1 - 2\Phi)dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\phi^2), \tag{3.218}$$

where

$$\Phi = -\frac{GM}{r} \tag{3.219}$$

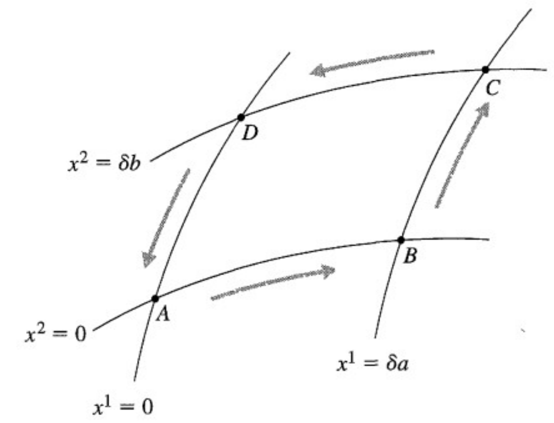
may be thought of as the familiar Newtonian gravitational potential. Here G is Newton's constant and M is the mass of the earth. For this problem Φ may be assumed to be small.

(a) Imagine a clock on the surface of the Earth at distance R_1 from the Earth's center, and another clock on a tall building at distance R_2 from the Earth's center. Calculate the time elapsed on each clock as a function of the coordinate time t. Which clock moves faster?

(b) Solve for a geodesic corresponding to a circular orbit around the equator of the Earth ($\theta = \pi/2$). What is $d\phi/dt$?

(c) How much proper time elapses while a satellite at radius R_1 (skimming along the surface of the earth, neglecting air resistance) completes one orbit? You can work to first order in Φ if you like. Plug in the actual numbers for the radius of the Earth and so on (don't forget to restore the speed of light) to get an answer in seconds. How does this number compare to the proper time elapsed on the clock stationary on the surface?

7. For this problem you will use the parallel propagator introduced in Appendix I to see how the Riemann tensor arises from parallel transport around an infinitesimal loop. Consider the following loop:



Using the infinite series expression for the parallel propagator, compute to lowest nontrivial order in δa and δb the transformation induced on a vector that is parallel transported around this loop from A to B to C to D and back to A, and show it is proportional to the appropriate components of the Riemann tensor. To make things easy, you can use x^1 and x^2 as parameters on the appropriate legs of the journey.

8. The metric for the three-sphere in coordinates $x^\mu = (\psi, \theta, \phi)$ can be written

$$ds^2 = d\psi^2 + \sin^2\psi\,(d\theta^2 + \sin^2\theta\, d\phi^2). \tag{3.220}$$

(a) Calculate the Christoffel connection coefficients. Use whatever method you like, but it is good practice to get the connection coefficients by varying the integral (3.49).
(b) Calculate the Riemann tensor, Ricci tensor, and Ricci scalar.
(c) Show that (3.191) is obeyed by this metric, confirming that the three-sphere is a maximally symmetric space (as you would expect).

9. Show that the Weyl tensor $C^{\mu}{}_{\nu\rho\sigma}$ is left invariant by a conformal transformation.

10. Show that, for $n \geq 4$, the Weyl tensor satisfies a version of the Bianchi identity,

$$\nabla_\rho C^{\rho}{}_{\sigma\mu\nu} = 2\frac{(n-3)}{(n-2)}\left(\nabla_{[\mu}R_{\nu]\sigma} + \frac{1}{2(n-1)}g_{\sigma[\mu}\nabla_{\nu]}R\right). \tag{3.221}$$

11. Since the Poincare half-plane with metric (3.192) is maximally symmetric, we might expect that it is rotationally symmetric around any point, although this certainly isn't evident in the $\{x, y\}$ coordinates. If that is so, it should be possible to put the metric in a form where the rotational symmetry is manifest, such as

$$ds^2 = f^2(r)[dr^2 + r^2 d\theta^2]. \tag{3.222}$$

To show that this works, calculate the curvature scalar for this metric and solve for the function $f(r)$ subject to the condition $R = -2/a^2$ everywhere. What is the range of the coordinate r?

12. Show that any Killing vector K^μ satisfies the relations mentioned in the text:

$$\begin{aligned} \nabla_\mu \nabla_\sigma K^\rho &= R^{\rho}{}_{\sigma\mu\nu}K^\nu \\ K^\lambda \nabla_\lambda R &= 0. \end{aligned} \tag{3.223}$$

13. Find explicit expressions for a complete set of Killing vector fields for the following spaces:
(a) Minkowski space, with metric $ds^2 = -dt^2 + dx^2 + dy^2 + dz^2$.
(b) A spacetime with coordinates $\{u, v, x, y\}$ and metric

$$ds^2 = -(du dv + dv du) + a^2(u)dx^2 + b^2(u)dy^2, \tag{3.224}$$

where a and b are unspecified functions of u. This represents a gravitational wave spacetime. (*Hints*, which you need not show: there are five Killing vectors in all, and all of them have a vanishing u component K^u.)

Be careful, in all of these cases, about the distinction between upper and lower indices.

14. Consider the three Killing vectors of the the two-sphere, (3.188). Show that their commutators satisfy the following algebra:

$$\begin{aligned} [R, S] &= T \\ [S, T] &= R \\ [T, R] &= S. \end{aligned} \tag{3.225}$$

15. Use Raychaudhuri's equation, discussed in Appendix F, to show that, if a fluid is flowing on geodesics through spacetime with zero shear and expansion, then spacetime must have a timelike Killing vector.

16. Consider again the metric on a three-sphere,

$$ds^2 = \mathrm{d}\psi^2 + \sin^2\psi\,(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2). \tag{3.226}$$

In this problem we make use of noncoordinate bases, discussed in Appendix J. In an orthonormal frame of one-forms $\hat{\theta}^{(a)}$ the metric would become

$$ds^2 = \hat{\theta}^{(1)} \otimes \hat{\theta}^{(1)} + \hat{\theta}^{(2)} \otimes \hat{\theta}^{(2)} + \hat{\theta}^{(3)} \otimes \hat{\theta}^{(3)}. \tag{3.227}$$

(a) Find such an orthonormal frame of one-forms, such that the matrix e_a^μ is diagonal. Don't worry about covering the entire manifold.

(b) Compute the components of the spin connection by solving $\mathrm{d}e^a + \omega^a{}_b \wedge e^b = 0$.

(c) Compute the components of the Riemann tensor $R^\rho{}_{\sigma\mu\nu}$ in the coordinate basis adapted to x^μ by computing the components of the curvature two-form $R^a{}_{b\mu\nu}$ and then converting.

-3 7 2 " 888

in empty space, Einstein-Cartan theory is indistinguishable from general relativity in experiments carried out in vacuum.

2.11 Connection coefficients in terms of the metric

The connection coefficients have been defined, equation (2.46), as derivatives of the tangent basis vectors $\boldsymbol{e}_\mu$. However, the connection coefficients can be expressed purely in terms of the (first derivatives of the) metric, without reference to the individual basis vectors. The partial derivatives of the metric are

$$\begin{aligned}
\frac{\partial g_{\lambda\mu}}{\partial x^\nu} &= \frac{\partial \boldsymbol{e}_\lambda \cdot \boldsymbol{e}_\mu}{\partial x^\nu} \\
&= \boldsymbol{e}_\lambda \cdot \frac{\partial \boldsymbol{e}_\mu}{\partial x^\nu} + \boldsymbol{e}_\mu \cdot \frac{\partial \boldsymbol{e}_\lambda}{\partial x^\nu} \\
&= \boldsymbol{e}_\lambda \cdot \boldsymbol{e}_\kappa \, \Gamma^\kappa_{\mu\nu} + \boldsymbol{e}_\mu \cdot \boldsymbol{e}_\kappa \, \Gamma^\kappa_{\lambda\nu} \\
&= g_{\lambda\kappa} \, \Gamma^\kappa_{\mu\nu} + g_{\mu\kappa} \, \Gamma^\kappa_{\lambda\nu} \\
&= \Gamma_{\lambda\mu\nu} + \Gamma_{\mu\lambda\nu} \ , \qquad (2.59)
\end{aligned}$$

which is a sum of two connection coefficients. Here $\Gamma_{\lambda\mu\nu}$ with all indices lowered is defined to be $\Gamma^\kappa_{\mu\nu}$ with the first index lowered by the metric,

$$\Gamma_{\lambda\mu\nu} \equiv g_{\lambda\kappa} \Gamma^\kappa_{\mu\nu} \ . \qquad (2.60)$$

Combining the metric derivatives in the following fashion yields an expression for a single connection,

$$\begin{aligned}
\frac{\partial g_{\lambda\mu}}{\partial x^\nu} + \frac{\partial g_{\lambda\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial x^\lambda} &= \Gamma_{\lambda\mu\nu} + \Gamma_{\mu\lambda\nu} + \Gamma_{\lambda\nu\mu} + \Gamma_{\nu\lambda\mu} - \Gamma_{\mu\nu\lambda} - \Gamma_{\nu\mu\lambda} \\
&= 2\,\Gamma_{\lambda\mu\nu} - S_{\lambda\mu\nu} - S_{\mu\nu\lambda} - S_{\nu\mu\lambda} \ , \qquad (2.61)
\end{aligned}$$

with $S_{\lambda\mu\nu} \equiv g_{\lambda\kappa} S^\kappa_{\mu\nu}$, which shows that, in the presence of torsion,

$$\Gamma_{\lambda\mu\nu} = \frac{1}{2} \left(\frac{\partial g_{\lambda\mu}}{\partial x^\nu} + \frac{\partial g_{\lambda\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial x^\lambda} + S_{\lambda\mu\nu} + S_{\mu\nu\lambda} + S_{\nu\mu\lambda} \right) \quad \textit{not} \text{ a coordinate tensor} \ . \qquad (2.62)$$

If torsion vanishes, as general relativity assumes, then

$$\boxed{\Gamma_{\lambda\mu\nu} = \frac{1}{2} \left(\frac{\partial g_{\lambda\mu}}{\partial x^\nu} + \frac{\partial g_{\lambda\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial x^\lambda} \right)} \quad \textit{not} \text{ a coordinate tensor} \ . \qquad (2.63)$$

This is the formula that allows connection coefficients to be calculated from the metric.

2.12 Torsion-free covariant derivative

Einstein's principle of equivalence postulates that a locally inertial frame exists at each point of spacetime, and this implies that torsion vanishes. However, torsion is of special interest as a generalization of general relativity because, as discussed in §2.19.2, the torsion tensor and the Riemann curvature tensor can be regarded as fields associated with local gauge groups of respectively displacements and Lorentz transformations. Together displacements and Lorentz transformations form the Poincaré group of symmetries of spacetime. Torsion arises naturally in extensions of general relativity such as supergravity (Nieuwenhuizen, 1981), which unify the Poincaré group by adjoining supersymmetry transformations.

The torsion-free part of the covariant derivative is a covariant derivative even when torsion is present (that is, it yields a tensor when acting on a tensor). The torsion-free covariant derivative is important, even when torsion is present, for several reasons. Firstly, as will be discovered from an action principle in Chapter 4, the covariant derivative that goes in the geodesic equation (2.88) is the torsion-free covariant derivative, equation (2.90). Secondly, the torsion-free covariant curl defines the exterior derivative in the theory of differential forms, §15.6. The exterior derivative has the property that it is inverse to integration over curved hypersurfaces. Integration is central to various aspects of general relativity, such as the development of Lagrangian and Hamiltonian mechanics. Thirdly, the Lie derivative, §7.34, is a covariant derivative defined in terms of torsion-free covariant derivatives. Finally, Yang-Mills gauge symmetries, such as the $U(1)$ gauge symmetry of electromagnetism, require the gauge field to be defined in terms of the torsion-free covariant derivative, in order to preserve the gauge symmetry.

When torsion is present and it is desirable to make the torsion part explicit, it is convenient to distinguish torsion-free quantities with a $^\circ$ overscript. The torsion-free part $\mathring{\Gamma}_{\lambda\mu\nu}$ of the connection, also called the **Levi-Civita connection**, is given by the right hand side of equation (2.63). When expressed in a coordinate frame (as opposed to a tetrad frame, §11.15), the components of the torsion-free connections $\mathring{\Gamma}_{\lambda\mu\nu}$ are also called **Christoffel symbols**. Sometimes, the components $\mathring{\Gamma}_{\lambda\mu\nu}$ with all indices lowered are called Christoffel symbols of the first kind, while components $\mathring{\Gamma}^{\lambda}_{\mu\nu}$ with first index raised are called Christoffel symbols of the second kind. There is no need to remember the jargon, but it is useful to know what it means if you meet it.

The torsion-full connection $\Gamma_{\lambda\mu\nu}$ is a sum of the torsion-free connection $\mathring{\Gamma}_{\lambda\mu\nu}$ and a tensor called the **contortion tensor** (not contorsion!) $K_{\lambda\mu\nu}$,

$$\Gamma_{\lambda\mu\nu} = \mathring{\Gamma}_{\lambda\mu\nu} + K_{\lambda\mu\nu} \quad \textit{not} \text{ a coordinate tensor} . \tag{2.64}$$

From equation (2.62), the contortion tensor $K_{\lambda\mu\nu}$ is related to the torsion tensor $S_{\lambda\mu\nu}$ by

$$K_{\lambda\mu\nu} = \tfrac{1}{2}\left(S_{\lambda\mu\nu} + S_{\mu\nu\lambda} + S_{\nu\mu\lambda}\right) = -\,S_{\nu\lambda\mu} + \tfrac{3}{2}S_{[\lambda\mu\nu]} \quad \text{a coordinate tensor} . \tag{2.65}$$

The contortion $K_{\lambda\mu\nu}$ is antisymmetric in its first two indices,

$$K_{\lambda\mu\nu} = -K_{\mu\lambda\nu} , \tag{2.66}$$

and thus like the torsion tensor $S_{\lambda\mu\nu}$ has $6 \times 4 = 24$ degrees of freedom. The torsion tensor $S_{\lambda\mu\nu}$ can be expressed in terms of the contortion tensor $K_{\lambda\mu\nu}$,

$$S_{\lambda\mu\nu} = K_{\lambda\mu\nu} - K_{\lambda\nu\mu} = -\,K_{\mu\nu\lambda} + 3\,K_{[\lambda\mu\nu]} \quad \text{a coordinate tensor} . \tag{2.67}$$

The torsion-full covariant derivative D_ν differs from the torsion-free covariant derivative $\mathring{D}_\nu$ by the contortion,

$$D_\nu A^\kappa \equiv \mathring{D}_\nu A^\kappa + K^{\kappa}_{\mu\nu} A^\mu \quad \text{a coordinate tensor} . \tag{2.68}$$

In this book torsion will not be assumed automatically to vanish, and thus by default the symbol D_ν will denote the torsion-full covariant derivative. When torsion is assumed to vanish, or when D_ν denotes the torsion-free covariant derivative, it will be explicitly stated so.

Concept question 2.5 Can the metric be Minkowski in the presence of torsion? In §2.10.1 it was argued that the postulate of the existence of locally inertial frames implies that torsion vanishes. The basis of the argument was the proposition that derivatives of the tangent axes vanish, equation (2.54b). Impose instead the weaker condition that the derivatives of the metric (i.e. scalar products of tangent axes) vanish,

$$\frac{\partial g_{\lambda\mu}}{\partial x^\nu} = 0 \ . \tag{2.69}$$

Can torsion be non-vanishing under this weaker condition? **Answer.** Yes. In fact torsion may exist even in flat (Minkowski) space, where the metric is everywhere Minkowski, $g_{\lambda\mu} = \eta_{\lambda\mu}$. The condition (2.69) of vanishing metric derivatives is equivalent to the vanishing of the torsion-free connections,

$$\frac{1}{2}\frac{\partial g_{\lambda\mu}}{\partial x^\nu} = \Gamma_{(\lambda\mu)\nu} = \mathring{\Gamma}_{(\lambda\mu)\nu} + K_{(\lambda\mu)\nu} = \mathring{\Gamma}_{(\lambda\mu)\nu} = 0 \ . \tag{2.70}$$

Thus the condition (2.69) of vanishing metric derivatives imposes no condition on torsion.

Exercise 2.6 Covariant curl and coordinate curl. Show that the covariant curl of a covariant vector A_λ is

$$D_\kappa A_\lambda - D_\lambda A_\kappa = \frac{\partial A_\lambda}{\partial x^\kappa} - \frac{\partial A_\kappa}{\partial x^\lambda} + S^\mu_{\kappa\lambda} A_\mu \ . \tag{2.71}$$

Conclude that the coordinate curl of a vector equals its torsion-free covariant curl,

$$\mathring{D}_\kappa A_\lambda - \mathring{D}_\lambda A_\kappa = \frac{\partial A_\lambda}{\partial x^\kappa} - \frac{\partial A_\kappa}{\partial x^\lambda} \ . \tag{2.72}$$

Of course, if torsion vanishes as general relativity assumes, then the covariant curl is the torsion-free covariant curl. Note that since both $D_\kappa A_\lambda - D_\lambda A_\kappa$ on the left hand side and $S^\mu_{\kappa\lambda} A_\mu$ on the right hand side of equation (2.71) are both tensors, it follows that the coordinate curl $\partial A_\lambda / \partial x^\kappa - \partial A_\kappa / \partial x^\lambda$ is a tensor even in the presence of torsion.

Exercise 2.7 Covariant divergence and coordinate divergence. Show that the covariant divergence of a contravariant vector A^μ is

$$D_\mu A^\mu = \frac{1}{\sqrt{-g}} \frac{\partial(\sqrt{-g} A^\mu)}{\partial x^\mu} + S^\nu_{\mu\nu} A^\mu \ , \tag{2.73}$$

where $g \equiv |g_{\mu\nu}|$ is the determinant of the metric matrix. Conclude that the torsion-free covariant divergence is

$$\mathring{D}_\mu A^\mu = \frac{1}{\sqrt{-g}} \frac{\partial(\sqrt{-g} A^\mu)}{\partial x^\mu} \ . \tag{2.74}$$

Of course, if torsion vanishes as general relativity assumes, then the covariant divergence is the torsion-free covariant divergence. Note that since both the covariant divergence on the left hand side of equation (2.73) and the torsion term on the right hand side of equation (2.73) are both tensors, the torsion-free covariant divergence (2.74) is a tensor even in the presence of torsion.

Solution. The covariant divergence is

$$D_\mu A^\mu = \frac{\partial A^\mu}{\partial x^\mu} + \Gamma^\nu_{\mu\nu} A^\mu \ . \tag{2.75}$$

From equation (2.62),

$$\begin{aligned} \Gamma^\nu_{\mu\nu} &= \frac{1}{2} g^{\lambda\nu} \frac{\partial g_{\lambda\nu}}{\partial x^\mu} + S^\nu_{\mu\nu} \\ &= \frac{\partial \ln |\sqrt{-g}|}{\partial x^\mu} + S^\nu_{\mu\nu} \ . \end{aligned} \tag{2.76}$$

The second line of equations (2.76) follows because for any matrix M,

$$\begin{aligned} \delta \ln |M| &= \ln |M + \delta M| - \ln |M| \\ &= \ln |M^{-1}(M + \delta M)| \\ &= \ln |1 + M^{-1} \delta M| \\ &= \ln (1 + \mathrm{Tr}\ M^{-1} \delta M) \\ &= \mathrm{Tr}\ M^{-1} \delta M \ . \end{aligned} \tag{2.77}$$

The torsion-free covariant divergence is

$$\mathring{D}_\mu A^\mu = \frac{\partial A^\mu}{\partial x^\mu} + \mathring{\Gamma}^\nu_{\mu\nu} A^\mu \ , \tag{2.78}$$

where the torsion-free coordinate connection is

$$\mathring{\Gamma}^\nu_{\mu\nu} = \frac{1}{2} g^{\lambda\nu} \frac{\partial g_{\lambda\nu}}{\partial x^\mu} = \frac{\partial \ln |\sqrt{-g}|}{\partial x^\mu} \ . \tag{2.79}$$

Concept question 2.8 If torsion does not vanish, does torsion-free covariant differentiation commute with the metric? Answer. Yes. Unlike the torsion-full covariant derivative, Concept Question 2.3, the torsion-free covariant derivative of the tangent basis vectors $\boldsymbol{e}_\kappa$ does *not* vanish, but rather depends on the contortion $K^\nu_{\kappa\mu} \boldsymbol{e}_\nu$,

$$\mathring{D}_\mu \boldsymbol{e}_\kappa = D_\mu \boldsymbol{e}_\kappa + K^\nu_{\kappa\mu} \boldsymbol{e}_\nu = K^\nu_{\kappa\mu} \boldsymbol{e}_\nu \ . \tag{2.80}$$

However, the torsion-free covariant derivative of the metric, that is, of scalar products of the tangent basis vectors, does vanish,

$$\mathring{D}_\mu g_{\kappa\lambda} = \mathring{D}_\mu (\boldsymbol{e}_\kappa \cdot \boldsymbol{e}_\lambda) = K^\nu_{\kappa\mu} \boldsymbol{e}_\nu \cdot \boldsymbol{e}_\lambda + K^\nu_{\lambda\mu} \boldsymbol{e}_\kappa \cdot \boldsymbol{e}_\nu = K_{\lambda\kappa\mu} + K_{\kappa\lambda\mu} = 0 \ , \tag{2.81}$$

thanks to the antisymmetry of the contortion tensor in its first two indices. As a corollary, torsion-free covariant differentiation commutes with the operations of raising and lowering indices, and of contraction.

2.13 Mathematical aside: What if there is no metric?

General relativity is a metric theory. Many of the structures introduced above can be defined mathematically without a metric. For example, it is possible to define the tangent space of vectors with basis $\boldsymbol{e}_\mu$, and to define a dual vector space with basis $\boldsymbol{e}^\mu$ such that $\boldsymbol{e}^\mu \cdot \boldsymbol{e}_\nu = \delta^\mu_\nu$, equation (2.36). Elements of the dual vector space are called covectors. Similarly it is possible to define connections and covariant derivatives without a metric. However, this book follows general relativity in assuming that spacetime has a metric.

2.14 Coordinate 4-velocity

Consider a particle following a worldline

$$x^\mu(\tau) \ , \tag{2.82}$$

where τ is the particle's proper time. The proper time along any interval of the worldline is $d\tau \equiv \sqrt{-ds^2}$.

Define the **coordinate 4-velocity** u^μ by

$$\boxed{u^\mu \equiv \frac{dx^\mu}{d\tau}} \quad \text{a coordinate 4-vector} \ . \tag{2.83}$$

The magnitude squared of the 4-velocity is constant

$$u_\mu u^\mu = g_{\mu\nu} \frac{dx^\mu}{d\tau} \frac{dx^\nu}{d\tau} = \frac{ds^2}{d\tau^2} = -1 \ . \tag{2.84}$$

The negative sign arises from the choice of metric signature: with the signature $-{+}{+}{+}$ adopted here, there is a $-$ sign between ds^2 and $d\tau^2$. Equation (2.84) can be regarded as an integral of motion associated with conservation of particle rest mass.

2.15 Geodesic equation

Let $\boldsymbol{u} \equiv \boldsymbol{e}_\mu u^\mu$ be the 4-velocity in coordinate-independent notation. The principle of equivalence (which imposes vanishing torsion) implies that the **geodesic equation**, the equation of motion of a freely-falling particle, is

$$\boxed{\frac{d\boldsymbol{u}}{d\tau} = 0} \ . \tag{2.85}$$

Why? Because $d\boldsymbol{u}/d\tau = 0$ in the particle's own free-fall frame, and the equation is coordinate-independent. In the particle's own free-fall frame, the particle's 4-velocity is $u^\mu = \{1, 0, 0, 0\}$, and the particle's locally inertial axes $\boldsymbol{e}_\mu = \{\boldsymbol{e}_0, \boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3\}$ are constant.

' & $

Exercise 11.6 Symmetry of the Riemann tensor. Show that the cyclic symmetry (11.63) implies the symmetry $kl \leftrightarrow mn$, given the antisymmetries $k \leftrightarrow l$ and $m \leftrightarrow n$. Given Exercise 11.5, this shows that the symmetry $kl \leftrightarrow mn$ is, like the cyclic symmetry, a consequence of vanishing torsion.
Solution. Show that

$$2(R_{klmn} - R_{mnkl}) = 3\left(R_{k[lmn]} - R_{l[kmn]} - R_{m[nkl]} + R_{n[mkl]}\right) \ , \tag{11.71}$$

or alternatively,

$$2(R_{klmn} - R_{mnkl}) = 3\left(R_{[klm]n} - R_{[kln]m} - R_{[mnk]l} + R_{[mnl]k}\right) \ . \tag{11.72}$$

Exercise 11.7 Number of components of the Riemann tensor. How many independent components does the Riemann tensor have, in 4-dimensional spacetime?
Solution. If torsion vanishes, 20. If torsion does not vanish, 36. The extra 16 components come from $R_{[klm]n}$, which is related to torsion by equation (11.69), and which has $4 \times 4 = 16$ components if torsion does not vanish.

Concept question 11.8 Must connections vanish if Riemann vanishes? Must the tetrad connections Γ_{lmn} vanish if the Riemann tensor vanishes identically, $R_{klmn} = 0$? **Answer.** No. For a counterexample, take flat (Minkowski) space expressed in spherical polar coordinates $\{t, r, \theta, \phi\}$. The non-vanishing tetrad-frame connections are $\Gamma_{212} = \Gamma_{313} = 1/r$ and $\Gamma_{323} = \cot\theta/r$ (compare equations (20.21)).

11.16.1 Riemann tensor in a mixed coordinate-tetrad frame

In Chapter 16, Einstein's equations will be obtained from an action principle, as first done by Hilbert (1915). The Hilbert Lagrangian takes a particularly insightful form if the Riemann tensor is expressed in a mixed coordinate-tetrad basis.

The coordinate-frame covariant derivative D_κ of a tetrad-frame vector a_n is

$$D_\kappa a_n = e^k{}_\kappa D_k a_n = \frac{\partial a_n}{\partial x^\kappa} - \Gamma^m_{n\kappa} a_m \quad \text{a coordinate-tetrad tensor} \ , \tag{11.73}$$

where $\Gamma^m_{n\kappa}$ is the tetrad-frame connection with its last index converted into the coordinate frame with the vierbein,

$$\Gamma^m_{n\kappa} \equiv e^k{}_\kappa \Gamma^m_{nk} \quad \text{a coordinate vector, but } \textit{not} \text{ a tetrad tensor} \ . \tag{11.74}$$

As usual, the connection with all indices lowered is defined by $\Gamma_{ln\kappa} \equiv \gamma_{lm}\Gamma^m_{n\kappa}$. The connections $\Gamma_{mn\kappa}$ should not be confused with the coordinate-frame connections (Christoffel symbols) $\Gamma_{\mu\nu\kappa}$. The relation between the two is, from equation (11.44),

$$\Gamma_{mn\kappa} = -\, e^k{}_\kappa \, d_{mnk} + e_m{}^\mu e_n{}^\nu \, \Gamma_{\mu\nu\kappa} \ . \tag{11.75}$$

In 4 dimensions there are $6 \times 4 = 24$ distinct connections $\Gamma_{mn\kappa}$ (with or without torsion), whereas there are $4 \times 10 = 40$ distinct coordinate-frame connections $\Gamma_{\mu\nu\kappa}$ (without torsion, or $4 \times 4 \times 4 = 64$ with torsion).

The last term on the right hand side of equation (11.60) for the Riemann tensor can be written, in view of equations (11.49) and (11.32),

$$(\Gamma^p_{kl} - \Gamma^p_{lk} - S^p_{kl})\Gamma_{mnp} = (\partial_l e_k{}^\kappa - \partial_k e_l{}^\kappa)\Gamma_{mn\kappa} \ . \tag{11.76}$$

The Riemann tensor $R_{\kappa\lambda mn}$ in the mixed coordinate-tetrad basis is then

$$\boxed{R_{\kappa\lambda mn} = \frac{\partial \Gamma_{mn\lambda}}{\partial x^\kappa} - \frac{\partial \Gamma_{mn\kappa}}{\partial x^\lambda} + \Gamma^p_{m\lambda}\Gamma_{pn\kappa} - \Gamma^p_{m\kappa}\Gamma_{pn\lambda}} \quad \text{a coordinate-tetrad tensor} \ , \tag{11.77}$$

which is valid with or without torsion. Equation (11.77) resembles superficially the coordinate-frame expression (2.112) for the Riemann tensor, but it is more economical in that there are only 24 connections $\Gamma_{mn\kappa}$ instead of the 40 (or 64, with torsion) coordinate-frame connections $\Gamma_{\mu\nu\kappa}$.

The torsion $S^m_{\kappa\lambda}$ in the mixed coordinate-tetrad basis is

$$\boxed{S^m_{\kappa\lambda} = -\frac{\partial e^m{}_\lambda}{\partial x^\kappa} + \frac{\partial e^m{}_\kappa}{\partial x^\lambda} - \Gamma^m_{l\kappa} e^l{}_\lambda + \Gamma^m_{k\lambda} e^k{}_\kappa} \quad \text{a coordinate-tetrad tensor} \ . \tag{11.78}$$

Equations (11.77) and (11.78) constitute Cartan's equations of structure (Cartan, 1904) (see §16.14.2).

11.17 Ricci, Einstein, Bianchi

The usual suite of formulae leading to Einstein's equations apply. Since all the quantities are tensors, and all the equations are tensor equations, their form follows immediately from their coordinate counterparts.

Ricci tensor:

$$\boxed{R_{km} \equiv \gamma^{ln} R_{klmn}} \ . \tag{11.79}$$

Ricci scalar:

$$\boxed{R \equiv \gamma^{km} R_{km}} \ . \tag{11.80}$$

Einstein tensor:

$$\boxed{G_{km} \equiv R_{km} - \tfrac{1}{2}\gamma_{km} R} \ . \tag{11.81}$$

Einstein's equations:

$$\boxed{G_{km} = 8\pi G T_{km}} \ . \tag{11.82}$$

The trace of the Einstein equations implies that $R = -8\pi G T$, so the Einstein equations (11.82) can equally well be written with the trace terms transferred from the left to the right hand side,

$$R_{km} = 8\pi G \left(T_{km} - \tfrac{1}{2}\gamma_{km} T\right) \ . \tag{11.83}$$

Bianchi identities in the absence of torsion:

$$\boxed{D_k R_{lmnp} + D_l R_{mknp} + D_m R_{klnp} = 0} \ , \tag{11.84}$$

which most importantly imply covariant conservation of the Einstein tensor, hence conservation of energy-momentum

$$\boxed{D^k T_{km} = 0} \ . \tag{11.85}$$

11.18 Expressions with torsion

If torsion does not vanish, then the Riemann tensor, and consequently also the Ricci and Einstein tensors, can be split into torsion-free (distinguished by a $^\circ$ overscript) and torsion parts (e.g. Hehl, Heyde, and Kerlick 1976). A similar split occurs in the ADM formalism where a certain gauge choice (fixing the time component $\boldsymbol{\gamma}_0$ of the tetrad to be orthogonal to hypersurfaces of constant time) splits the tetrad connection into a tensor part, the extrinsic curvature, and a remainder, equation (17.27).

The contortion tensor K_{lmn} was defined previously as the torsion part of the connection Γ_{lmn}, equation (11.55). The unique non-vanishing contraction of the contortion tensor defines the contortion vector K_m,

$$K_m \equiv K^n_{mn} = S^n_{mn} \ . \tag{11.86}$$

The torsion-full Riemann tensor R_{klmn} is a sum of the torsion-free Riemann tensor $\mathring{R}_{klmn}$ and a torsion part (note that $K_{pkl} - K_{plk} - S_{pkl} = 0$, so the "extra" term in R_{klmn}, equation (11.60), vanishes when K_{pkl} is the contortion),

$$R_{klmn} = \mathring{R}_{klmn} + \mathring{D}_k K_{mnl} - \mathring{D}_l K_{mnk} + K^p_{ml} K_{pnk} - K^p_{mk} K_{pnl} \ . \tag{11.87}$$

The Ricci tensor is

$$R_{km} = \mathring{R}_{km} - \mathring{D}_k K_m - \mathring{D}^n K_{mnk} + K_{mpn} K^{np}{}_k - K_{mpk} K^p \ , \tag{11.88}$$

and the Ricci scalar is

$$R = \mathring{R} - 2\mathring{D}_n K^n + K_{mpn} K^{npm} - K_n K^n \ . \tag{11.89}$$

The antisymmetric part of the Einstein tensor is, from contracting equation (11.69),

$$G_{[km]} = \tfrac{3}{2} R_{[klm]}{}^l = \tfrac{3}{2} \left(D_{[k} S^l_{lm]} + S^p_{[kl} S^l_{m]p} \right) \ , \tag{11.90}$$

which vanishes for vanishing torsion.

The Jacobi identity (2.126) implies, in addition to the 16 conditions (11.69), the 24 Bianchi identities

$$D_{[k} R_{lm]np} + S^q_{[kl} R_{m]qnp} = 0 \ . \tag{11.91}$$

The doubly-contracted Bianchi identities are

$$-\tfrac{3}{2}\gamma^{kn}\gamma^{lp} \left(D_{[k} R_{lm]np} + S^q_{[kl} R_{m]qnp} \right) = D^k G_{mk} - \tfrac{1}{2} S^q_{kl} R_{mq}{}^{kl} - S^q_{km} R_q{}^k = 0 \ . \tag{11.92}$$

11.19 General relativity in 2 spacetime dimensions

General relativity in 2 spacetime dimensions is weird. There are zero Bianchi identities (2.128) in 2 spacetime dimensions, so the Bianchi identities do not identify any covariantly conserved tensor. The Einstein tensor itself vanishes identically in 2 spacetime dimensions.

There are consistent extensions of general relativity in 2 spacetime dimensions, such as string-inspired dilaton gravity (Grumiller, Kummer, and Vassilevich, 2002). However, those will not be considered here.

Historically, the main application of 2-dimensional relativity has been to explore quantum field theory in curved spacetime, since in 2 spacetime dimensions the quantum energy-momentum tensor induced by any prescribed geometry can be calculated exactly (even though the classical energy-momentum tensor is indeterminate).

The closest thing to a consistent realization of classical general relativity in 2 spacetime dimensions is as follows.

In 2 spacetime dimensions, the Riemann tensor has just one distinct component, R_{0101}, and that component is determined entirely by the Ricci scalar R. The tetrad-frame Riemann and Ricci tensors are related to the Ricci scalar R by

$$R_{klmn} = \tfrac{1}{2} \left(\gamma_{km} \gamma_{ln} - \gamma_{kn} \gamma_{lm} \right) R \ , \quad R_{km} = \tfrac{1}{2} \gamma_{km} R \ . \tag{11.93}$$

In an arbitrary number of N spacetime dimensions, contracting the Einstein equations implies that the Ricci scalar R is proportional to the trace T of the energy-momentum tensor,

$$(1 - \tfrac{1}{2} N) R = \kappa_N T \ , \tag{11.94}$$

where κ_N is Newton's gravitational constant in N spacetime dimensions, suitably normalized. For $N = 2$, the factor on the left of equation (11.94) vanishes; but one can imagine absorbing the zero factor into a redefinition of the gravitational constant κ_N, so that

$$R = \kappa_2' T \tag{11.95}$$

for some κ_2'. Now impose that the energy-momentum tensor T_{km} is covariantly conserved,

$$D^k T_{km} = 0 \ . \tag{11.96}$$

In $N = 2$ spacetime dimensions, the trace relation (11.95) together with the covariant conservation condition (11.96) imply almost uniquely the form of the energy-momentum tensor.

The conserved energy-momentum tensor T_{km} takes its simplest expression when the metric is expressed in conformally flat form. The metric in $N = 2$ spacetime dimensions is a symmetric 2×2 matrix. By a suitable coordinate transformation of the 2 coordinates, the metric can be brought to the conformally flat form

$$ds^2 = e^{2\xi} (- dt^2 + dx^2) = - e^{2\xi} dv du \ , \tag{11.97}$$

where $v \equiv t + x$ and $u \equiv t - x$ are null coordinates, and ξ is a function of the two coordinates. The

Newman-Penrose tetrad-frame components of the conserved energy-momentum tensor T_{km} are then

$$-\frac{R}{2} = -4e^{-2\xi}\frac{\partial^2\xi}{\partial v\partial u} = -\kappa_2'\frac{T}{2} = \kappa_2' T_{vu} \ , \tag{11.98a}$$

$$4e^{-2\xi}\left[\frac{\partial^2\xi}{\partial v^2} - \left(\frac{\partial\xi}{\partial v}\right)^2 + f^+(v)\right] = \kappa_2' T_{vv} \ , \tag{11.98b}$$

$$4e^{-2\xi}\left[\frac{\partial^2\xi}{\partial u^2} - \left(\frac{\partial\xi}{\partial u}\right)^2 + f^-(u)\right] = \kappa_2' T_{uu} \ , \tag{11.98c}$$

where $f^+(v)$ and $f^-(u)$ are arbitrary functions of respectively v and u. There is a residual gauge freedom $v \to V(v)$ and $u \to U(u)$ in the choice of null coordinates that allows the conformal function to be adjusted $\xi \to \xi + \xi^+(v) + \xi^-(u)$ by arbitrary additive functions of v and u. This residual gauge freedom allows the functions $f^+(v)$ and $f^-(u)$ in equations (11.98b) and (11.98c) to be adjusted arbitrarily. If desired, $f^+(v)$ and $f^-(u)$ can be set to zero.

The classical 2-dimensional general relativity described by equations (11.98) is not very interesting; for example there is no 2-dimensional analogue of the Schwarzschild black hole, Exercise 11.9.

Where equations (11.98) prove more interesting is that they also describe the expectation value $\langle T_{kl}\rangle$ of the renormalized quantum energy-momentum induced by a given geometry in 2 spacetime dimensions (Birrell and Davies, 1982). That is, the expectation value $\langle T\rangle$ of the quantum trace in 2 spacetime dimensions is proportional to the Ricci scalar (Birrell and Davies, 1982, eq. (6.121)), and the quantum energy-momentum tensor $\langle T_{kl}\rangle$ is covariantly conserved, therefore equations (11.98) are satisfied by $\langle T_{kl}\rangle$. In 4 spacetime dimensions the quantum energy-momentum tensor $\langle T_{kl}\rangle$ is extremely difficult to calculate in a general spacetime, so clues from 2 spacetime dimensions can be illuminating.

Exercise 11.9 Black holes in 2 spacetime dimensions? Does the analogue of a Schwarzschild black hole exist in 2 spacetime dimensions?

Solution. No. Require the spacetime to be empty outside some radius. The vanishing of the Ricci scalar (11.98a) implies that

$$\xi = \xi^+(v) + \xi^-(u) \tag{11.99}$$

for some functions ξ^+ and ξ^- of the null coordinates v and u. But then the coordinate tranformations of the null coordinates

$$dV = e^{2\xi^+(v)}dv \ , \quad dU = e^{2\xi^-(u)}du \tag{11.100}$$

bring the line element to

$$ds^2 = -dV dU \ , \tag{11.101}$$

which is just flat (Minkowski) space in $N = 2$ dimensions.

Exercise 11.10 Tidal forces falling into a Schwarzschild black hole. In the Schwarzschild or that the energy-momentum tensor is symmetric, equation (16.279). This motivates the ADM strategy of simply discarding the 6 antisymmetric components of the Einstein equations. These 6 components comprise the 3 antisymmetric components of the 9 equations of motion (16.331b), corresponding to the 3 antisymmetric space-space Einstein equations, and the 3 equations of motion (16.332), corresponding to the 3 antisymmetric time-space Einstein equations. Discarding the antisymmetric Einstein's equations seems innocent enough, until one realises that the antisymmetry of the energy-momentum is a consequence of the law of conservation of spin angular-momentum, equation (16.278), which law is responsible for the Gaussian constraints (16.334b) and (16.334c). Thus discarding the 6 antisymmetric Einstein equations is equivalent to using up the 6 Gaussian constraints. As a corollary, the 6 Gaussian constraints can no longer be treated as constraints; rather, they must be treated as identities. This should raise a red flag: it may not be a good numerical strategy to trade hyperbolic equations of motion for elliptic identities.

Finally, the usual ADM strategy (though not a necessary one — see Chapter 17), is to work entirely with coordinate-frame quantities. An advantage of this approach is that all quantities are spatially Lorentz gauge-invariant (the ADM gauge choice (16.325) removes the gauge freedom of Lorentz boosts). In particular, the 9 spatial vierbein $e_{a\alpha}$ reduce to the 6 components of the Lorentz gauge-invariant spatial metric $g_{\alpha\beta}$, and the 24 Lorentz connections are replaced by the 6 components of the symmetric (for vanishing torsion) extrinsic curvatures $\Gamma_{\alpha 0\beta}$ together with the $3 \times 6 = 18$ torsion-free coordinate-frame spatial connections (Christoffel symbols) $\Gamma_{\alpha\beta\gamma}$. In summary, in the ADM formalism there are $6 + 6 = 12$ equations of motion for $g_{\alpha\beta}$ and $\Gamma_{\alpha 0\beta}$, 18 identities for $\Gamma_{\alpha\beta\gamma}$, and 4 Hamiltonian constraints.

16.15.7 BSSN formalism

The BSSN formalism, discussed further in Chapter 17, §17.7, has gained popularity because it proves to have better numerical stability when applied to problems such as the merger of two black holes (Shibata and Nakamura, 1995; Baumgarte and Shapiro, 1998; Shinkai, 2009; Baumgarte and Shapiro, 2010; Brown et al., 2012).

The BSSN formalism follows ADM for the most part, in particular imposing the ADM gauge choice (16.325). However, BSSN retains the 3 momentum Einstein equations (16.332) as equations of motion, and restores the 3 Gaussian constraints (16.334c). Like the Hamiltonian constraints, the Gaussian constraints must be arranged to be satisfied in the initial conditions, but may be discarded thereafter.

16.15.8 An alternative strategy for solving the gravitational equations numerically

A drawback of the ADM and BSSN approaches is that expending 3 of the Lorentz gauge conditions on the vierbein, equation (16.325), preempts being able to use those Lorentz gauge conditions in potentially advantageous ways on the Lorentz connections, as is done for example in proofs of singularity theorems (conditions (18.26), for example). Moreover, as discussed in §16.15.6, transferring Lorentz gauge conditions from the Lorentz connections to the vierbein has the side-effect of replacing "nice" hyperbolic equations of motion with "nasty" elliptic identities.

This suggests that better numerical behaviour could result from using the Hamiltonian system gravitational equations in the native form derived in §16.15.3, where they consist of $12 + 12$ equations of motion, $6 + 4$ constraints, and 6 identities, equations (16.317) and (16.318) (as opposed to the $6 + 6$ equations of motion, 4 constraints, and 18 identities of the ADM formalism). As remarked previously, the system of gravitational equations derived in §16.15.3 resembles the Hamiltonian system of electromagnetic equations, which consist of $3 + 3$ equations of motion, 1 constraint, and 3 identities, equations (16.76) and (16.77).

Consider briefly the problem of solving the system of gravitational equations (16.317) and (16.318) numerically. First, all 40 equations must be arranged to be satisfied on an initial hypersurface of constant time. Subsequently, the 10 constraint equations may be discarded (or kept as a check of numerical accuracy). In integrating the remaining system of 30 equations from one hypersurface of constant time to the next, the first step is to use the $12 + 12$ equations of motion to find the 12 gravitational coordinates $\boldsymbol{e}$ and their 12 conjugate momenta $\boldsymbol{\pi}$ on the next (upper) hypersurface. As in ADM, coordinate gauge freedom allows the time components $\boldsymbol{e}_{\bar{t}}$ of the vierbein (the lapse and shift) to be chosen arbitrarily. The 12 components of $\boldsymbol{e}$ and the 4 components of $\boldsymbol{e}_{\bar{t}}$ account for all 16 components of the vierbein. Lorentz gauge freedom allows the time components $\boldsymbol{\Gamma}_{\bar{t}}$ of the Lorentz connection to be chosen arbitrarily. The 12 components of $\boldsymbol{\pi}$ and the 6 components of $\boldsymbol{\Gamma}_{\bar{t}}$ account for 18 of the 24 degrees of freedom of the Lorentz connection. The remaining 6 degrees of freedom of the Lorentz connection are determined by the 6 identities.

The 6 identities are packaged together with the 6 Gaussian constraints in the 12 equations (16.321a). Now the 12 equations (16.321a) comprise an expression for the 12 components of the spatial vector 2-form $\frac{1}{2}[\boldsymbol{\Gamma}, \boldsymbol{e}]$ in terms of spatial exterior derivatives $\mathrm{d}\boldsymbol{e}$ of the spatial vierbein and the spin angular-momentum (the latter vanishing if torsion is assumed to vanish). Since $\boldsymbol{e}$ over the upper spatial hypersurface of constant time is already in hand from integrating the equations of motion, taking the spatial exterior derivative $\mathrm{d}\boldsymbol{e}$ is a matter of differentiating numerically over the spatial hypersurface. The 12 components of $\frac{1}{2}[\boldsymbol{\Gamma}, \boldsymbol{e}]$ are

$$\tfrac{1}{2}[\boldsymbol{\Gamma}, \boldsymbol{e}] = \boldsymbol{\Gamma} \cdot \boldsymbol{e} = -2\, \Gamma_{k[\alpha\beta]}\, \boldsymbol{\gamma}^k\, d^2 x^{\alpha\beta} \ . \tag{16.336}$$

The Gaussian constraints involve the 6 components of $\frac{1}{2}[\boldsymbol{\Gamma}, \boldsymbol{e}]$ comprising

$$\boldsymbol{e} \wedge \tfrac{1}{2}[\boldsymbol{\Gamma}, \boldsymbol{e}] = -12\, e_{k\alpha}\, \Gamma_{l[\beta\gamma]}\, \boldsymbol{\gamma}^k \wedge \boldsymbol{\gamma}^l\, d^3 x^{\alpha\beta\gamma} \ , \tag{16.337}$$

summed over distinct antisymmetric sequences of indices kl and $\alpha\beta\gamma$. The components of equation (16.337) may be regarded as a 6×12 matrix acting on a 12-component vector consisting of the $\Gamma_{k[\alpha\beta]}$. The null space of the 6×12 matrix is another 6×12 matrix which, when acting on the 12-component vector $\Gamma_{k[\alpha\beta]}$, gives the 6 linear combinations of $\frac{1}{2}[\boldsymbol{\Gamma}, \boldsymbol{e}]$ whose values are determined by the 6 identities distinct from the 6 Gaussian constraints. Actually, it is not essential to choose the 6 identities to lie in the 6-dimensional null space; it suffices that the 6 identities span the null space. That is, the 6 identities and 6 Gaussian constraints should together span the full 12-dimensional space of $\frac{1}{2}[\boldsymbol{\Gamma}, \boldsymbol{e}]$. Equivalently, no linear combination of the 6 identities should be a constraint.

En los ejercicios 16–20 determine el círculo osculador de la curva dada en el (los) punto(s) indicado(s).

16. $y = x^2$, en el origen de coordenadas.

17. $y = \cos x$, en el punto $(0, 1)$.

18. $y = x^3$, en el punto $(1, 1)$ y en el punto $(-1, -1)$.

19. $y = \dfrac{1}{1+x^2}$, en el punto $(0, 1)$.

20. $y = e^{-x^2}$, en el punto $(0, 1)$. (Compare con los resultados de los ejercicios 16 y 19).

21. Sea $F\colon U \subseteq \mathbb{R}^2 \to \mathbb{R}$ una función de clase $\mathscr{C}^2$ tal que grad $F(x, y) \neq 0$ $\forall (x, y) \in U$. Si $c \in \mathbb{R}$ pertenece al rango de F, la expresión $F(x, y) = c$ define una curva en el plano cuya curvatura en un punto (x, y) de ella (demuestre que) es igual a

$$k = \frac{-\left(\dfrac{\partial F}{\partial y}\right)^2 \dfrac{\partial^2 F}{\partial x^2} + 2\dfrac{\partial F}{\partial x}\dfrac{\partial F}{\partial y}\dfrac{\partial^2 F}{\partial x \partial y} - \left(\dfrac{\partial F}{\partial x}\right)^2 \dfrac{\partial^2 F}{\partial y^2}}{\|\operatorname{grad} F\|^3}$$

22. Se llama *evoluta* de una curva $\mathbf{f}\colon I \subseteq \mathbb{R} \to \mathbb{R}^2$ a la curva que describen los centros de curvatura de $\mathbf{f}$.

a. Determine la evoluta de la curva $\mathbf{f}\colon \mathbb{R} \to \mathbb{R}^2$, $\mathbf{f}(t) = (t, t^2)$.

b. Determine la evoluta de la curva $\mathbf{f}\colon \mathbb{R} \to \mathbb{R}^2$, $\mathbf{f}(t) = (t, t^3)$.

(*) 5.8 Curvas paralelas

El contenido de esta sección es (con algunas modificaciones de estilo) un artículo escrito independientemente del libro (referencia [PiIII]), y motivado por una pregunta "inocente" de un estudiante de ingeniería, cuya respuesta resultó ser bastante poco inocente (este es el tipo de preguntas interesantes en matemáticas: de contenido profundo y de formulación sencilla). La pregunta fue: "¿es la curva paralela a una parábola también una parábola?". Más bien, supongamos que en cada punto de la parábola $y = x^2$ nos alejamos de ella sobre la recta normal una distancia r constante. Formamos así una nueva curva "paralela" a $y = x^2$. La figura que queda tiene al menos todo el aspecto de una nueva parábola. ¿Esta nueva curva es efectivamente una parábola? Al intentar contestar esta pregunta surgieron una gran cantidad de ideas interesantes que culminaron en lo que ahora se presenta en esta sección. La parte de la matemática que más intervino en la respuesta es la que hemos desarrollado en el presente capítulo (geometría diferencial de curvas en el plano).

En realidad, el problema que abordaremos es más ambicioso que el planteado inicialmente. Estudiaremos curvas que tienen la propiedad de mantenerse a una distancia constante de una curva dada (medida sobre la normal de esta curva en cada punto), llamadas "curvas paralelas" (a la curva dada). Exploraremos las relaciones que existen entre algunas propiedades (como la regularidad) y aspectos geométricos (como curvatura, longitud de la curva y área encerrada) de la curva dada y las correspondientes de sus curvas paralelas. Se presentan —a manera de ejemplos ilustrativos—, los estudios correspondientes a las curvas paralelas a elipses y a parábolas.

Las curvas que aparecen en esta sección se suponen infinitamente derivables (de clase $\mathscr{C}^\infty$), de modo que "curva regular" significa una curva de clase $\mathscr{C}^\infty$ cuyo vector velocidad nunca es nulo.

Consideremos la curva regular $\boldsymbol{\alpha}: I \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (x(t), y(t))$. Sea $\mathbf{n}(t)$ el vector normal unitario obtenido al girar $\boldsymbol{\alpha}'(t)$ (normalizado) un ángulo de $\pi/2$ en dirección antihoraria. Sea $\boldsymbol{\beta}: I \to \mathbb{R}^2$ la curva definida como $\boldsymbol{\beta}(t) = \boldsymbol{\alpha}(t) + r\mathbf{n}(t)$, donde r es un número real no nulo dado. Obsérvese que para cada $t \in I$ se tiene que $\|\boldsymbol{\beta}(t) - \boldsymbol{\alpha}(t)\| = |r|$, es decir $\boldsymbol{\beta}$, es una curva que se mantiene a una distancia constante —igual a $|r|$— de $\boldsymbol{\alpha}$. LLamaremos a $\boldsymbol{\beta}$ "la curva r-paralela a $\boldsymbol{\alpha}$". Se entiende que r puede ser positivo o negativo, (por razones obvias se descarta el caso $r = 0$).

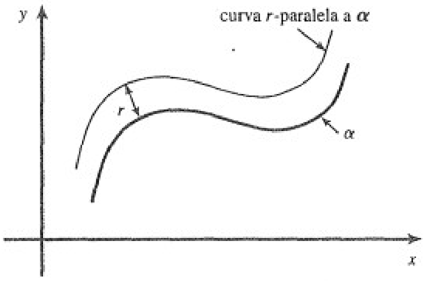

Figura 1. Curva paralela a $\boldsymbol{\alpha}$.

Comencemos por hacer explícitas las funciones coordenadas de la curva $\boldsymbol{\beta}$. Como $\boldsymbol{\alpha}'(t) = (x'(t), y'(t))$, se tiene que el vector $\mathbf{n}(t)$ es

$$\mathbf{n}(t) = \frac{1}{\|\boldsymbol{\alpha}'(t)\|}(-y'(t), x'(t))$$

de modo que

$$\boldsymbol{\beta}(t) = \boldsymbol{\alpha}(t) + r\mathbf{n}(t) = \left(x(t) - \frac{ry'(t)}{\|\boldsymbol{\alpha}'(t)\|}, y(t) + \frac{rx'(t)}{\|\boldsymbol{\alpha}'(t)\|}\right) \tag{1}$$

Obtengamos una expresión para el vector velocidad $\boldsymbol{\beta}'(t)$. Se tiene, derivando, (haciendo uso de que $(\|\boldsymbol{\rho}(t)\|)' = (\boldsymbol{\rho}(t) \cdot \boldsymbol{\rho}'(t))/\|\boldsymbol{\rho}(t)\|$ en donde $'$ denota derivación respecto de t de la norma del vector $\boldsymbol{\rho}(t)$) lo siguiente

$$\begin{aligned}\boldsymbol{\beta}'(t) = \Bigg(&\|x'(t)\| - r\frac{\|\boldsymbol{\alpha}'(t)\|y''(t) - y'(t)(\boldsymbol{\alpha}'(t) \cdot \boldsymbol{\alpha}''(t))/\|\boldsymbol{\alpha}'(t)\|}{\|\boldsymbol{\alpha}'(t)\|^2}, \\ &y'(t) + r\frac{\|\boldsymbol{\alpha}'(t)\|x''(t) - x'(t)(\boldsymbol{\alpha}'(t) \cdot \boldsymbol{\alpha}''(t))/\|\boldsymbol{\alpha}'(t)\|}{\|\boldsymbol{\alpha}'(t)\|^2}\Bigg)\end{aligned}$$

Simplificando nos queda

$$\boldsymbol{\beta}'(t) = \left(x'(t) - r\frac{x'(t)(x'(t)y''(t) - x''(t)y'(t))}{\|\boldsymbol{\alpha}'(t)\|^3}, y'(t) + r\frac{y'(t)(x''(t)y'(t) - x'(t)y''(t))}{\|\boldsymbol{\alpha}'(t)\|^3}\right)$$

o sea

$$\boldsymbol{\beta}'(t) = \left(1 - r\frac{x'(t)y''(t) - x''(t)y'(t)}{\|\boldsymbol{\alpha}'(t)\|^3}\right)(x'(t), y'(t))$$

Recordando que la curvatura con signo de la curva $\boldsymbol{\alpha}$, que denotaremos por $k_{\alpha}(t)$, está dada por

$$k_{\alpha}(t) = \frac{x'(t)y''(t) - x''(t)y'(t)}{\|\boldsymbol{\alpha}'(t)\|^3}$$

nos queda finalmente la fórmula para $\boldsymbol{\beta}'(t)$ como

$$\boxed{\boldsymbol{\beta}'(t) = (1 - rk_{\alpha}(t))\boldsymbol{\alpha}'(t)} \tag{2}$$

Siendo la curva $\boldsymbol{\alpha}$ regular, nos preguntamos si la curva r-paralela $\boldsymbol{\beta}$ también lo es. Con la fórmula que obtuvimos para $\boldsymbol{\beta}'(t)$ es fácil contestar esta pregunta.

> **Teorema 5.8.1** Sea $\boldsymbol{\alpha}: I \to \mathbb{R}^2$ una curva regular, y sea $\boldsymbol{\beta}: I \to \mathbb{R}^2$ la curva r-paralela a $\boldsymbol{\alpha}$. La curva $\boldsymbol{\beta}$ es regular si y sólo si r^{-1} no pertenece al rango de $k_{\alpha}(t)$ $(t \in I)$.

Demostración Puesto que $\|\boldsymbol{\beta}'(t)\| = |1 - rk_{\alpha}(t)|\|\boldsymbol{\alpha}'(t)\|$, y por hipótesis $\|\boldsymbol{\alpha}'(t)\| \neq 0$, se tiene que $\boldsymbol{\beta}'(t) \neq 0$ si y sólo si $1 - rk_{\alpha}(t) \neq 0$ $\forall t \in I$, lo cual significa que $r^{-1} \neq k_{\alpha}(t)$ $\forall t \in I$, es decir que $r^{-1} \notin$ rango de $k_{\alpha}(t)$. Q.E.D.

Por ejemplo, si consideramos la curva regular $\boldsymbol{\alpha}: [a, b] \to \mathbb{R}^2$, definida en el intervalo compacto $[a, b]$ de $\mathbb{R}$, la función curvatura $k_{\alpha}(t)$, $t \in [a, b]$ alcanzará su máximo absoluto dentro del intervalo $[a, b]$, de modo que si tomamos $r = \pm\epsilon$, $(\epsilon > 0)$, con

$$\epsilon^{-1} > \text{máx}_{t\in[a,b]} |k_{\alpha}(t)|$$

las curvas $\boldsymbol{\beta}_1(t) = \boldsymbol{\alpha}(t) + \epsilon\mathbf{n}(t)$ y $\boldsymbol{\beta}_2(t) = \boldsymbol{\alpha}(t) - \epsilon\mathbf{n}(t)$, que son curvas regulares ϵ-paralelas a $\boldsymbol{\alpha}$, (y que cada una de ellas se encuentra en "lados distintos de $\boldsymbol{\alpha}(t)$", es decir, $\boldsymbol{\beta}_1$ se encuentra en el lado marcado por la dirección del vector $\mathbf{n}(t)$, mientras que $\boldsymbol{\beta}_2$ se encuentra en el lado opuesto) constituyen la frontera de la vecindad abierta

$$V_{\epsilon}(\boldsymbol{\alpha}) = \{(x, y) \in \mathbb{R}^2 \mid \|(x, y) - \boldsymbol{\beta}_i(t)\| < \epsilon,\ i = 1, 2, t \in I\}$$

la cual es un ejemplo de un tipo de vecindades abiertas de curvas llamadas "vecindades tubulares".

A manera de ejemplo, consideremos la curva $\boldsymbol{\alpha}: [0, 2\pi] \to \mathbb{R}^2$, dada por $\boldsymbol{\alpha}(t) = (t, \operatorname{sen} t)$. La curva r-paralela a $\boldsymbol{\alpha}$ es $\boldsymbol{\beta}: [0, 2\pi] \to \mathbb{R}^2$

$$\boldsymbol{\beta}(t) = \left(t - (r\cos t)/(1 + \cos^2 t)^{1/2}, \operatorname{sen} t + r/(1 + \cos^2 t)^{1/2}\right)$$

La curvatura de $\boldsymbol{\alpha}$ en t es

$$k_{\alpha}(t) = -(\operatorname{sen} t)/(1 + \cos^2 t)^{3/2}$$

que alcanza su máximo en $t = 3\pi/2$, el cual vale $k_{\alpha}(3\pi/2) = 1$. Entonces, tomando $\epsilon > 0$ de modo que $\epsilon^{-1} > 1$, es decir que $\epsilon < 1$, tenemos que las curvas regulares ϵ-paralelas $\boldsymbol{\beta}(t)$ dadas en

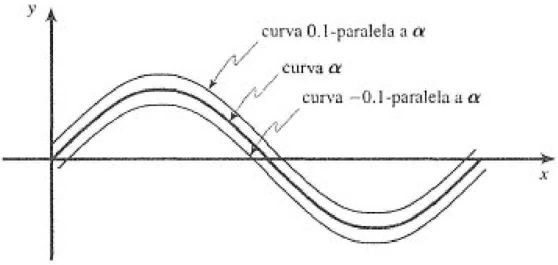

Figura 2. Curvas ±0.1-paralelas a la gráfica de $y = \operatorname{sen} x$, $0 \leq x \leq 2\pi$.

la fórmula anterior con $r = \pm\epsilon$, constituyen la frontera de una vecindad tubular de $\boldsymbol{\alpha}$. La siguiente figura muestra el caso en que $\epsilon = 0.1$.

Veamos ahora cómo están relacionadas las curvaturas k_α, de la curva $\boldsymbol{\alpha}$, con la de su paralela $\boldsymbol{\beta}$, k_β. Tomemos $r^{-1} \notin$ rango de $k_\alpha(t)$, de modo que la curva r-paralela $\boldsymbol{\beta}$ es regular. Se tiene, derivando la expresión (2), que

$$\boldsymbol{\beta}''(t) = (1 - rk_\alpha(t))\boldsymbol{\alpha}''(t) - rk'_\alpha(t)\boldsymbol{\alpha}'(t)$$

de modo que

$$\boldsymbol{\beta}'(t) \times \boldsymbol{\beta}''(t) = \big((1 - rk_\alpha(t))\boldsymbol{\alpha}'(t)\big) \times \big((1 - rk_\alpha(t))\boldsymbol{\alpha}''(t) - rk'_\alpha(t)\boldsymbol{\alpha}'(t)\big) = (1 - rk_\alpha(t))^2\boldsymbol{\alpha}'(t) \times \boldsymbol{\alpha}''(t)$$

y entonces

$$k_\beta(t) = \frac{\|\boldsymbol{\beta}'(t) \times \boldsymbol{\beta}''(t)\|}{\|\boldsymbol{\beta}'(t)\|^3} = \frac{(1 - rk_\alpha(t))^2\|\boldsymbol{\alpha}'(t) \times \boldsymbol{\alpha}''(t)\|}{|1 - rk_\alpha(t)|^3\|\boldsymbol{\alpha}'(t)\|^3}$$

Por las hipótesis hechas sobre r se tiene que $1 - rk_\alpha(t) > 0\ \forall t \in I$, o bien $1 - rk_\alpha(t) < 0\ \forall t \in I$, y entonces la fórmula anterior queda como

$$\boxed{k_\beta(t) = \pm\frac{|k_\alpha(t)|}{1 - rk_\alpha(t)}}$$

con los signos correspondientes a cada uno de los casos mencionados. Con esta fórmula es fácil ver que si la curva $\boldsymbol{\alpha}$ tiene un vértice en t_0 (es decir que $k'_\alpha(t_0) = 0$) entonces su curva r-paralela $\boldsymbol{\beta}$ (regular) tendrá también un vértice en ese punto. En efecto, se tiene que

$$k_\beta(t) = \pm(1 - rk_\alpha(t))^{-2}k'_\beta$$

de donde se ve, de hecho, que los vértices de $\boldsymbol{\alpha}$ y de $\boldsymbol{\beta}$ coinciden.

Consideremos, a manera de ejemplo la elipse $\boldsymbol{\alpha}\colon [0, 2\pi] \to \mathbb{R}^2$ dada por $\boldsymbol{\alpha}(t) = (a\cos t, b\operatorname{sen} t)$ donde $a > b > 0$. La curvatura $k_\alpha(t)$ es

$$k_\alpha(t) = \frac{ab}{(a^2\operatorname{sen}^2 t + b^2\cos^2 t)^{3/2}}$$

Los extremos absolutos de esta función en el intervalo $[0, 2\pi]$ se alcanzan en $t = 0, \pi$ (máximo absoluto) y en $t = \pi/2, 3\pi/2$ (mínimo absoluto), los cuales valen $k_{\boldsymbol{\alpha}}(0) = k_{\boldsymbol{\alpha}}(\pi) = a/b^2$ y $k_{\boldsymbol{\alpha}}(\pi/2) = k_{\boldsymbol{\alpha}}(3\pi/2) = b/a^2$. Tomando entonces r tal de modo $r^{-1} \notin [b/a^2, a/b^2]$, la curva r-paralela a $\boldsymbol{\alpha}$, que según (1) es

$$\boldsymbol{\beta}(t) = \left(\cos t\left(a - \frac{rb}{(a^2 \operatorname{sen}^2 t + b^2 \cos^2 t)^{1/2}}\right), \operatorname{sen} t\left(b - \frac{ra}{(a^2 \operatorname{sen}^2 t + b^2 \cos^2 t)^{1/2}}\right)\right)$$

será una curva regular con curvatura

$$k_{\boldsymbol{\beta}}(t) = \pm\frac{k_{\boldsymbol{\alpha}}(t)}{1 - rk_{\boldsymbol{\alpha}}(t)} = \pm\frac{ab}{(a^2 \operatorname{sen}^2 t + b^2 \cos^2 t)^{3/2} - rab}$$

donde el signo más corresponde al caso en el que $r < b^2/a$ (pues en este caso $r^{-1} > a/b^2 =$ máximo absoluto de $k_{\boldsymbol{\alpha}}(t)$ en $[0, 2\pi]$, y por lo tanto se tiene que $1 - rk_{\boldsymbol{\alpha}}(t) > 0\ \forall t \in [0, 2\pi]$), y el signo menos corresponde al caso en que $r > a^2/b$ (pues en este caso $r^{-1} < b/a^2 =$ mínimo absoluto de $k_{\boldsymbol{\alpha}}(t)$ en $[0, 2\pi]$, y por lo tanto se tiene que $1 - rk_{\boldsymbol{\alpha}}(t) < 0\ \forall t \in [0, 2\pi]$). La siguiente figura muestra el caso en que $a = 2$, $b = 1$, con $\boldsymbol{\beta}_1$ una curva r-paralela a $\boldsymbol{\alpha}$ siendo $r = 0.25 < 0.5 = b^2/a$, y $\boldsymbol{\beta}_2$ una curva r-paralela a $\boldsymbol{\alpha}$ con $r = 5 > 4 = a^2/b$. Obsérvese que la curva $\boldsymbol{\alpha}$ tiene curvatura positiva, al igual que las curvas $\boldsymbol{\beta}_1$ y $\boldsymbol{\beta}_2$. Sin embargo, el vector velocidad de $\boldsymbol{\beta}_1$ siempre tiene la misma dirección que el vector velocidad de $\boldsymbol{\alpha}$, en tanto que el de $\boldsymbol{\beta}_2$ siempre tiene la dirección contraria al correspondiente de $\boldsymbol{\alpha}$ (hecho que se ve fácilmente de la fórmula (2)). Nótese también que cualquier curva r-paralela a $\boldsymbol{\alpha}$ con $r < 0$, es automáticamente regular, pues siendo $k_{\boldsymbol{\alpha}}(t) > 0\ \forall t \in [0, 2\pi]$, se tiene $1 - rk_{\boldsymbol{\alpha}}(t) > 0\ \forall t \in [0, 2\pi]$ (figura 3).

x
curva 5-paralela a $\boldsymbol{\alpha}$

Figura 3. Curvas 0.25 y 5-paralelas a la elipse $\boldsymbol{\alpha}_t = (2\cos t, \operatorname{sen} t)$ $0 \le t \le 2\pi$.

Ahora estudiaremos la relación entre la longitud de la curva regular dada $\boldsymbol{\alpha}\colon [a, b] \to \mathbb{R}^2$ con la correspondiente de su curva r-paralela $\boldsymbol{\beta}\colon [a, b] \to \mathbb{R}^2$. Solamente se considerará el caso en que la curva $\boldsymbol{\beta}$ sea regular, es decir, cuando $\boldsymbol{\beta}$ es una curva r-parelela a $\boldsymbol{\alpha}$, con r^{-1} fuera del rango de $k_{\alpha}(t)$ $(t \in [a, b])$.

Recordemos que para la curva regular $\boldsymbol{\alpha}$ se tiene bien definida su longitud (denotada como $L_{[a,b]}(\boldsymbol{\alpha})$) como

$$L_{[a,b]}(\boldsymbol{\alpha}) = \int_a^b \|\boldsymbol{\alpha}'(t)\|\, dt$$

Siendo la curva $\boldsymbol{\beta}$ también regular, su longitud se calcula como

$$L_{[a,b]}(\boldsymbol{\beta}) = \int_a^b \|\boldsymbol{\beta}'(t)\|\, dt$$

o bien, puesto que $\boldsymbol{\beta}'(t) = (1 - rk_{\alpha}(t))\boldsymbol{\alpha}'(t)$, se tiene

$$\begin{aligned}
L_{[a,b]}(\boldsymbol{\beta}) &= \int_a^b |1 - rk_{\alpha}(t)|\|\boldsymbol{\alpha}'(t)\|\, dt \\
&= \int_a^b \big(\operatorname{sgn}(1 - rk_{\alpha}(t))\big)(1 - rk_{\alpha}(t))\|\boldsymbol{\alpha}'(t)\|\, dt \\
&= \operatorname{sgn}(1 - rk_{\alpha}(t))\left[\int_a^b \|\boldsymbol{\alpha}'(t)\|\, dt - r\int_a^b k_{\alpha}(t)\|\boldsymbol{\alpha}'(t)\|\, dt\right] \\
&= \operatorname{sgn}(1 - rk_{\alpha}(t))\left[L_{[a,b]} - r\int_a^b k_{\alpha}(t)\|\boldsymbol{\alpha}'(t)\|\, dt\right]
\end{aligned}$$

Por otra parte, si llamamos $\theta(t)$ al ángulo formado por el vector velocidad $\boldsymbol{\alpha}'(t)$ (que por hipótesis es no nulo para toda $t \in [a, b]$) con la parte positiva del eje de las abscisas $(0 \leq \theta(t) < \pi)$, se tiene

$$\theta(t) = \arctan \frac{y'(t)}{x'(t)}$$

de donde

$$\begin{aligned}
\theta'(t) &= \frac{1}{1 + \left(\dfrac{y'(t)}{x'(t)}\right)^2}\left(\frac{x'(t)y''(t) - y'(t)x''(t)}{(x'(t))^2}\right) \\
&= \frac{x'(t)y''(t) - y'(t)x''(t)}{((x'(t))^2 + (y'(t))^2)^{3/2}}\big(x'(t)^2 + (y'(t))^2\big)^{1/2} \\
&= k_{\alpha}(t)\|\boldsymbol{\alpha}'(t)\|
\end{aligned}$$

de modo que

$$\int_a^b k_{\alpha}(t)\|\boldsymbol{\alpha}'(t)\|\, dt = \int_a^b \theta'(t)dt = \theta(b) - \theta(a)$$

y por lo tanto finalmente podemos escribir la fórmula de $L_{[a,b]}(\boldsymbol{\beta})$ como

$$\boxed{L_{[a,b]}(\boldsymbol{\beta}) = \operatorname{sgn}(1 - rk_{\alpha}(t))\big[L_{[a,b]}(\boldsymbol{\alpha}) - r(\theta(b) - \theta(a))\big]} \tag{3}$$

Más aún, si la curva $\boldsymbol{\alpha}$ es cerrada, la diferencia $\theta(b) - \theta(a)$ es un múltiplo de 2π. En forma más precisa se tiene que $\theta(b) - \theta(a) = 2\pi I$, en I se llama índice de rotación de la curva (que de manera intuitiva lo pensamos como la cantidad de vueltas completas que da el vector tangente sobre la curva). Así pues, en este caso la fórmula (3) se ve como

$$L_{[a,b]}(\boldsymbol{\beta}) = \operatorname{sgn}(1 - rk_{\boldsymbol{\alpha}}(t))\left[L_{[a,b]}(\boldsymbol{\alpha}) - 2\pi r|I|\right]$$

de modo que si $1 - rk_{\boldsymbol{\alpha}}(t) > 0\ \forall t \in [a, b]$ (situación que se presenta si $r^{-1} > \text{máx}_{t\in[a,b]} |k_{\boldsymbol{\alpha}}(t)|$, o bien, en particular, si la curva $\boldsymbol{\alpha}$ es una curva simple convexa positivamente orientada y $r < 0$), la longitud de la curva $\boldsymbol{\beta}$, r-paralela a $\boldsymbol{\alpha}$ es

$$L_{[a,b]}(\boldsymbol{\beta}) = L_{[a,b]}(\boldsymbol{\alpha}) - 2\pi r|I|$$

en tanto que si $1 - rk_{\boldsymbol{\alpha}}(t) < 0\ \forall t \in [a, b]$ (por ejemplo, si $r^{-1} < \text{mín}_{t\in[a,b]} |k_{\boldsymbol{\alpha}}(t)|$), la curva regular $\boldsymbol{\beta}$, r-paralela a $\boldsymbol{\alpha}$ tiene por longitud

$$L_{[a,b]}(\boldsymbol{\beta}) = -L_{[a,b]}(\boldsymbol{\alpha}) + 2\pi r|I|$$

Retomando el ejemplo de la elipse $\boldsymbol{\alpha}: [0, 2\pi] \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (2\cos t, \operatorname{sen} t)$, habíamos ya considerado curvas r-paralelas a ella con $r = 0.25$ (caso en el que $1 - rk_{\boldsymbol{\alpha}}(t) > 0\ \forall t \in [0, 2\pi]$), que llamamos $\boldsymbol{\beta}_1$, y con $r = 5$ (caso en el que $1 - rk_{\boldsymbol{\alpha}}(t) < 0\ \forall t \in [0, 2\pi]$), que llamamos $\boldsymbol{\beta}_2$ (ver figura 3). Tanto $\boldsymbol{\beta}_1$ como $\boldsymbol{\beta}_2$ son regulares y para calcular su longitud podemos usar las fórmulas recientemente obtenidas. Se tiene

$$\begin{aligned} L_{[0,2\pi]}(\boldsymbol{\beta}_1) &= L_{[0,2\pi]}(\boldsymbol{\alpha}) - 2\pi r = 9.6885 - 0.5\pi = 8.1177 \\ L_{[0,2\pi]}(\boldsymbol{\beta}_2) &= -L_{[0,2\pi]}(\boldsymbol{\alpha}) + 2\pi r = -9.6885 + 10\pi = 21.7275 \end{aligned}$$

Consideremos ahora una curva regular cerrada simple $\boldsymbol{\alpha}: [a, b] \to \mathbb{R}^2$ (es decir, se tiene $\boldsymbol{\alpha}^{(j)}(a) = \boldsymbol{\alpha}^{(j)}(b)$, $j = 0, 1, 2, \ldots$, y $\boldsymbol{\alpha}(t_1) \neq \boldsymbol{\alpha}(t_2)$ para toda pareja $t_1, t_2 \in [a, b)$, $t_1 \neq t_2$). Así si tiene sentido hablar del "área encerrada por la curva $\boldsymbol{\alpha}$". De hecho, con ayuda del Teorema de Green que estudiaremos en el capítulo 7, podemos calcular dicha área (que denotaremos por $A(\boldsymbol{\alpha})$) como (con la curva $\boldsymbol{\alpha}(t) = (x(t), y(t))$ positivamente orientada)

$$A(\boldsymbol{\alpha}) = \frac{1}{2}\int_a^b [x(t)y'(t) - x'(t)y(t)]\, dt$$

(en este momento, aceptemos que esta fórmula proporciona efectivamente el área mencionada). Vamos ahora a estudiar cómo está relacionada esta área con la correspondiente de su curva r-paralela (cuando tenga sentido hablar del área de esta curva). Primero obsérvese que si la curva $\boldsymbol{\alpha}$ es cerrada entonces la curva $\boldsymbol{\beta}$ será también cerrada (hecho que se ve fácilmente por la manera como está definida $\boldsymbol{\beta}$). La propiedad de regularidad de la curva $\boldsymbol{\alpha}$, como ya se ha visto, se puede perder en la curva $\boldsymbol{\beta}$; esto depende de la existencia de raíces de la ecuación $1 - rk_{\boldsymbol{\alpha}}(t) = 0$ en $[a, b]$. Este hecho, sin embargo, no nos impide usar la fórmula del Teorema de Green para calcular el área encerrada por la curva, pues ésta sigue siendo válida para curvas regulares por secciones en $[a, b]$. Entonces la propiedad importante que debe conservar la curva $\boldsymbol{\beta}$ para poder seguir hablando del área que ésta encierra es la de ser una curva simple (sin autointersecciones). Notemos también que la orientación positiva de $\boldsymbol{\alpha}$ puede perderse en $\boldsymbol{\beta}$, aun conservando esta última la propiedad de ser simple (ver el ejemplo de la curva $\boldsymbol{\beta}$, 1.5-paralela a la elipse $\boldsymbol{\alpha}(t) = (2\cos t, \operatorname{sen} t)$, que tiene orientación negativa). De cualquier modo, este conflicto se arregla fácilmente con una reparametrización de la curva que invierta su orientación.

Partamos entonces de una curva $\boldsymbol{\alpha}\colon [a, b] \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (x(t), y(t))$ regular, cerrada, simple y positivamente orientada y consideremos la curva $\boldsymbol{\beta}\colon [a, b] \to \mathbb{R}^2$, r-paralela a $\boldsymbol{\alpha}$, con r de modo que $\boldsymbol{\beta}$ sea simple. Supongamos también, por el momento, que $\boldsymbol{\beta}$ queda orientada positivamente. Escribiendo

$$\boldsymbol{\beta}(t) = (x_{\boldsymbol{\beta}}(t), y_{\boldsymbol{\beta}}(t)), \quad \boldsymbol{\beta}'(t) = (x'_{\boldsymbol{\beta}}(t), y'_{\boldsymbol{\beta}}(t))$$

donde entonces

$$\begin{aligned} x_{\boldsymbol{\beta}}(t) &= x(t) - \frac{ry'(t)}{\|\boldsymbol{\alpha}'(t)\|}, \qquad & y_{\boldsymbol{\beta}}(t) &= y(t) + \frac{rx'(t)}{\|\boldsymbol{\alpha}'(t)\|}, \\ x'_{\boldsymbol{\beta}}(t) &= (1 - rk_{\boldsymbol{\alpha}}(t))x'(t) & y'_{\boldsymbol{\beta}}(t) &= (1 - rk_{\boldsymbol{\alpha}}(t))y'(t) \end{aligned}$$

tenemos que el área encerrada por $\boldsymbol{\beta}$, que denotaremos por $A(\boldsymbol{\beta})$ es

$$\begin{aligned} A(\boldsymbol{\beta}) &= \frac{1}{2}\int_a^b \Big[x_{\boldsymbol{\beta}}(t)y'_{\boldsymbol{\beta}}(t) - x'_{\boldsymbol{\beta}}(t)y_{\boldsymbol{\beta}}(t)\Big]\,dt \\ &= \frac{1}{2}\int_a^b \left[\left(x(t) - \frac{ry'(t)}{\|\boldsymbol{\alpha}'(t)\|}\right)((1 - rk_{\boldsymbol{\alpha}}(t))y'(t)) - \left(y(t) - \frac{rx'(t)}{\|\boldsymbol{\alpha}'(t)\|}\right)((1 - rk_{\boldsymbol{\alpha}}(t))x'(t))\right] dt \\ &= \frac{1}{2}\int_a^b (1 - rk_{\boldsymbol{\alpha}}(t))\big(x(t)y'(t) - y(t)x'(t) - r\|\boldsymbol{\alpha}'(t)\|\big)\,dt \\ &= \frac{1}{2}\int_a^b \big(x(t)y'(t) - y(t)x'(t)\big)\,dt - \frac{1}{2}r\int_a^b \|\boldsymbol{\alpha}'(t)\|dt \\ &\quad - \frac{1}{2}r\int_a^b \big(x(t)y'(t) - y(t)x'(t)\big)k_{\boldsymbol{\alpha}}(t)\,dt + \frac{1}{2}r^2\int_a^b k_{\boldsymbol{\alpha}}(t)\|\boldsymbol{\alpha}'(t)\|\,dt \end{aligned}$$

El primero, segundo y cuarto sumandos son expresiones fácilmente reconocibles. En efecto, el primero no es más que el área encerrada por la curva $\boldsymbol{\alpha}$. La integral que aparece en el segundo sumando es la longitud de la curva $\boldsymbol{\alpha}$ (que denotaremos por $L(\boldsymbol{\alpha})$), y, por último, la integral que aparece en el cuarto sumando es (como ya habíamos observado en los cálculos correspondientes a la longitud de la curva paralela $\boldsymbol{\beta}$)

$$\int_a^b k_{\boldsymbol{\alpha}}(t)\|\boldsymbol{\alpha}'(t)\|\,dt = \theta(b) - \theta(a) = 2\pi$$

pues la curva $\boldsymbol{\alpha}$ es simple y positivamente orientada (su índice de rotación es $+1$). Entonces la última expresión nos queda como

$$A(\boldsymbol{\beta}) = A(\boldsymbol{\alpha}) - 0.5rL(\boldsymbol{\alpha}) + \pi r^2 - 0.5r\int_a^b \big(x(t)y'(t) - y(t)x'(t)\big)k_{\boldsymbol{\alpha}}(t)dt$$

Trabajemos con la integral que aparece en esta fórmula. Llamémosla ξ. Se tiene que ejemplo de la curva $\boldsymbol{\beta}$, 1.5-paralela a la elipse $\boldsymbol{\alpha}(t) = (2\cos t, \operatorname{sen} t)$, que tiene orientación negativa). De cualquier modo, este conflicto se arregla fácilmente con una reparametrización de la curva que invierta su orientación.

Partamos entonces de una curva $\boldsymbol{\alpha}\colon [a, b] \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (x(t), y(t))$ regular, cerrada, simple y positivamente orientada y consideremos la curva $\boldsymbol{\beta}\colon [a, b] \to \mathbb{R}^2$, r-paralela a $\boldsymbol{\alpha}$, con r de modo que $\boldsymbol{\beta}$ sea simple. Supongamos también, por el momento, que $\boldsymbol{\beta}$ queda orientada positivamente. Escribiendo

$$\boldsymbol{\beta}(t) = (x_{\beta}(t), y_{\beta}(t)), \quad \boldsymbol{\beta}'(t) = (x'_{\beta}(t), y'_{\beta}(t))$$

donde entonces

$$x_{\beta}(t) = x(t) - \frac{ry'(t)}{\|\boldsymbol{\alpha}'(t)\|}, \qquad y_{\beta}(t) = y(t) + \frac{rx'(t)}{\|\boldsymbol{\alpha}'(t)\|},$$
$$x'_{\beta}(t) = (1 - rk_{\alpha}(t))x'(t) \qquad y'_{\beta}(t) = (1 - rk_{\alpha}(t))y'(t)$$

tenemos que el área encerrada por $\boldsymbol{\beta}$, que denotaremos por $A(\boldsymbol{\beta})$ es

$$\begin{aligned}
A(\boldsymbol{\beta}) &= \frac{1}{2}\int_a^b \left[x_{\beta}(t)y'_{\beta}(t) - x'_{\beta}(t)y_{\beta}(t)\right] dt \\
&= \frac{1}{2}\int_a^b \left[\left(x(t) - \frac{ry'(t)}{\|\boldsymbol{\alpha}'(t)\|}\right)\left((1 - rk_{\alpha}(t))y'(t)\right) - \left(y(t) - \frac{rx'(t)}{\|\boldsymbol{\alpha}'(t)\|}\right)\left((1 - rk_{\alpha}(t))x'(t)\right)\right] dt \\
&= \frac{1}{2}\int_a^b (1 - rk_{\alpha}(t))\big(x(t)y'(t) - y(t)x'(t) - r\|\alpha'(t)\|\big)\, dt \\
&= \frac{1}{2}\int_a^b \big(x(t)y'(t) - y(t)x'(t)\big)\, dt - \frac{1}{2}r\int_a^b \|\alpha'(t)\| dt \\
&\quad - \frac{1}{2}r\int_a^b \big(x(t)y'(t) - y(t)x'(t)\big)k_{\alpha}(t)\, dt + \frac{1}{2}r^2\int_a^b k_{\alpha}(t)\|\alpha'(t)\|\, dt
\end{aligned}$$

El primero, segundo y cuarto sumandos son expresiones fácilmente reconocibles. En efecto, el primero no es más que el área encerrada por la curva α. La integral que aparece en el segundo sumando es la longitud de la curva α (que denotaremos por $L(\alpha)$), y, por último, la integral que aparece en el cuarto sumando es (como ya habíamos observado en los cálculos correspondientes a la longitud de la curva paralela $\boldsymbol{\beta}$)

$$\int_a^b k_{\alpha}(t)\|\boldsymbol{\alpha}'(t)\|\, dt = \theta(b) - \theta(a) = 2\pi$$

pues la curva $\boldsymbol{\alpha}$ es simple y positivamente orientada (su índice de rotación es $+1$). Entonces la última expresión nos queda como

$$A(\boldsymbol{\beta}) = A(\boldsymbol{\alpha}) - 0.5rL(\boldsymbol{\alpha}) + \pi r^2 - 0.5r\int_a^b \big(x(t)y'(t) - y(t)x'(t)\big)k_{\alpha}(t)dt$$

Trabajemos con la integral que aparece en esta fórmula. Llamémosla ξ. Se tiene que

Para la curva 5-paralela a la elipse tenemos

$$A(\boldsymbol{\beta}) = 2\pi - 5(9.6885) + \pi(5)^2 = 36.3807$$

y para la curva 1.5-paralela a la elipse se tiene

$$A(\boldsymbol{\beta}) = 2\pi - 1.5(9.6885) + \pi(1.5)^2 = -1.18095$$

Nótese que el valor del área encerrada por esta curva 1.5-paralela a la elipse es negativo, pues, como ya habíamos comentado, la orientación que tiene esta curva es negativa. Es claro, sin embargo, que en este caso el valor absoluto de nuestro resultado es el área procurada.

En el caso particular de la elipse $\boldsymbol{\alpha}\colon [0, 2\pi] \to \mathbb{R}^2$, dada por $\boldsymbol{\alpha}(t) = (a\cos t, b\,\mathrm{sen}\,t)$, con $a > b > 0$, podemos ser más explícitos en cuanto a la utilización de la fórmula del área encerrada por sus curvas r-paralelas $\boldsymbol{\beta}\colon [0, 2\pi] \to \mathbb{R}^2$

$$\boldsymbol{\beta}(t) = \left(\cos t\left(a - \frac{rb}{(a^2\,\mathrm{sen}^2\,t + b^2\cos^2 t)^{1/2}}\right), \mathrm{sen}\,t\left(b - \frac{ra}{(a^2\,\mathrm{sen}^2\,t + b^2\cos^2 t)^{1/2}}\right)\right)$$

Estudiemos las intersecciones de esta curva con el eje x. Haciendo

$$y(t) = \mathrm{sen}\,t\left(b - \frac{ra}{(a^2\,\mathrm{sen}^2\,t + b^2\cos^2 t)^{1/2}}\right) = 0$$

Nótese que siempre hay dos raíces de esta ecuación en $[0, 2\pi)$, a saber $t = 0, \pi$. Es decir, la curva $\boldsymbol{\beta}$ corta al eje x al menos en estos dos puntos. Puede, sin embargo, haber otras raíces de la ecuación, provenientes de

$$b - \frac{ra}{(a^2\,\mathrm{sen}^2\,t + b^2\cos^2 t)^{1/2}} = 0$$

Obsérvese que si $r < 0$, estas raíces no existen (las curvas paralelas hacia el exterior de la elipse cortan solamente en $t = 0$ y $t = \pi$ al eje de las x). Tomemos entonces $r > 0$. En este caso se tiene que

$$\mathrm{sen}^2\,t = \frac{r^2a^2 - b^4}{b^2a^2 - b^4}$$

Estos valores de t existen (y son diferentes de 0 y π) si y sólo si

$$0 < \frac{r^2a^2 - b^4}{b^2a^2 - b^4} < 1$$

es decir, si $b^2/a < r < b$. En tal caso, obsérvese que existen dos raíces de la ecuación $y(t) = 0$ (además de las ya mencionadas 0 y π) entre 0 y 2π, a saber

$$t_1 = \mathrm{arcsen}\left(\frac{r^2a^2 - b^4}{b^2a^2 - b^4}\right)^{1/2}, \qquad t_2 = t_1 + \pi$$

y que además se tiene $x_{\boldsymbol{\beta}}(t_1) = x_{\boldsymbol{\beta}}(t_2)$. Esto significa que bajo la condición $b^2/a < r < b$, existe una autointersección de la curva $\boldsymbol{\beta}$, la cual ocurre sobre el eje de las x (en el punto $\boldsymbol{\beta}(t_1) = \boldsymbol{\beta}(t_2)$).

De manera análoga se ve que la curva $\boldsymbol{\beta}$ siempre tiene dos intersecciones con el eje y, en $t = \pi/2$ y en $t = 3\pi/2$, y que puede tener más, provenientes de la ecuación

$$a - \frac{rb}{(a^2 \operatorname{sen}^2 t + b^2 \cos^2 t)^{1/2}} = 0$$

de donde se ve también que de ser $r < 0$, tales nuevas intersecciones (las raíces de esta ecuación) no existen (las curvas paralelas hacia el exterior de la elipse cortan al eje de las y solamente en $t = \pi/2$ y $t = 3\pi/2$). Escribiendo la última ecuación como

$$\cos^2 t = \frac{a^4 - r^2b^2}{a^4 - a^2b^2}$$

vemos que las nuevas raíces existen si y sólo si

$$0 < \frac{a^4 - r^2b^2}{a^4 - a^2b^2} < 1$$

o sea si $a < r < a^2/b$. En tal caso, existen dos raíces, a saber

$$t_1 = \arccos\left(\frac{a^4 - r^2b^2}{a^4 - a^2b^2}\right), \qquad t_2 = t_1 + \pi$$

teniéndose además que $y_{\boldsymbol{\beta}}(t_1) = y_{\boldsymbol{\beta}}(t_2)$. Esto significa entonces que con la condición $a < r < a^2/b$, hay dos intersecciones en el eje y (además de las correspondientes a $t = \pi/2$ y $t = 3\pi/2$) las cuales son autointersecciones de la curva $\boldsymbol{\beta}$.

En conclusión: si $b^2/a < r < b$, la curva $\boldsymbol{\beta}$ tiene autointersecciones (en el eje x); si $a < r < a^2/b$, la curva $\boldsymbol{\beta}$ tiene autointersecciones (en el eje y). Como $a > b$, observamos que en el intervalo $b \leq r \leq a$, la curva $\boldsymbol{\beta}$ no tiene autointersecciones (nótese que en este intervalo la curva $\boldsymbol{\beta}$ no es regular pues, como habíamos ya visto, la región en la cual la curva $\boldsymbol{\beta}$ pierde su regularidad corresponde a valores de r tales que $b^2/a \leq r \leq a^2/b$). Más aún, con el valor de r en el intervalo $[b, a]$, la curva r-paralela $\boldsymbol{\beta}$, siendo cerrada, simple y regular por partes, tiene orientación negativa (un ejemplo de esta situación es la curva 1.5-paralela a la elipse $\boldsymbol{\alpha}(t) = (2\cos t, \operatorname{sen} t)$ que ya ha sido estudiada, pues en este caso $r = 1.5 \in [1, 2] = [b, a]$). A manera de resumen de las variaciones que tienen las propiedades de regularidad, simplicidad y positividad en la orientación de la curva r-paralela $\boldsymbol{\beta}$, al variar r, presentamos el esquema siguiente

$$\text{———}\overset{0}{*}\text{———}\overset{b^2/a}{*}\text{——————}\overset{b}{*}\text{——————}\overset{a}{*}\text{——————}\overset{a^2/b}{*}\text{——————}\!\rightarrow r$$

Las siguientes figuras ilustran cada una de estas situaciones

En consecuencia, la fórmula para calcular el área encerrada por la curva r-paralela $\boldsymbol{\beta}$ a la elipse $\boldsymbol{\alpha}$, tiene sentido cuando $r \notin (b^2/a, b) \cup (a, a^2/b)$. En todos los demás casos la curva $\boldsymbol{\beta}$ es simple,

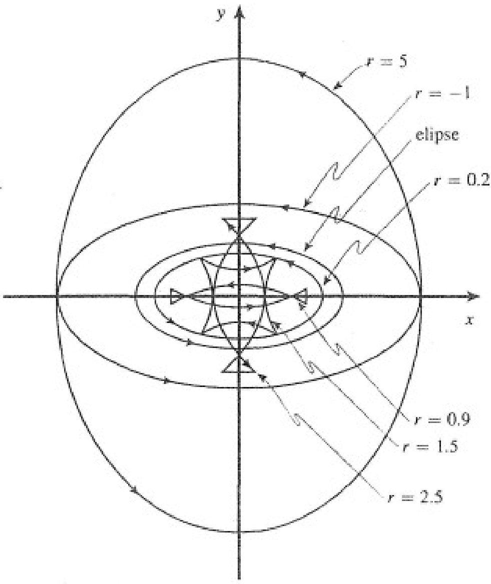

Figura 4. Curvas paralelas a la elipse $\alpha(t) = (a \cos t, b \operatorname{sen} t)$, $0 \leq t \leq 2\pi$.

propiedad fundamental para que tenga sentido hablar del área encerrada por la curva. Más aún, cuando $r \leq b^2/a$, o $r \geq a^2/b$, siendo $\boldsymbol{\beta}$ una curva positivamente orientada, el área que ésta encierra es

$$A(\boldsymbol{\beta}) = A(\boldsymbol{\alpha}) - rL(\boldsymbol{\alpha}) + \pi r^2 = \pi ab - rL(\boldsymbol{\alpha}) + \pi r^2$$

mientras que si $b \leq r \leq a$, la curva simple $\boldsymbol{\beta}$ tiene orientación negativa, y entonces el área encerrada por ella debe ser

$$A(\boldsymbol{\beta}) = -\pi ab + rL(\boldsymbol{\alpha}) - \pi r^2$$

En el teorema siguiente se recopilan los resultados obtenidos respecto a longitud y área encerradas por las curvas paralelas a una elipse.

Teorema 5.8.2 Sea $\boldsymbol{\alpha}: [0, 2\pi] \to \mathbb{R}^2$ la elipse

$$\boldsymbol{\alpha}(t) = (a \cos t, b \operatorname{sen} t)$$

en donde $a > b > 0$. La curva $\boldsymbol{\beta}: [0, 2\pi] \to \mathbb{R}^2$

$$\boldsymbol{\beta}(t) = \left(\cos t \left(a - \frac{rb}{(a^2 \operatorname{sen}^2 t + b^2 \cos^2 t)^{1/2}} \right), \operatorname{sen} t \left(b - \frac{ra}{(a^2 \operatorname{sen}^2 t + b^2 \cos^2 t)^{1/2}} \right) \right)$$

es una curva r-paralela a $\boldsymbol{\alpha}$. Sean $L(\boldsymbol{\alpha})$ y $L(\boldsymbol{\beta})$ la longitud de las curvas $\boldsymbol{\alpha}$ y $\boldsymbol{\beta}$, y $A(\boldsymbol{\alpha})$ y $A(\boldsymbol{\beta})$ el área que éstas encierran, respectivamente.

a. Si $r \leq b^2/a$, la longitud de la curva $\boldsymbol{\beta}$ se calcula como

$$L(\boldsymbol{\beta}) = L(\boldsymbol{\alpha}) - 2\pi r$$

b. Si $r \geq a^2/b$, la longitud de la curva $\boldsymbol{\beta}$ se calcula como

$$L(\boldsymbol{\beta}) = -L(\boldsymbol{\alpha}) + 2\pi r$$

c. Si $r \in (-\infty, b^2/a] \cup [a^2/b, +\infty)$, el área encerrada por la

$$A(\boldsymbol{\beta}) = \pi ab - rL(\boldsymbol{\alpha}) + \pi r^2$$

d. Si $r \in [b, a]$, el área encerrada por la curva $\boldsymbol{\beta}$ es

$$A(\boldsymbol{\beta}) = -\pi ab + rL(\boldsymbol{\alpha}) - \pi r^2 \qquad \blacksquare$$

Para finalizar esta sección, estudiaremos las curvas paralelas a una parábola. Consideremos la parábola $\boldsymbol{\alpha}\colon I \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (t, pt^2)$, donde I es un intervalo de $\mathbb{R}$ simétrico respecto del origen, y p es un real positivo dado. Según la fórmula (1), la curva $\boldsymbol{\beta}$, r-paralela a $\boldsymbol{\alpha}$ es

$$\boldsymbol{\beta}(t) = \left(t - \frac{2rpt}{(1 + 4p^2t^2)^{1/2}}, t^2 + \frac{r}{(1 + 4p^2t^2)^{1/2}} \right)$$

Ciertamente ésta es una curva simétrica respecto del eje de ordenadas. Una pregunta natural sobre ella es: ¿esta curva —paralela a la parábola $y = px^2$—, también es una parábola? (Como se dijo al inicio, esta pregunta fue la que motivó en principio el presente estudio). No es difícil imaginar que la respuesta a la pregunta será negativa, pues, como hemos visto ya en varias ocasiones, la curva $\boldsymbol{\beta}$ puede llegar a perder su regularidad (propiedad que debe poseer cualquier curva parabólica). En efecto, la curvatura de $\boldsymbol{\alpha}$ en t viene dada por

$$k_{\alpha}(t) = \frac{2p}{(1 + 4p^2t^2)^{3/2}}$$

El rango de esta función es (pensando que $\boldsymbol{\alpha}$ está definida en todo $\mathbb{R}$) el intervalo $(0, 2p]$, de modo que, según el teorema 1, tomando $r^{-1} \in (0, 2p]$, la curva $\boldsymbol{\beta}$, r-paralela a $\boldsymbol{\alpha}$, no es regular, y no se puede esperar que ésta sea una parábola. Sin embargo, la inquietud puede persistir al imaginar una curva r-paralela a $\boldsymbol{\alpha}$ con $r < 0$ muy pequeño en valor absoluto (con $\boldsymbol{\beta}$ "muy cerca de la parte exterior de $\boldsymbol{\alpha}$"). En este caso, sin embargo, la respuesta sigue siendo negativa. En efecto, si la curva $\boldsymbol{\beta}$ fuera una parábola, ésta tendría que ser del tipo $y = \mu x^2 + \nu$, para ciertas constantes μ y ν. (En efecto, la curva $\boldsymbol{\beta}$ es simétrica respecto del eje de ordenadas y posee un extremo local en $\boldsymbol{\beta}(0) = (0, r)$, el cual corresponde al punto que está a r unidades del vértice de la parábola —que es, además, el único vértice de la curva, i.e. el punto en que $k'_{\alpha}(t) = 0$. Así, la única curva parabólica con estas características es $y = \mu x^2 + \nu$). Para probar nuestra afirmación ("la curva $\boldsymbol{\beta}$ no es una parábola") usaremos la siguiente caracterización de este tipo de curvas.

Lema La (traza de la) curva regular $\boldsymbol{\alpha}\colon \mathbb{R} \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (x(t), y(t))$, simétrica respecto del eje de ordenadas, es una parábola del tipo $y = \mu x^2 + \nu$, si y sólo si

$$y'(t)(x'(t))^2 - x(t)(x'(t)y''(t) - x''(t)y'(t)) = 0$$

Demostración. Primeramente veremos que la expresión anterior es invariante por reparametrizaciones de $\boldsymbol{\alpha}$. Sea $\tilde{\boldsymbol{\alpha}}: \mathbb{R} \to \mathbb{R}^2$ una reparametrización de $\boldsymbol{\alpha}$. Entonces $\tilde{\boldsymbol{\alpha}}(t) = \boldsymbol{\alpha}(\phi(t))$ para alguna función $\phi: \mathbb{R} \to \mathbb{R}$ diferenciable con derivada nunca nula en $\mathbb{R}$. Se tiene que

$$\tilde{\boldsymbol{\alpha}}'(t) = \phi'(t)\boldsymbol{\alpha}'(\phi(t)), \quad \tilde{\boldsymbol{\alpha}}''(t) = \phi''(t)\boldsymbol{\alpha}'(\phi(t)) + (\phi'(t))^2\boldsymbol{\alpha}''(\phi(t))$$

de modo que, escribiendo $\tilde{\boldsymbol{\alpha}}(t) = (\tilde{x}(t), \tilde{y}(t))$, se tiene

$$\begin{aligned}\tilde{y}'(t)\left(\tilde{x}'(t)\right)^2 - \tilde{x}(t)\left(\tilde{x}'(t)\tilde{y}''(t) - \tilde{x}''(t)\tilde{y}'(t)\right) &= \phi'(t)y'(\phi(t))[\phi'(t)x'(\phi(t))]^2 \\ &\quad - x(\phi(t))\left\{\phi'(t)x'(\phi(t))\left[\phi''(t)y'(\phi(t)) + (\phi'(t))^2 y''(\phi(t))\right]\right. \\ &\quad \left.- \phi'(t)y'(\phi(t))\left[\phi''(t)x'(\phi(t)) + (\phi'(t))^2 x''(\phi(t))\right]\right\} \\ &\quad (\phi'(t))^3\left[y'(t)(x'(t))^2 - x(t)(x'(t)y''(t) - x''(t)y'(t))\right] = 0\end{aligned}$$

Supongamos entonces que la (traza de la) curva α es de la forma mencionada en el lema. Es decir, supongamos que $y(t) = \mu(x(t))^2 + \nu$, $\forall t \in \mathbb{R}$. Tomemos $x(t) = t$, y entonces $y(t) = \mu t^2 + \nu$. Se tiene

$$y'(t)(x'(t))^2 - x(t)(x'(t)y''(t) - x''(t)y'(t)) = (2\mu t) - t(2\mu) = 0$$

En forma recíproca, suponga que se cumple la relación dada. Poniendo $x(t) = t$, nos queda que $y(t)$ satisface

$$y'(t) - t(y''(t)) = 0$$

de donde, integrando nos queda

$$y(t) = \mu t^2 + \nu$$

como queríamos. Q.E.D.

Ahora es fácil ver que nuestra curva $\boldsymbol{\beta}$, r-paralela a la parábola $\boldsymbol{\alpha}$, no es una parábola del tipo $y = \mu x^2 + \nu$. De hecho se tiene (escribiendo las funciones coordenadas de $\boldsymbol{\beta}$ como $x_{\beta}(t)$ y $y_{\beta}(t)$)

$$y'_{\beta}(t)(x'_{\beta}(t))^2 - x_{\beta}(t)(x'_{\beta}(t)y''_{\beta}(t) - x''_{\beta}(t)y'_{\beta}(t)) = 8rp^3t^3k_{\alpha}(t)(1 - rk_{\alpha}(t))^2 \neq 0$$

Si consideramos la parábola $y = px^2$ en todo su dominio, es decir, la (traza de la) curva $\boldsymbol{\alpha}: \mathbb{R} \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (t, pt^2)$, como dijimos anteriormente, la curva $\boldsymbol{\beta}$, r-paralela a $\boldsymbol{\alpha}$, será regular si y sólo si $r^{-1} \notin (0, 2p] =$ rango de $k_{\alpha}(t)$. Es decir, $\boldsymbol{\beta}$ es regular si y sólo si $r < 1/2p$. Esto significa que, globalmente, sólo se pueden tener curvas regulares paralelas a la parábola $y = px^2$ por afuera de ella ($r < 0$), o bien, por adentro hasta $r = 1/2p$ (no incluso, o sea $0 < r < 1/2p$). Para $r \geq 1/2p$, la curva $\boldsymbol{\beta}$ no es regular, teniéndose de hecho que si $r > 1/2p$, esta curva presentará una autointersección sobre el eje de las ordenadas. En efecto, haciendo $x_{\beta}(t) = 0$, es decir

$$t - \frac{2rpt}{(1 + 4p^2t^2)^{1/2}} = 0$$

vemos que una raíz de esta ecuación es siempre $t = 0$ (la curva $\boldsymbol{\beta}$ siempre pasa por el eje de ordenadas en $\boldsymbol{\beta}(0) = (0, r)$), teniéndose además la posibilidad de que

$$1 - \frac{2rpt}{(1 + 4p^2t^2)^{1/2}} = 0$$

(Nótese que esta ecuación no tiene solución si $r < 0$, es decir, las curvas r-paralelas hacia el exterior de la parábola solamente cruzan el eje de ordenadas en el punto $(0, r)$), de donde

$$\bar{t}_{1,2} = \pm(1/2p)(4r^2p^2 - 1)^{1/2}$$

(nótese también que si $r < 1/2p$ estas raíces no existen). Para $r > 1/2p$, éstas son dos raíces reales distintas en las que (puesto que $y_{\boldsymbol{\beta}}(t)$ es una función par) $y_{\boldsymbol{\beta}}(\bar{t}_1) = y_{\boldsymbol{\beta}}(\bar{t}_2)$. Estas raíces corresponden entonces a una autointersección de la curva $\boldsymbol{\beta}$ sobre el eje de ordenadas. Para $r = 1/2p$ (las raíces $\bar{t}_{1,2}$ son iguales —a cero), la curva $\boldsymbol{\beta}$, aunque no regular (de hecho $\boldsymbol{\beta}'(0) = 0$), es simple.

Veamos un poco más de cerca qué ocurre cuando $r \geq 1/2p$ (es decir, cuando la curva $\boldsymbol{\beta}$ no es regular). En este caso la ecuación

$$1 - rk_{\alpha}(t) = 1 - \frac{2pr}{(1 + 4p^2t^2)^{3/2}} = 0$$

posee dos raíces en

$$t^*_{1,2} = \pm(1/2p)\left((2pr)^{2/3} - 1\right)^{1/2}$$

Nuevamente observamos que si $r = 1/2p$, estas raíces son iguales, y la curva $\boldsymbol{\beta}$, aunque no regular (pierde su regularidad únicamente en $t^*_1 = t^*_2$), es una curva simple (en este caso todas las raíces $\bar{t}_1$, $\bar{t}_2$, t^*_1, t^*_2 son iguales a cero). Cuando $r > 1/2p$, las raíces t^*_1 y t^*_2 son distintas, y se tiene además que $\bar{t}_1 < t^*_1 < t^*_2 < \bar{t}_2$. Por la simetría de la curva $\boldsymbol{\beta}$ respecto del eje de ordenadas, podemos concluír que la parte de la curva $\boldsymbol{\beta}$ entre $\bar{t}_1$ y $\bar{t}_2$, corresponde a un "loop" (simétrico respecto del eje de ordenadas) dentro del cual la curva pierde su regularidad en los puntos $\boldsymbol{\beta}(t^*_1)$ y $\boldsymbol{\beta}(t^*_2)$.

La figura 5 (tomando $p = 1$) ilustra los casos en los que $r = -1$ (curva regular paralela hacia el exterior de la parábola $y = x^2$), $r = 0.25 < 0.5 = 1/2p$ (curva regular paralela hacia el interior de la parábola) y $r = 1.8 > 1/2p$ (curva no regular paralela hacia el interior de la parábola).

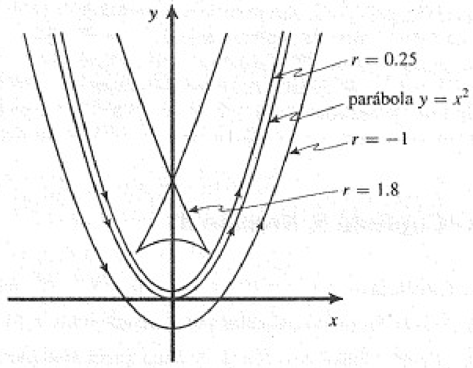

Figura 5. La parábola $y = x^2$ y sus curvas r-paralelas con $r = -1, 0.25, 1.8$.

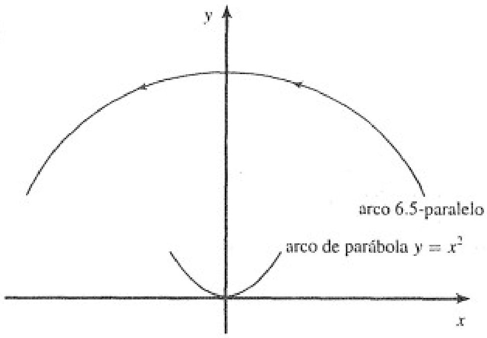

Figura 6. El arco de parábola $y = x^2$, $-1 \leq x \leq 1$ y su curva 6.5-paralela.

Si consideramos solamente un arco de parábola (simétrico respecto del eje de ordenadas), digamos $\boldsymbol{\alpha}: [-a, a] \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (t, pt^2)$, es posible hacer algunas observaciones adicionales a las anteriormente hechas en el caso general. En este caso la función curvatura $k_{\boldsymbol{\alpha}}: [-a, a] \to \mathbb{R}$

$$k_{\alpha}(t) = \frac{2p}{(1 + 4p^2t^2)^{3/2}}$$

alcanza su máximo absoluto en $t = 0$, que vale $k_{\alpha}(0) = 2p$, y alcanza también su mínimo absoluto en $t = \pm a$, que vale $k_{\alpha}(\pm a) = 2p/(1 + 4p^2a^2)^{3/2}$. LLamemos q a este valor. Se tiene entonces que la curva $\boldsymbol{\beta}$ será regular si y sólo si $r^{-1} \notin [q, 2p]$, es decir, si $r < 1/2p$ (como en el caso general) o si $r > 1/q = (1 + 4p^2a^2)^{3/2}/2p$. Este valor de q es positivo, lo indica la curva r-paralela $\boldsymbol{\beta}$ que está en la parte "interna" de la parábola. Es posible entonces tener una "imagen paralela al arco de parábola $y = px^2$, que sea regular". Observe sin embargo que el valor $1/q$ es en general muy grande (del orden de $4a^3$), lo que significa que "hay que despegarse mucho —hacia adentro, paralelamente— de la parábola para poder recuperar la regularidad de la curva r-paralela $\boldsymbol{\beta}$". Consideremos a manera de ejemplo el arco de parábola $\boldsymbol{\alpha}: [-1, 1] \to \mathbb{R}^2$, $\boldsymbol{\alpha}(t) = (t, t^2)$. En este caso $1/2p = 1/2$ y $q = 2/(5)^{3/2} = 0.1789$. Cuando $r < 1/2$, la curva $\boldsymbol{\beta}: [-1, 1] \to \mathbb{R}^2$, r-paralela a $\boldsymbol{\alpha}$, es regular, estando ésta en el exterior de la parábola cuando $r < 0$ y en su interior cuando $0 < r < 1/2$. Mientras r se encuentre entre $1/2$ y $1/q = 5.59016$, la curva $\boldsymbol{\beta}$ (en el interior de la parábola) no será regular y ésta vuelve a ser regular para $r > 5.59016$. La figura 6 ilustra esta situación.

Ejercicios (Capítulo 5, Sección 8)

1. Estudie las curvas paralelas a una recta $\boldsymbol{\lambda}: \mathbb{R} \to \mathbb{R}^2$, $\boldsymbol{\lambda}(t) = (t, mt + b)$.

2. Estudie las curvas paralelas a una circunferencia $\boldsymbol{\lambda}: [0, 2\pi] \to \mathbb{R}^2$, $\boldsymbol{\lambda}(t) = (a \cos t, a \operatorname{sen} t)$.

(***) **3.** ¿Cierto o falso? Sea $F(x, y) = 0$ una curva en el plano. Considere sus curvas ϵ-paralelas con ϵ pequeño. Estas pueden escribirse como $G(x, y) = 0$ si y sólo si la curva $F(x, y) = 0$ es una recta o una circunferencia.

of $> 10^6$ years. This could occur much more quickly on grain surfaces, or with charged particles. If the exchange is slow, the ortho and para modifications of a particular species behave like different molecules; a comparison of ortho and para populations might give an estimate of temperatures in the distant past, perhaps at the time of molecular formation.

For the H_2 molecule, the symmetry of the rotational wavefunction depends on the total angular momentum J as $(-1)^J$. In the $J = 0$ state the rotational wavefunction is symmetric. However, the total wavefunction must be antisymmetric since protons are fermions. Thus, the $J = 0, 2, 4$, etc., rotational levels are para-H_2, while the $J = 1, 3, 5$, etc., are ortho-H_2. Spectral lines can connect only one modification. In the case of H_2, dipole rotational transitions are not allowed, but quadrupole rotational transitions ($\Delta J = \pm 2$) are. Thus, the 28 μm line of H_2 connects the $J = 2$ and $J = 0$ levels of para-H_2. Transitions between the ground and vibrational states are also possible.

Finally, as a more complex example of the relation of identical nuclei, we consider the case of three identical nuclei. This is the case for NH_3, CH_3CN and CH_3C_2H. Exchanging two of the nuclei is equivalent to a rotation by 120°. An exchange as was used for the case of two nuclei would not, in general, lead to a suitable symmetry. Instead combinations of spin states must be used (see Townes and Schawlow 1975). These lead to the result that the ortho to para ratio is two to one if the identical nuclei are protons. That is, NH_3, CH_3CN or CH_3C_2H the ortho form has $S(J, K) = 2$, while the para form has $S(J, K) = 1$. In summary, the division of molecules with identical nuclei into ortho and para species determines selection rules for radiative transitions and also rules the for collisions.

15.5.3 Hyperfine Structure

For symmetric top molecules, examples of hyperfine spectra are found for the inversion doublet transitions of NH_3. Since both the upper and lower levels have the same quantum numbers (J, K), there will be five groups of hyperfine components separated by a few MHz. Because of interactions between the spins of H nuclei there will be an additional splitting, within each group, of order a few kHz. In Table 15.1 we give the relative intensities of the NH_3 satellites for the case of low optical depth and LTE. For a molecule such as OH, one of the electrons is unpaired. The interaction of the nuclear magnetic moment with the magnetic moment of an unpaired electron is described as magnetic hyperfine structure. This splits a specific line into a number of components. In the case of the OH molecule, this interaction gives rise to a hyperfine splitting of the energy levels, in addition to the much larger Λ doubling. Together with the Λ doublet splitting, this gives rise to a quartet of energy levels in the OH ground state. Transitions between these energy levels produce the four ground state lines of OH at 18 cm wavelength (see Fig. 15.9).

NH_3 is an example of an oblate symmetric top molecule commonly found in the ISM. A diagram of the lower energy levels of NH_3 are shown in Fig. 15.5. A prolate top molecule has a cigar-like shape. Then the value A replaces C, and A>B. The energy-level diagrams for prolate symmetric top molecules found in the ISM, such as CH_3CCH and CH_3CN, follow this rule. However, since these molecules are much heavier than NH_3, the rotational transitions give rise to lines in the millimeter wavelength range, whereas the rotational lines of ammonia are in the sub-mm range (see Churchwell and Hollis 1983).

Differences in the orientation of the nuclei can be of importance. If a reflection of all particles about the center of mass leads to a configuration which cannot be obtained by a rotation of the molecule, these reflections represent two different states. For NH_3, we show this situation in the upper part of Fig. 15.5. Then there are two separate, degenerate states which exist for each value of (J, K) for $J \geq 1$. The $K = 0$ ladder is an exception because of the Pauli principle. These states are doubly degenerate as long as the potential barrier separating the two configurations is infinitely high. However, in molecules such as NH_3 the two configurations are separated only by a smaller potential barrier. This gives rise to a measurable splitting of the degenerate energy levels, which is referred to as inversion doubling. For NH_3, transitions between these inversion doublet levels are caused by the quantum mechanical tunneling of the nitrogen nucleus through the plane of the three protons. The wavefunctions of the two inversion doublet states have opposite parities, so that dipole transitions are possible. Thus dipole transitions occur between states with the same (J, K) quantum numbers. The splitting of the (J, K) levels for NH_3 shown in Fig. 15.5 is exaggerated; the inversion transitions give rise to spectral lines in the wavelength range near 1 cm. For CH_3CCH or CH_3CN, the splitting caused by inversion doubling is very small since the barrier is much higher than for NH_3.

The direction of the dipole moment of symmetric top molecules is parallel to the K axis. Spectral line radiation can be emitted only by a changing dipole moment. Since radiation will be emitted perpendicular to the direction of the dipole moment, there can be no radiation along the symmetry axis. Thus the K quantum number *cannot* change in dipole radiation, so allowed dipole transitions cannot connect different K ladders. The different K ladders are connected by octopole radiative transitions which require $\Delta K = \pm 3$. These are very slow, however, and collisions are far more likely to cause an exchange of population between different K ladders. We will discuss this in Sect. 15.6.3 in connection with the determination of T_K using the ratio of populations of different (J, K) states in symmetric top molecules.

Fig. 15.5 The energy-level diagram of the vibrational ground state of ammonia, NH_3, an oblate symmetric top molecule. Ortho-NH_3 has $K = 0, 3, 6, 9, \cdots$, while para-NH_3 has all other K values (see text). Rotational transitions with $\Delta J = 1$, $\Delta K = 0$, give rise to lines in the far IR. This molecule also has transitions with $\Delta J = 0$, $\Delta K = 0$ between inversion doublet levels. The interaction of the nuclear spin of ^{14}N with the electrons causes quadrupole hyperfine structure. In the $\Delta J = 0$, $\Delta K = 0$ transitions, the line is split into five groups of components. A sketch of the structure of the groups of hyperfine components of the $(J, K) = (1,1)$ inversion doublet line is indicated in the *lower right*; the separation is of order of MHz. In the *upper right* is a sketch of the molecule before and after an inversion transition, which gives rise to a 1.3 cm photon (Adapted from Wilson et al. 2006)

3)*+,)))- !) . 0 $ /"
' $ 1 (

By generating retrograde motion through this final construction, Eudoxus demonstrates his mastery of geometry. Below, we discuss some details of the construction. The presentation fully exploits mathematics that were not available to Eudoxus, including trigonometry, Cartesian coordinates, analytic geometry, linear algebra, and Euler angles. With these tools, not fully developed until two millennia after Eudoxus, the solution is manageable. Before continuing, take a moment to imagine the orbit of a point along the equator of a spinning sphere fixed on another spinning sphere that is then again fixed on another spinning sphere, which is finally tethered to an outermost spinning sphere. Imagine, without our modern mathematical tools, structuring the correct alignment of the axes and the speed of the spins to create a desired motion, such as retrograde motion. As you imagine this, Eudoxus earns your respect.[1]

The Whole

Eudoxus' heavens, the universal sphere and all other spheres perfectly centered around the earth, fit together as a whole through a system ordered according to distance from the earth. The center of the universe is Earth. On the closest sphere sits the moon. The next occupied sphere hosts Mercury, followed by Venus, the sun, Mars, Jupiter, Saturn, and finally the universal sphere. Aristotle, memorialized this universe in his writings. Later in time, the Church would deify Aristotle and in the process, canonize Eudoxus' universe.

THE MATH

Below we present the mathematics of Eudoxus' solar orbit and the orbit of a planet with retrograde motion. To begin, let us describe the construction of the orbits as an algorithm. Once this verbal description is available, we can associate mathematical operations with each step. The algorithm applies to each body separately.

Preliminary Step. Suspend the spheres concentrically so that they are all centered on the earth and so that their axes of rotation are all aligned along the north–south axis of the earth. Seat the planet or sun upon the equator of the innermost sphere.

Step 1. Among the stationary spheres, spin the innermost one at its appropriate speed and direction.

Step 2. Tilt the axis of the sphere from step 1 at an appropriate angle, and affix the axis to the immediate sphere that envelopes it.

Step 3. Return to step 1 until all the spheres are spinning.

---

[1] As an aid, a nice visual that displays the retrograde motion of a planet along three concentric circles is available on the website http://hsci.cas.ou.edu/images/applets/hippopede.html.

Two operations are of interest: (1) spinning a sphere with its axis aligned along the north–south direction and (2) tilting and affixing the sphere. These operations proceed from the innermost sphere outward toward the universal sphere.

To describe these operations mathematically, some notation is necessary. We consider three-dimensional Euclidean space in which (x,y,z) form the standard orthogonal coordinate system. Center the earth at the origin of the system and point the z axis directly north. The z axis is the axis of rotation for the universal sphere. Alongside Euclidean space, we append a time variable t, with the solar year as its unit measurement. A vector $(x(t), y(t), z(t))^T$ gives the (x,y,z) position of the sun or planet at time t.

Each sphere has a rate and direction of rotation designated by the real number ω_j. A positive value of ω_j indicates spin in a clockwise direction as viewed by an individual on the z axis looking down on the universal sphere from the outside. The subscript j identifies the associated sphere from the innermost to the universal sphere. With this notation, ω_1 is the angular velocity of the innermost sphere, ω_2 is the angular velocity of its immediate outer neighbor, ω_3 is the angular velocity of the third most inner sphere, and so forth. If there are m spheres, then ω_m is the angular velocity of the universal sphere.

Aside from the angular velocity, each sphere, excluding the universal sphere, has a tilt angle with respect to the axis of its immediate outer neighbor. We designate the tilt angle by θ_j, whereas with the angular velocity, the subscript j identifies the associated sphere.

With this notation, we are ready to mathematically describe the algorithm. The preliminary step sets the position of the body prior to performing any operations. The body maintains a constant distance from the earth that we arbitrarily set at one. This requires that the innermost sphere's radius be one. The preliminary step initially seats the body at the position $(0, 0, 1)^T$ on the innermost sphere; note that this position lies on the sphere's equator.

Step 1 imputes a rotation about the z axis through the angle $\omega_j t$, the angle is the product of the angular velocity and time. A vector executes the desired rotation when operated on by the following matrix.

$$R_{\omega_j}(t) = \begin{bmatrix} \cos(\omega_j t) & -\sin(\omega_j t) & 0 \\ \sin(\omega_j t) & \cos(\omega_j t) & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

For example, applying the matrix to the vector $(1, 0, 3)^T$ yields the following result:

$$R_{\omega_j}(t)\begin{bmatrix}1\\0\\3\end{bmatrix} = \begin{bmatrix} \cos(\omega_j t) & -\sin(\omega_j t) & 0 \\ \sin(\omega_j t) & \cos(\omega_j t) & 0 \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix}1\\0\\3\end{bmatrix} = \begin{bmatrix}\cos(\omega_j t)\\ \sin(\omega_j t)\\ 3\end{bmatrix}$$

The (x,y) components of the vector $(1, 0, 3)^T$ are rotated to the values $(\cos(\omega_j t), \sin(\omega_j t))$, while the z component remains fixed at the value 3.

Step 2 tilts the sphere at a prescribed angle θ_j. A tilt is also a rotation that we perform in the (y, z) plane leaving the x axis fixed. The rotation matrix is given as follows.

$$T_{\theta_j} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(\theta_j) & -\sin(\theta_j) \\ 0 & \sin(\theta_j) & \cos(\theta_j) \end{bmatrix}$$

For example, applying the matrix to the vector $(3, 0, 1)^T$ yields the following result:

$$T_{\theta_j}\begin{bmatrix} 3 \\ 0 \\ 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(\theta_j) & -\sin(\theta_j) \\ 0 & \sin(\theta_j) & \cos(\theta_j) \end{bmatrix}\begin{bmatrix} 3 \\ 0 \\ 1 \end{bmatrix} = \begin{bmatrix} 3 \\ -\sin(\theta_j) \\ \cos(\theta_j) \end{bmatrix}$$

The x value of the vector remains fixed, while the (y,z) components are tilted through the angle θ_j.

We are now in a position to mathematically describe the motion of the sun as follows:

$$\begin{bmatrix} x(t) \\ y(t) \\ z(t) \end{bmatrix} = R_{\omega_2}(t)T_{\theta_1}R_{\omega_1}(t)\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} \cos(\omega_2 t) & -\sin(\omega_2 t) & 0 \\ \sin(\omega_2 t) & \cos(\omega_2 t) & 0 \\ 0 & 0 & 1 \end{bmatrix}$$
$$\times \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(\theta_1) & -\sin(\theta_1) \\ 0 & \sin(\theta_1) & \cos(\theta_1) \end{bmatrix}\begin{bmatrix} \cos(\omega_1 t) & \sin(\omega_1 t) & 0 \\ \sin(\omega_1 t) & \cos(\omega_1 t) & 0 \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}$$

We can march through the algorithm by reading the expression from right to left, reflecting the fact that the first operation on the initial vector is the far-right matrix, the second operation is the next matrix in the center, and the final operation is the far-left matrix.

Preliminary Step. The sun's preliminary position is set at (1,0,0).

Step 1. Since the solar ring completes one revolution annually, the value ω_1 is -2π. The matrix,

$$\begin{bmatrix} \cos(-2\pi t) & -\sin(-2\pi t) & 0 \\ \sin(-2\pi t) & \cos(-2\pi t) & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

spins the initial vector in a counterclockwise direction.

Step 2. The value θ_1 is equal to the angle of the ecliptic with the equatorial plane. The matrix,

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\left(2\pi\dfrac{23.5}{360}\right) & -\sin\left(2\pi\dfrac{23.5}{360}\right) \\ 0 & \sin\left(2\pi\dfrac{23.5}{360}\right) & \cos\left(2\pi\dfrac{23.5}{360}\right) \end{bmatrix},$$

tilts the solar ring through an angle of 23.5 degrees aligning the sun's orbit with the ecliptic.

Return to Step 1. Since the stars circle about the universal axis 366 times per year, the value ω_2 is 732π. The matrix,

$$\begin{bmatrix} \cos(732\pi t) & -\sin(732\pi t) & 0 \\ \sin(732\pi t) & \cos(732\pi t) & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

rotates the universal sphere clockwise. We are done.

Performing the matrix multiplications and simplification gives the following result for the sun's trajectory:

$$\begin{bmatrix} x(t) \\ y(t) \\ z(t) \end{bmatrix} = \begin{bmatrix} \cos(\omega_2 t)\cos(\omega_1 t) - \cos(\theta_1)\sin(\omega_2 t)\sin(\omega_1 t) \\ \sin(\omega_2 t)\cos(\omega_1 t) - \cos(\theta_1)\cos(\omega_2 t)\sin(\omega_1 t) \\ -\sin(\theta_1)\sin(\omega_2 t) \end{bmatrix}$$

There are a few notable features in this solution. As expressed by the z value, the sun oscillates up to a maximum value of $\sin(\theta_1)$ and a minimum value of $-\sin(\theta_1)$. The way everything has been set, the initial time represents the fall equinox, where the ecliptic and the equatorial plane intersect. The sun first attains its minimum and maximum values at $t = \frac{1}{4}$, the winter solstice, and $t = \frac{3}{4}$, the summer solstice, and annually after that. The maximum angle of latitude is θ_1, which, as previously noted, is the angle between the ecliptic and the equatorial plane.

Because the rates of rotation, ω_1 and ω_2, are both integral multiples of 2π, the values $(x(t),y(t),z(t))$ are cyclic with an annual period. Indeed, the sun returns to its initial position at (1,0,0) after one year and then repeats its orbit.

After this solar warmup exercise, we are ready to chase the planets and capture retrograde motion. The rotate, tilt, rotate, tilt ... algorithm applied to four spheres expresses itself through the following mathematical equation:

$$\begin{bmatrix} x(t) \\ y(t) \\ z(t) \end{bmatrix} = R_{\omega_4}(t)T_{\theta_3}R_{\omega_3}(t)T_{\theta_2}R_{\omega_2}(t)T_{\theta_1}R_{\omega_1}(t)\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}$$

Here we are concerned primarily with the first and second spheres as these spheres are most responsible for the retrograde motion. Set the angular velocities of the two innermost spheres equal in magnitude but opposite in direction to one another: $\omega_2 = -\omega_1$. We examine this case for an arbitrary tilt angle θ_1.

Evaluating the expression

$$R_{-\omega_1}(t)T_{\theta_1}R_{\omega_1}(t)\begin{bmatrix}1\\0\\0\end{bmatrix}$$

gives the following result:

$$\begin{aligned}\begin{bmatrix}\tilde{x}(t)\\\tilde{y}(t)\\\tilde{z}(t)\end{bmatrix} &= R_{-\omega_1}(t)T_{\theta_1}R_{\omega_1}(t)\begin{bmatrix}1\\0\\0\end{bmatrix}\\ &= \begin{bmatrix}\cos^2(\omega_1 t)+\cos(\theta_1)\sin^2(\omega_1 t)\\(\cos(\theta_1)-1)\sin(\omega_1 t)\cos(\omega_1 t)\\\sin(\theta_1)\sin(\omega_1 t)\end{bmatrix}\end{aligned}\tag{2.1}$$

Our first problem is to describe the path of the planet absent the influence of the third sphere and universal sphere. (The tildas emphasize that this is not a complete description of the path since not all spheres are considered.) First let us describe the relation between $\tilde{x}(t)$ and $\tilde{y}(t)$. Using trigonometric identities, it is possible to solve for both $\sin(\omega_1 t)$ and $\cos(\omega_1 t)$ in terms of $\tilde{x}$. On substituting the solutions into the equation for $\tilde{y}(t)$, the relation between $\tilde{x}$ and $\tilde{y}$ emerges. The steps are as follows:

$$\begin{aligned}\tilde{x} &= \cos^2(\omega_1 t)+\cos(\theta_1)\sin^2(\omega_1 t)\\ &= 1-\sin^2(\omega_1 t)+\cos(\theta_1)\sin^2(\omega_1 t)\\ &= 1+(\cos(\theta_1)-1)\sin^2(\omega_1 t)\end{aligned}$$

Solving for $\sin^2(\omega_1 t)$ yields the following equality:

$$\sin^2(\omega_1 t) = \frac{\tilde{x}-1}{\cos(\theta_1)-1}\tag{2.2}$$

A similar calculation in which one uses the Pythagorean identity to substitute for $\sin^2(\omega_1 t)$ yields the following result:

$$\cos^2(\omega_1 t) = \frac{\tilde{x}-\cos(\theta_1)}{1-\cos(\theta_1)}\tag{2.3}$$

Substituting expressions (2.2) and (2.3) into the equation for $\tilde{y}(t)$ [i.e., (2.1)] and simplifying gives the following relation between $\tilde{x}$ and $\tilde{y}$:

$$\begin{aligned}
\tilde{y} &= (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t) \\
\tilde{y}^2 &= (\cos(\theta_1) - 1)^2 \sin^2(\omega_1 t)\cos^2(\omega_1 t) \\
&= (\cos(\theta_1) - 1)^2 \left(\frac{\tilde{x} - 1}{\cos(\theta_1) - 1}\right)\left(\frac{\tilde{x} - \cos(\theta_1)}{1 - \cos(\theta_1)}\right) \\
&= (1 - \tilde{x})(\tilde{x} - \cos(\theta_1)) \\
&= -\tilde{x}^2 + (1 + \cos(\theta_1))\,\tilde{x} - \cos(\theta_1) \\
&= -\left(\tilde{x} - \frac{1 + \cos(\theta_1)}{2}\right)^2 + \left(\frac{1 + \cos(\theta_1)}{2}\right)^2 - \cos(\theta_1) \\
&= -\left(\tilde{x} - \frac{1 + \cos(\theta_1)}{2}\right)^2 + \left(\frac{1 - \cos(\theta_1)}{2}\right)^2
\end{aligned}$$

In two dimensions the path of $\tilde{x}(t)$ and $\tilde{y}(t)$ is the circle centered at $(\tilde{x}, \tilde{y}) = \left(\frac{1+\cos(\theta_1)}{2}, 0\right)$ with radius $\frac{1-\cos(\theta_1)}{2}$:

$$\left(\tilde{x} - \frac{1 + \cos(\theta_1)}{2}\right)^2 + \tilde{y}^2 = \left(\frac{1 - \cos(\theta_1)}{2}\right)^2 \tag{2.4}$$

Returning to three-dimensional space, the result obtained above necessitates that the planet's orbit confine itself to the surface of the cylinder whose cross section at any constant value of z is the circle of equation (2.4). Also note that in three dimensions, because the inner sphere's center always remains fixed and the inner sphere's radius is one, the planet meanders about the sphere $\tilde{x}^2 + \tilde{y}^2 + \tilde{z}^2 = 1$. The shape of the planet's path, absent the influence of the third sphere and the universal sphere, is then the intersection of these two surfaces (see Figure 2.5).

The resulting intersection appears like a figure eight that has been stamped on a sphere. A further analysis of the path given by equation (2.1) reveals that the planet begins at the cross of the figure eight and skates about the upper loop (assuming that θ_1 ranges between 0 and 180 degrees). After returning to the cross, the planet skates about the lower loop. Eudoxus calls the figure a hippopede, meaning horse fetter.

Before continuing, note the influence of the tilt angle θ_1 as it ranges from 0 to 180 degrees. When the tilt angle is 0 degree, the two spheres are aligned and spinning in opposite directions. The planet never moves but remains at its initial point. One can see that the circle of equation (2.4) shrinks to a point at which the corresponding cylinder shrinks to its central axis and intersects the sphere tangentially at the point (1,0,0). As we increase the tilt angle toward 90 degrees, the radius of the cylinder increases, while its surface remains tangent to the sphere at the point (1,0,0). This increases the size of the figure eight, and

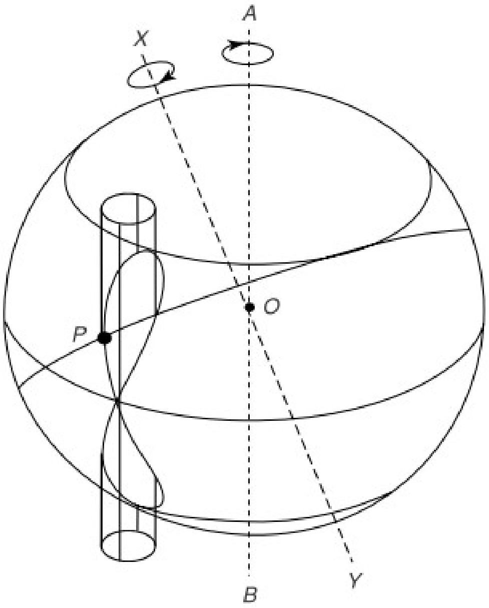

Figure 2.5. The hippopede.

the figure reaches its greatest vertical extent when the angle is 90 degrees and the loops touch the poles. Beyond 90 degrees the loops begin to approach one another, sliding toward the equator around the poles until at 180 degrees they meet up with one another and the planet spins around the equatorial plane at the rate $2\omega_1$.

Proceeding to step 2 of the algorithm, we tilt the figure eight and affix it to the third sphere. Let the tilt angle θ_2 be 90 degrees so that the figure eight lies on its side, becoming an infinity sign. Applying the tilt yields the following result:

$$\begin{aligned}
\begin{bmatrix} \tilde{x}(t) \\ \tilde{y}(t) \\ \tilde{z}(t) \end{bmatrix} &= T_{\theta_2} R_{-\omega_1}(t) T_{\theta_1} R_{\omega_1}(t) \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \\
&= T_{\theta_2} \begin{bmatrix} \cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t) \\ (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t) \\ \sin(\theta_1)\sin(\omega_1 t) \end{bmatrix} \\
&= \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & -1 \end{bmatrix} \begin{bmatrix} \cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t) \\ (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t) \\ \sin(\theta_1)\sin(\omega_1 t) \end{bmatrix} \\
&= \begin{bmatrix} \cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t) \\ -\sin(\theta_1)\sin(\omega_1 t) \\ (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t) \end{bmatrix}
\end{aligned}$$

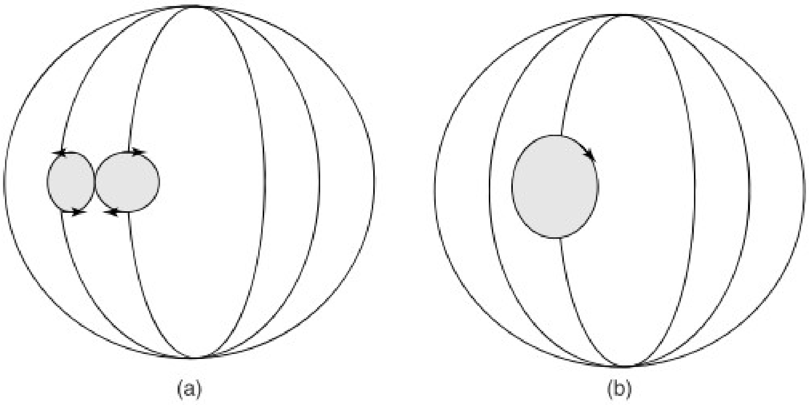

Figure 2.6. Comparison of motion along hippopede (a) and circle (b).

After this tilt, the planet skates around the resting figure eight traversing back and forth somewhat along the universal equator (see Figure 2.6a). The next step is to impute a rotation that governs the drift of the planet through the zodiac. It is the combination of the uniform drift along with the skate around the figure eight that creates retrograde motion. As an aid toward visualizing what occurs, let's consider a simpler construction with a similar feature.

For the simplified construct, assume that the planet lies at the intersection of a cylinder whose central axis is the x axis and a sphere. The intersection is a circle as displayed in Figure 2.6b, which contrasts this construct with that of Eudoxus. As displayed in the figure, the planet rotates uniformly about the intersecting circle, causing it to change direction, just as Eudoxus' skating planet. Next let's rotate this planet about the heavens. To make a mechanical device that replicates the motion, build a track around a great circle of the universal sphere and place a wheel connected to Earth with an axle on the track. Somewhat closer to Earth, on the axle, attach a pointer that rotates with the wheel. As the wheel rotates uniformly about its track, the tip of the pointer gives the location of the planet. As Figure 2.7 illustrates, while following a trend through the constellations, the orbit loops about itself in retrograde motion. Eudoxus' skating planet, skating back and forth along its figure eight as it trends through the zodiac, produces retrograde motion in a similar manner.

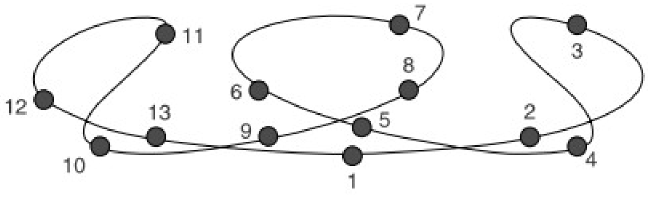

Figure 2.7. Simplified model yielding three retrograde loops every trip around the zodiac.

Returning to Eudoxus' construction, we next spin the third sphere. The third sphere governs the rate at which the planet floats through the constellations, requiring that the angular velocity ω_3 give the radian measurement of the planet's cycle through the universal sphere in one year's time. (Recall that the sun cycles through the zodiac one time per year, so the angular velocity of its sphere is 2π.) Mars skates through the zodiac around 1.06 times every 2 years or gets a little over halfway through in one year. The associated angular velocity ω_3 is about -1.06π. Applying the spin of the third sphere to the planet results in the following trajectory:

$$\begin{aligned}
\begin{bmatrix} \tilde{x}(t) \\ \tilde{y}(t) \\ \tilde{z}(t) \end{bmatrix} &= R_{\omega_3} T_{\theta_2} R_{-\omega_1}(t) T_{\theta_1} R_{\omega_1}(t) \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \\
&= R_{\omega_3} \begin{bmatrix} \cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t) \\ -\sin(\theta_1)\sin(\omega_1 t) \\ (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t) \end{bmatrix} \\
&= \begin{bmatrix} \cos(\omega_3 t) & \sin(\omega_3 t) & 0 \\ -\sin(\omega_3 t) & \cos(\omega_3 t) & 0 \\ 0 & 0 & 1 \end{bmatrix} \\
&\quad \times \begin{bmatrix} \cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t) \\ -\sin(\theta_1)\sin(\omega_1 t) \\ (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t) \end{bmatrix} \\
&= \begin{bmatrix} \left(\cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t)\right)\cos(\omega_3 t) \\ -\sin(\theta_1)\sin(\omega_1 t)\sin(\omega_3 t) \\ -\left(\cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t)\right)\sin(\omega_3 t) \\ +\sin(\theta_1)\sin(\omega_1 t)\cos(\omega_3 t) \\ (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t) \end{bmatrix}
\end{aligned}$$

As the $\tilde{z}(t)$ component of the trajectory indicates, the planet oscillates about the equatorial plane $\tilde{z} = 0$. In reality, the planets hug the ecliptic. A tilt of the third sphere toward the ecliptic ($\theta_3 = 23.5$ degrees) reorients the planet:

$$\begin{aligned}
\begin{bmatrix} \tilde{x}(t) \\ \tilde{y}(t) \\ \tilde{z}(t) \end{bmatrix} &= T_{\theta_3} R_{\omega_3} T_{\theta_2} R_{-\omega_1}(t) T_{\theta_1} R_{\omega_1}(t) \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \\
&= T_{\theta_3} \begin{bmatrix} \left(\cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t)\right)\cos(\omega_3 t) \\ -\sin(\theta_1)\sin(\omega_1 t)\sin(\omega_3 t) \\ -\left(\cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t)\right)\sin(\omega_3 t) \\ +\sin(\theta_1)\sin(\omega_1 t)\cos(\omega_3 t) \\ (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t) \end{bmatrix}
\end{aligned}$$

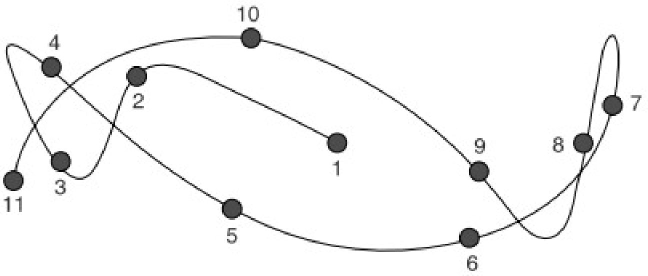

Figure 2.8. Eudoxus' planet with retrograde orbit.

$$T_{\theta_3} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos(\theta_3) & -\sin(\theta_3) \\ 0 & \sin(\theta_3) & \cos(\theta_3) \end{bmatrix}$$

The results for $(\tilde{x}(t), \tilde{y}(t), \tilde{z}(t))$ are as follows:

$$\begin{aligned} \tilde{x}(t) &= \left(\cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t)\right)\cos(\omega_3 t) \\ &\quad - \sin(\theta_1)\sin(\omega_1 t)\sin(\omega_3 t) \\ \tilde{y}(t) &= \left[-\left(\cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t)\right)\sin(\omega_3 t)\right. \\ &\quad \left. + \sin(\theta_1)\sin(\omega_1 t)\cos(\omega_3 t)\right]\cos(\theta_3) \\ &\quad - (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t)\sin(\theta_3) \\ \tilde{z}(t) &= \left[-\left(\cos^2(\omega_1 t) + \cos(\theta_1)\sin^2(\omega_1 t)\right)\sin(\omega_3 t)\right. \\ &\quad \left. + \sin(\theta_1)\sin(\omega_1 t)\cos(\omega_3 t)\right]\sin(\theta_3) \\ &\quad + (\cos(\theta_1) - 1)\sin(\omega_1 t)\cos(\omega_1 t)\cos(\theta_3) \end{aligned}$$

These equations encode retrograde motion through the zodiac. Figure 2.8 is a graph of the orbit. The animation at http://hsci.cas.ou.edu/images/applets/hippopede.html uses these equations. There is only one more operation left to complete the description: to spin the universal sphere to endow the planet with its daily motion. We leave Eudoxus' model incomplete and allow the reader seeking perfection to remove the tildas and complete it.

APOLLONIUS’ OSCULATING CIRCLE AND THE ELLIPSE

We restrict our investigation to the case of the ellipse. Begin with the equation for an ellipse

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \tag{4.1}$$

where a is the major axis and b is the minor axis of the ellipse.

Let (x_0, y_0) be an arbitrary point in the plane of the ellipse. We seek an equation for a normal line from the ellipse to the point. The equation for a general line passing through the point (x_0, y_0) is $y - y_0 = m(x - x_0)$, where m is the slope of the line. It is necessary to determine the slope for a normal line. As Apollonius neatly demonstrates, it is possible to solve this without resorting to calculus.[4] Here we fully employ the power of calculus. With the knowledge that the gradient of a function points in the normal direction of the function’s constant level surfaces, we find the gradient of the function $f(x, y) = \frac{x^2}{a^2} + \frac{y^2}{b^2}$, from which it is possible to determine the slope of the normal line:

$$\left(\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y}\right) = \left(\frac{2x}{a^2}, \frac{2y}{b^2}\right)$$

---

[4] Select an arbitrary point on the ellipse, (x_e, y_e) and write a general equation for all lines passing through that point:

$$\begin{aligned} y - y_e &= m_t(x - x_e) \\ y &= m_t(x - x_e) + y_e \end{aligned}$$

Next, substitute for the y variable in (4.1) using the right-hand side (RHS) of this equation. The result is a quadratic equation.

$$\begin{aligned} \frac{x^2}{a^2} + \frac{(m_t(x - x_e) + y_e)^2}{b^2} &= 1 \\ \left(\frac{1}{a^2} + \frac{m_t^2}{b^2}\right)x^2 + \left(\frac{2m_t(y_e - m_t x_e)}{b^2}\right)x + \frac{(y_e - m_t x_e)^2}{b^2} - 1 &= 0 \end{aligned}$$

As the tangent line intersects this equation in one point, we look for a single solution to the quadratic equation:

$$x = \frac{-\left(\frac{2m_t(y_e - m_t x_e)}{b^2}\right) \pm \sqrt{\left(\frac{2m_t(y_e - m_t x_e)}{b^2}\right)^2 - 4\left(\frac{1}{a^2} + \frac{m_t^2}{b^2}\right)\left(\frac{(y_e - m x_e)^2}{b^2} - 1\right)}}{2\left(\frac{1}{a^2} + \frac{m_t^2}{b^2}\right)}$$

The solution reduces to a single point when the expression under the radical vanishes. The reader can check that this occurs when $m_t = -\frac{b^2 x_e}{a^2 y_e}$. The normal line is at right angles to the tangent line and accordingly has slope $m = \frac{a^2 y_e}{b^2 x_e}$.

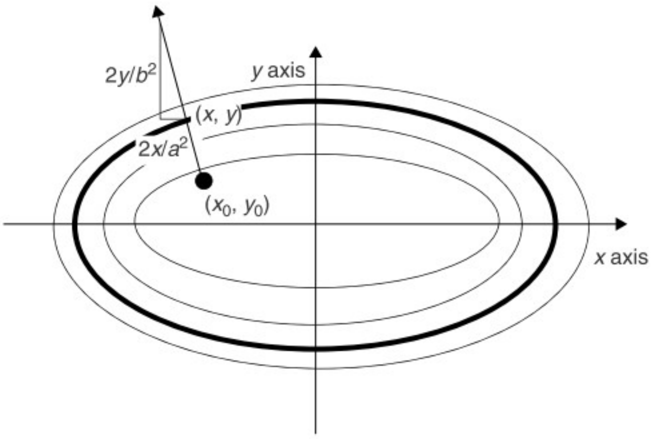

Figure 4.2. Gradient vector gives slope of normal line.

Then the slope of the normal line is given by the following equation (see Figure 4.2):

$$m = \frac{a^2 y}{b^2 x} \tag{4.2}$$

Placing the value of m into the equation of the normal line passing through the point (x_0, y_0) and simplifying results in an equation that describes a double branched hyperbola:

$$\begin{aligned} y - y_0 &= m(x - x_0) \\ y - y_0 &= \frac{a^2 y}{b^2 x}(x - x_0) \\ b^2 x(y - y_0) &= a^2 y(x - x_0) \\ (a^2 - b^2)xy + b^2 y_0 x - a^2 x_0 y &= 0 \end{aligned} \tag{4.3}$$

We can conclude that when the normal line to the point (x_0, y_0) intersects the ellipse of equation (4.1) at coordinates (x, y), it also intersects the double-branched hyperbola of equation (4.3) at the same coordinates (x, y). Several more conclusions are possible:

1. The point (x_0, y_0) determines the configuration of the hyperbola and hence the number of intersections with the ellipse.
2. We conclude that the number of intersections between the ellipse and the hyperbola gives the number of normal lines, which is the answer to Apollonius' problem. Figure 4.3 illustrates the possible ways in which the figures can intersect. We can see that at most there can be four normal lines to

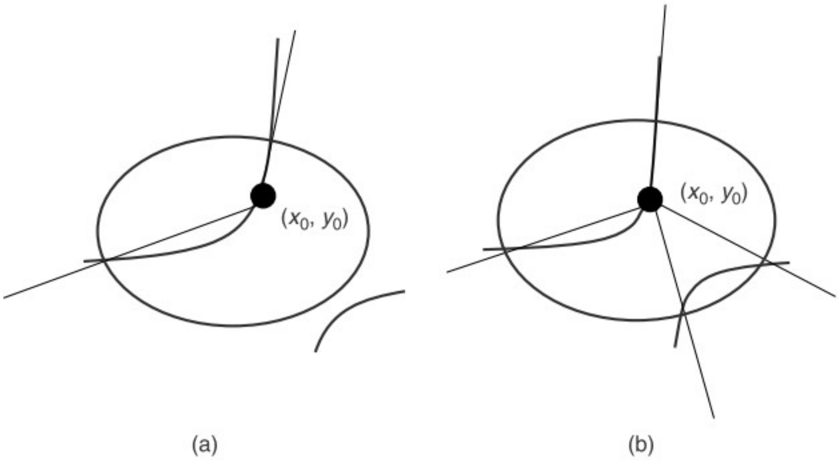

Figure 4.3. Intersection of hyperbola with ellipse: (a) two intersections, two normal lines; (b) four intersections, four normal lines.

a point as given by four points of intersection (Figure 4.3b). Noting that the minimum and maximum distances from the ellipse to a point are given by the length of the normal section, we can also conclude that there are at least two normals to a point, one associated with the minimum distance and one associated with the maximum distance. In fact, since one branch of the hyperbola passes through the origin and extends to infinity in two directions, there must be at least two points of intersection (Figure 4.3a).

3. Finally, we note that three normals to a point occur when one branch of the hyperbola is tangent to the ellipse, yielding a single point of intersection (Figure 4.4). This final conclusion is critical in our further analysis.

An algebraic analysis also yields some of the same conclusions. Let us find an equation for the intersections between the ellipse of equation (4.1) and the hyperbola of equation (4.3). Rearranging equation (4.3) and squaring results in the following equation:

$$(a^2 - b^2)xy + b^2xy_0 - a^2yx_0 = 0$$

$$(a^2 - b^2)xy - a^2yx_0 = -b^2xy_0$$

$$\left((a^2 - b^2)x - a^2x_0\right) y = -b^2xy_0$$

$$\left((a^2 - b^2)x - a^2x_0\right)^2 y^2 = b^4x^2y_0^2$$

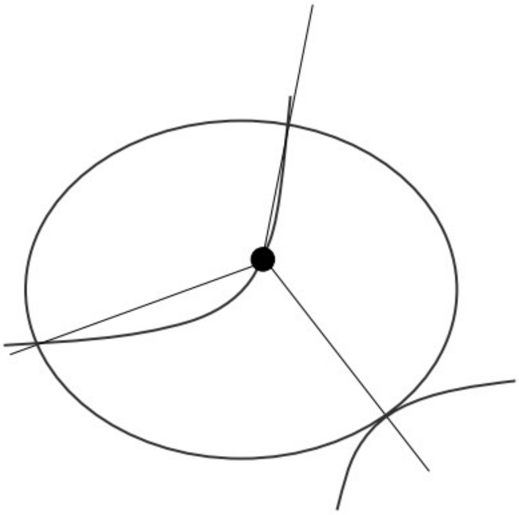

Figure 4.4. Intersection of hyperbola with ellipse: three intersections, three normal lines.

Next, solving for the value y^2 in equation (4.1) and substituting the result into this equation yields a quartic polynomial in x:

$$\begin{aligned}\frac{x^2}{a^2}+\frac{y^2}{b^2}&=1\\ y^2&=b^2\left(1-\frac{x^2}{a^2}\right)\\ \left((a^2-b^2)x-a^2x_0\right)^2y^2&=b^4x^2y_0^2\\ \left((a^2-b^2)x-a^2x_0\right)^2\left(1-\frac{x^2}{a^2}\right)&=b^2x^2y_0^2\\ \left((a^2-b^2)x-a^2x_0\right)^2(a^2-x^2)-a^2b^2x^2y_0^2&=0 \qquad (4.4)\end{aligned}$$

Before continuing, we make the following observations. At most, there are four solutions to the quartic polynomial, indicating that any point has at most four normals. Evaluating the quartic polynomial at the points $x=\pm a$ and $x=0$ yields the following:

$$\begin{aligned}\left((a^2-b^2)a^2-a^2x_0\right)^2(a^2-a^2)-b^2a^4y_0^2&=-b^2a^4y_0^2\\ \left((a^2-b^2)0-a^2x_0\right)^2(a^2-0^2)-a^2b^20^2y_0^2&=a^6x_0^2\end{aligned}$$

Since the sign of the quartic changes between $x=-a$ and $x=0$, there is at least one root between these values. By the same argument, there is at least one root between $x = 0$ and $x = a$. So there are at least two roots, equating to two normal lines to any point.[5] The algebraic analysis is consistent with the geometric analysis.

The first individual to solve the quartic polynomial was Lodovico Ferarri in the sixteenth century.[6] This solution was not available to Apollonius. Nevertheless, Apollonius went on to discover further relations that allow one to specify the number of normal lines to any given point. Below, we find the solution without explicitly solving the quartic polynomial.

It is of interest to find the set of points where there are three normals. It turns out that this set defines a closed curve; within the curve there are four normals, on the curve there are three normals, and outside the curve there are two normals. To determine the curve, let x_0 and y_0 be variables and seek a curve of the form $g(x_0, y_0) = 0$.

Note that equation (4.3) is linear in both x_0 and y_0. Using the observation that a branch of the hyperbola associated with a point having three normals is tangent to the ellipse (see Figure 4.4), one can obtain another relation between x_0 and y_0. At the tangent point the normal to the ellipse is aligned with that of the hyperbola. Using equation (4.3), we set $h(x, y) = (a^2 - b^2)xy + b^2xy_0 - a^2yx_0$, giving a family of hyperbolas. The gradient of $h(x, y)$ is aligned with the normal vector:

$$\left(\frac{\partial h}{\partial x}, \frac{\partial h}{\partial y}\right) = \left((a^2 - b^2)y + b^2y_0, (a^2 - b^2)x - a^2x_0\right)$$

The slope of the normal line is $m = \frac{(a^2-b^2)x-a^2x_0}{(a^2-b^2)y+b^2y_0}$, which we can equate with the slope from the previous calculation, equation (4.2):

$$\begin{aligned} m &= \frac{(a^2 - b^2)x - a^2x_0}{(a^2 - b^2)y + b^2y_0} \\ &= \frac{a^2y}{b^2x} \end{aligned} \tag{4.5}$$

Simplifying the expression yields another linear equation in x_0 and y_0:

$$\begin{aligned} \frac{(a^2 - b^2)x - a^2x_0}{(a^2 - b^2)y + b^2y_0} &= \frac{a^2y}{b^2x} \\ \left((a^2 - b^2)x - a^2x_0\right)b^2x &= \left((a^2 - b^2)y + b^2y_0\right)a^2y \end{aligned}$$

---

[5] Because of the symmetry of the ellipse of equation (4.1), no spurious roots were introduced by squaring equation (4.2).

[6] An interesting story surrounds the discovery of the solution to the quartic polynomial. Ferarri and a compatriot, Tartaglia, went at one another over priority rights for discovery of the cubic. Their public argument culminated in a public mathematical duel. For details, see *The Ellipse* by the author [(Mazer 2010); see Bibliography at end of this book].

$$-a^2b^2(xx_0 + yy_0) = \frac{a^2 - b^2}{a^2b^2}(b^2x^2 - a^2y^2)$$

$$xx_0 + yy_0 = \frac{a^2 - b^2}{a^2b^2}(b^2x^2 - a^2y^2) \tag{4.6}$$

Equations (4.3) and (4.6) form a pair of linear equations in the variables x_0 and y_0. We next solve this system of equations for the variable x_0:

$$a^2yx_0 - b^2xy_0 = -(a^2 - b^2)xy$$

$$xx_0 + yy_0 = \frac{a^2 - b^2}{a^2b^2}(b^2x^2 - a^2y^2)$$

Multiplying the top equation by y and the bottom equation by b^2x and adding the two outcomes eliminates the y_0 variable and results in an equation in x_0:

$$(a^2y^2 + b^2x^2)x_0 = -(a^2 - b^2)xy^2 + \frac{a^2 - b^2}{a^2}(b^2x^3 - a^2xy^2)$$

$$(a^2y^2 + b^2x^2)x_0 = \frac{a^2 - b^2}{a^2}b^2x^3$$

Next, using the equation for the ellipse [eq. (4.1)], note that $a^2y^2 + b^2x^2 = a^2b^2$. Substituting this identity into the expression above results in a relationship between x and x_0:

$$(a^2y^2 + b^2x^2)x_0 = \frac{a^2 - b^2}{a^2}b^2x^3$$

$$a^2b^2x_0 = \frac{a^2 - b^2}{a^2}b^2x^3 \tag{4.7}$$

$$x_0 = \frac{a^2 - b^2}{a^4}x^3$$

Equation (4.7) has a nice geometric interpretation as follows. Assume that we start off with a point on the ellipse, (x, y) and ask ourselves at what value x_0 does the normal line to (x, y) intersect exactly two other normal lines. Equation (4.7) answers this question. With this relationship it is possible to find the curve of interest: $g(x_0, y_0)$.

One can make a similar calculation, or assert by symmetry the following equation between y and y_0:

$$y_0 = \frac{b^2 - a^2}{b^4}y^3 \tag{4.8}$$

From equations (4.7) and (4.8) one obtains the following:

$$\left(\frac{ax_0}{a^2-b^2}\right)^{2/3} = \frac{x^2}{a^2}$$

$$\left(\frac{by_0}{a^2-b^2}\right)^{2/3} = \frac{y^2}{b^2}$$

Adding these equations, using the equation for the ellipse, and simplifying yields the desired curve:

$$\left(\frac{ax_0}{a^2-b^2}\right)^{2/3} + \left(\frac{by_0}{a^2-b^2}\right)^{2/3} = \frac{x^2}{a^2} + \frac{y^2}{b^2}$$

$$\left(\frac{ax_0}{a^2-b^2}\right)^{2/3} + \left(\frac{by_0}{a^2-b^2}\right)^{2/3} = 1$$

$$(ax_0)^{2/3} + (by_0)^{2/3} = \left(a^2-b^2\right)^{2/3} \tag{4.9}$$

With one caveat that we address below, the points on the curve given by equation (4.9) are intersections of three normal lines from the ellipse. Figure 4.5 illustrates this curve. Apollonius demonstrates that within this curve, each point stands on four normal lines from the ellipse while outside this curve, each point stands on only two normal lines from the ellipse. The curve is known as the *evolute of the ellipse*. After addressing the caveat, we will return to the evolute.[7]

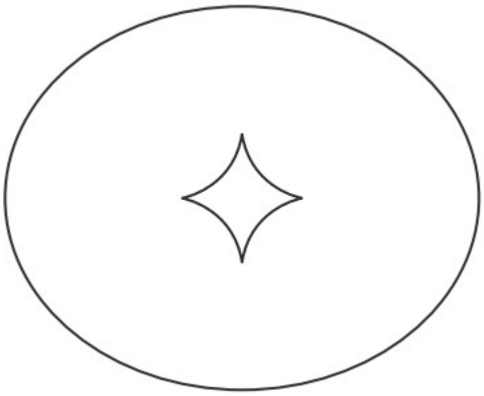

Figure 4.5. The evolute of the ellipse. The evolute consists of all points having three normal lines to the ellipse.

---

[7] Because ancient Greek mathematicians, who called themselves *geometers*, did not express functional relationships as we do today, Apollonius did not find an expression for the evolute that is equivalent

-3 / ## # # # > ! !/ ! 99 0
/! ! !" ! ? / ' @ !

At this point, a judge would most certainly uphold an objection that the reader may wish to place forward. Twice in the derivation the author was less than careful concerning possible divisions by zero. This occurs when determining the slope value m once using the ellipse and once using the tangent hyperbola. The reader can verify that all the divisions by zero occur when either x and x_0 are zero or y and y_0 are zero; that is, the location of all illegal operations is on the x axis or the y axis. Using symmetry, one can deduce that any point on either axis stands on an even number of normals, precluding the possibility of standing on only three normals. One can see this for a point on the x axis as follows. If (x_0, y_0) lies on the x axis, then the point stands on two normals emanating from the points $(a, 0)$ and $(-a, 0)$. Suppose that there is a third normal emanating from the ellipse at the point (x_n, y_n). Then, by symmetry, another normal emanates from the point $(x_n, -y_n)$, precluding the possibility of only three normals. There can be only two or four normals. Figure 4.6 illustrates the argument; the point (x_0, y_0) lies at the corner of the evolute. On the corner point there are only two normals. A similar argument applies to points on the y axis. The outcome is that points on both the evolute and the coordinate axes stand on only two normal lines, not three. With this statement the caveat has been put to rest.

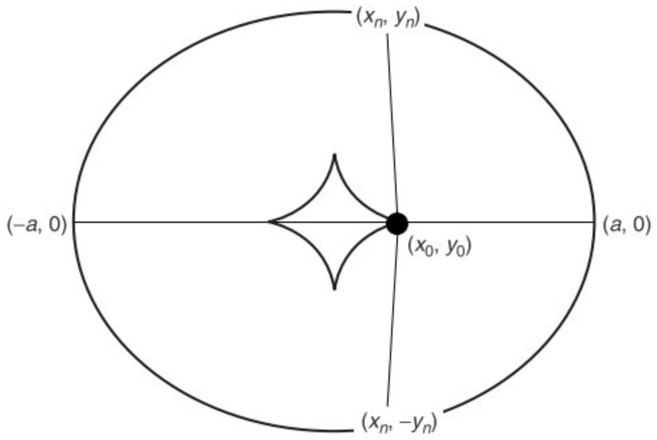

Figure 4.6. A point on the x axis cannot be on the evolute as well. By symmetry, there must be an even number of normals to a point on the x axis.

to equation (4.8). Nevertheless, he did find all the relationships necessary to derive the evolute. In particular, Apollonius writes relations similar to that of the ellipse [eq. (4.1)], the hyperbola [eq. (4.3)], and the slope of the tangent hyperbola [eq. (4.5)]. In his book, *A History of Greek Mathematics*, Heath uses Apollonius' relations to derive the evolute in its modern form (Heath 1921).

The Radius of Curvature

In the spirit of this chapter, just for fun, we now take an alternative path to the evolute. The path leads to a generalized evolute for any given curve, but the solution for the ellipse indicates a direction. For the ellipse, one may consider the point (x, y) at which the hyperbola of equation (4.3) becomes tangent as a limiting point at which two intersections of the receding hyperbola collide. The corresponding point on the evolute, namely, (x_0, y_0), is then the limiting point of intersection for two colliding normal lines (see Figure 4.7). Let us calculate the limiting point of intersection for a general curve given by $f(x, y) = 0$.

Before proceeding, some notation is necessary. Let $\mathbf{n}(x, y)$ be the unit normal vector to the curve having components $\mathbf{n} = (n_1, n_2)$. Note that both components are also functions: $n_1 = n_1(x, y)$ and $n_2 = n_2(x, y)$. Also since $\mathbf{n}$ is the unit normal, its length is one: $n_1^2 + n_2^2 = 1$. Below, we will indicate the direction in which $\mathbf{n}(x, y)$ points. Let (x, y) be on the curve $f(x, y) = 0$ and (x_a, y_a) also be on the curve with x_a close to x so that $x_a = x + \Delta$. Associated with both points (x, y) and (x_a, y_a) are normal lines that intersect at some point denoted by (x_0, y_0). With this notation the problem is to determine $\lim_{\Delta \to 0}(x_0, y_0)$ (see Figure 4.8).

The expression $(x + n_1(x, y)r, y + n_2(x, y)r)$ yields the normal line to (x, y) as the value r ranges over all real numbers. Similarly, the expression $(x_a + n_1(x_a, y_a)s, y_a + n_2(x_a, y_a)s)$ yields the normal line to (x_a, y_a) as the value s ranges over all real numbers. Because it is at the intersection of these two lines, the point (x_0, y_0) must satisfy the following set of equations for specified values of r and s:

$$\begin{aligned} x_0 &= x + n_1(x, y)r = x_a + n_1(x_a, y_a)s \\ y_0 &= y + n_2(x, y)r = y_a + n_2(x_a, y_a)s \end{aligned} \tag{4.10}$$

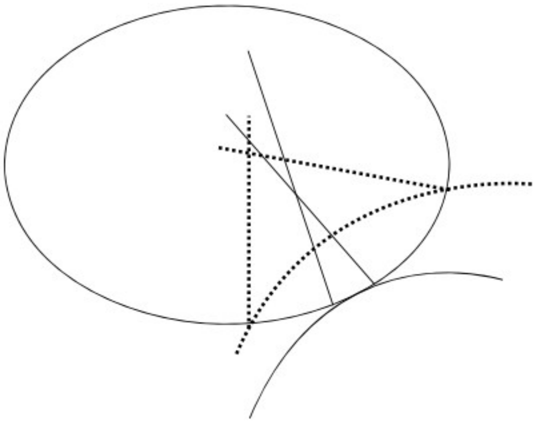

Figure 4.7. Intersections of normals associated with hyperbolas. As the hyperbolas recede and become tangent to the ellipse, the intersections approach a point on the evolute.

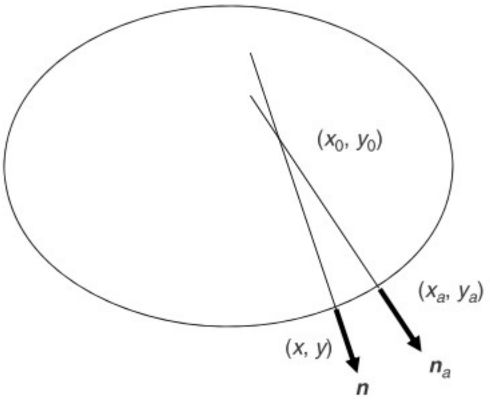

Figure 4.8. The limit of (x_0, y_0) as (x_a, y_a) approaches (x, y) is a point on the evolute.

These equations allow one to solve for the values of r and s that specify the point of intersection. The values r and s converge in the limit as $\Delta \to 0$. Accordingly, we focus on r:

$$\begin{aligned} n_1(x, y)r - n_1(x_a, y_a)s &= x_a - x \\ n_2(x, y)r - n_2(x_a, y_a)s &= y_a - y \end{aligned}$$

Eliminating the s variable and solving for r yields the following equation:

$$\begin{aligned} (n_1(x, y)n_2(x_a, y_a) - n_2(x, y)n_1(x_a, y_a))\, r = n_2(x_a, y_a)(x_a - x) \\ -n_1(x_a, y_a)(y_a - y) \end{aligned}$$

From this equation one obtains the value of r:

$$r = \frac{n_2(x_a, y_a)(x_a - x) - n_1(x_a, y_a)(y_a - y)}{n_1(x, y)n_2(x_a, y_a) - n_2(x, y)n_1(x_a, y_a)} \tag{4.11}$$

The objective is to determine $\lim_{\Delta \to 0} r$. Toward this end, the expressions are expanded to first order as a series in Δ. By assumption, the term $x_a - x = \Delta$. Next, let's determine the series expansion for the term y_a in terms of Δ, $y_a = y(x) + y'(x)\Delta +$ higher-order terms. To accomplish this, we assume that the equation $f(x, y) = 0$ allows one to express y as a differentiable function of x.[8] With this assumption, we note the following:

$$f(x_a, y_a) = f(x, y) + \frac{\partial f}{\partial x}\Delta + \frac{\partial f}{\partial y}\Delta_y + \text{higher-order terms}$$

---

[8] The necessary conditions are known from the implicit function theorem.

Both (x, y) and (x_a, y_a) lie on the curve yielding the following expression:

$$\frac{\partial f}{\partial x}\Delta + \frac{\partial f}{\partial y}\Delta_y + \text{higher-order terms} = 0$$
$$\frac{\partial f}{\partial x}\Delta + \frac{\partial f}{\partial y}\frac{dy}{dx}\Delta + \text{higher-order terms} = 0$$
$$\left(\frac{\partial f}{\partial x} + \frac{\partial f}{\partial y}\frac{dy}{dx}\right)\Delta + \text{higher-order terms} = 0$$

It follows that the coefficient $\frac{\partial f}{\partial x} + \frac{\partial f}{\partial y}\frac{dy}{dx}$ is identically zero, from which we calculate the derivative, $y'(x)$:

$$\frac{\partial f}{\partial x} + \frac{\partial f}{\partial y}\frac{dy}{dx} = 0$$
$$y'(x) = \frac{dy}{dx} = -\frac{\frac{\partial f}{\partial x}}{\frac{\partial f}{\partial y}}$$

Since the gradient and normal vectors are aligned, $\frac{\frac{\partial f}{\partial x}}{\frac{\partial f}{\partial y}} = \frac{n_1}{n_2}$ and we obtain the result for $y'(x)$.

$$y'(x) = -\frac{n_1}{n_2} \tag{4.12}$$

Finally, we determine the expansion for the normal components, $n_1(x_a, y_a)$ and $n_2(x_a, y_a)$, in which the higher-order terms are ignored:

$$\begin{aligned} n_1(x_a, y_a) &= n_1(x, y) + \frac{\partial n_1}{\partial x}\Delta + \frac{\partial n_1}{\partial y}\Delta_y \\ &= n_1(x, y) + \frac{\partial n_1}{\partial x}\Delta + \frac{\partial n_1}{\partial y}\frac{dy}{dx}\Delta \\ &= n_1(x, y) + \frac{\partial n_1}{\partial x}\Delta - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\Delta \\ &= n_1(x, y) + \left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)\Delta \end{aligned} \tag{4.13}$$

Similarly, the expansion for $n_2(x_a, y_a)$ is the following:

$$n_2(x_a, y_a) = n_2(x, y) + \left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right)\Delta \tag{4.14}$$

Substituting the first-order expansions [eqs. (4.13) and (4.14)] into equation (4.11) results in the following expression for r:

$$r = \frac{\left[n_2 + \left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right)\Delta\right]\Delta + \left[n_1 + \left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)\Delta\right]\frac{n_1}{n_2}\Delta}{n_1\left[n_2 + \left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right)\Delta\right] - n_2\left[n_1 + \left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)\Delta\right]}$$

Eliminating all higher-order terms, simplifying, and taking the limit as $\Delta \to 0$ results in the desired expression:

$$\lim_{\Delta\to 0} r = \lim_{\Delta\to 0} \frac{\left[n_2 + \left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right)\Delta\right]\Delta + \left[n_1 + \left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)\Delta\right]\frac{n_1}{n_2}\Delta}{n_1\left[n_2 + \left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right)\Delta\right] - n_2\left[n_1 + \left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)\Delta\right]}$$

$$\lim_{\Delta\to 0} r = \lim_{\Delta\to 0} \frac{n_2\Delta + n_1\frac{n_1}{n_2}\Delta}{n_1\left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right)\Delta - n_2\left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)\Delta}$$

$$\lim_{\Delta\to 0} r = \frac{n_2 + n_1\frac{n_1}{n_2}}{n_1\left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right) - n_2\left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)}$$

$$\lim_{\Delta\to 0} r = \frac{n_2^2 + n_1^2}{n_1 n_2\left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right) - n_2^2\left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)}$$

$$\lim_{\Delta\to 0} r = \frac{1}{n_1 n_2\left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right) - n_2^2\left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)}$$

One final simplification provides the result:

$$\lim_{\Delta\to 0} r = \frac{1}{n_1 n_2\left(\frac{\partial n_2}{\partial x} + \frac{\partial n_1}{\partial y}\right) - \left(n_1^2\frac{\partial n_2}{\partial y} + n_2^2\frac{\partial n_1}{\partial x}\right)} \tag{4.15}$$

To complete the description of the limiting value, we take the direction of **n** in such a manner to ensure that the limit of equation (4.15) is positive. Once the limiting value of r is available, the limiting expressions for x_0 and y_0 are also available. Below we use the following notation for the limiting values:

$$\lim_{\Delta\to 0} r = r^* \quad \text{and} \quad \lim_{\Delta\to 0} (x_0, y_0) = (x_0^*, y_0^*)$$

By definition, the point (x_0^*, y_0^*) is on the evolute. With this notation, the following identities hold:

$$x_0^* = x + n_1 r^* \quad \text{and} \quad y_0^* = y + n_2 r^* \tag{4.16}$$

The Osculating Circle

We could return to the ellipse and use equations (4.16) to establish a relationship between x_0^* and y_0^*. But there is something else even more fun.

Note that r^* is a function of the point (x, y), $r^* = r^*(x, y)$, and the value r^* is the distance from the point (x, y) to the point (x_0^*, y_0^*). The distance r^* is known as the radius of curvature[9] at the point (x, y), and the point (x_0^*, y_0^*) is the center of curvature. Assume that the original curve, $f(x, y) = 0$, is a circle of radius R. Then, because all normal lines intersect at the center, r^* is the same value as R. Now return to the general case, $f(x, y) = 0$, any arbitrary curve. Because, at a given point (x, y), the general curve and a circle tangent to the curve at (x, y) with radius r^* both yield the same value for the radius of curvature, the curves are similar around the point (x, y). In fact, among all tangent circles, that of radius r^* is the circle that best approximates the original curve, as we next demonstrate.

First consider what is meant by the "best approximating circle to the original curve at a point (x, y)." Three choices specify any circle: two to designate its center, (x_c, y_c), and one for the radius, R. Let (x_a, y_a) be a point on the circle in the vicinity of (x, y), and express y_a as a function of x_a.[10] As above, it is possible to expand the functions in a Taylor series about the value x. A similar Taylor series about the value x is available using the original curve, $f(x, y) = 0$. As there are three parameter choices for the circle, it is possible to choose them so that the first three terms of each Taylor series formed from the circle match the first three terms from the Taylor series formed from the original curve. The circle that matches the first three terms is the best approximating circle at the point (x,y). Let us find this circle.

The following expression is the Taylor series of a function expanded about the value x:

$$y_a = y(x) + y'(x)\Delta + \tfrac{1}{2}y''(x)\Delta^2 + \text{higher-order terms} \tag{4.17}$$

The first three terms of two power series are equal when the value of y and its first two derivatives are the same at the given value x. Equation (4.16) gives the value of the first term, $y = y_0^* - r^* n_1$. Equation (4.12) provides the first-order term, $y'(x)\Delta = -\frac{n_1}{n_2}\Delta$; equivalently, $y'(x) = -\frac{n_1}{n_2}$.

Differentiating $y'(x)$ gives the second derivative:

$$y''(x) = -\frac{n_2\left(\dfrac{dn_1}{dx}\right) - n_1\left(\dfrac{dn_2}{dx}\right)}{n_2^2}$$

---

[9] The value $\kappa = \frac{1}{r^*}$ is known as the *curvature*.

[10] We assume that the conditions of the implicit function theorem hold so that the expression holds.

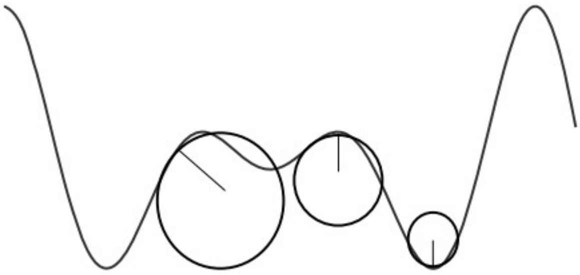

Figure 4.9. The osculating circle at different points on a curve.

Since y_a is considered as a function of x_a, the normal component n_1 can be considered as a function of x_a with expansion, $n_1(x_a) = n_1(x) + \frac{d}{dx}n_1(x)\Delta$ + higher-order terms. Equation (4.13) provides the first-order term of the expansion yielding the expression $\frac{d}{dx}n_1(x) = \left(\frac{\partial n_1}{\partial x} - \frac{\partial n_1}{\partial y}\frac{n_1}{n_2}\right)$. Similarly, from equation (4.14), $\frac{d}{dx}n_2(x) = \left(\frac{\partial n_2}{\partial x} - \frac{\partial n_2}{\partial y}\frac{n_1}{n_2}\right)$. Using these expressions and equation (4.15) results in the following expression for the second derivative of y:[11]

$$\begin{aligned} y''(x) &= -\frac{n_2\left(\dfrac{\partial n_1}{\partial x} - \dfrac{\partial n_1}{\partial y}\dfrac{n_1}{n_2}\right) - n_1\left(\dfrac{\partial n_2}{\partial x} - \dfrac{\partial n_2}{\partial y}\dfrac{n_1}{n_2}\right)}{n_2^2} \\ &= -\frac{n_2^2\left(\dfrac{\partial n_1}{\partial x} - \dfrac{\partial n_1}{\partial y}\dfrac{n_1}{n_2}\right) - n_2 n_1\left(\dfrac{\partial n_2}{\partial x} - \dfrac{\partial n_2}{\partial y}\dfrac{n_1}{n_2}\right)}{n_2^3} \\ &= \frac{1}{r^* n_2^3} \end{aligned} \tag{4.18}$$

For any curve, the three values $y(x)$, $y'(x)$, and $y''(x)$ depend only on the curve's normal components n_1 and n_2, the curve's radius of curvature r^*, and the curve's center of curvature (x_0^*, y_0^*). As such, the first three terms in a Taylor series of two curves sharing common normal components, radius of curvature, and center of curvature are identical. Figure 4.9 illustrates three circles tangent to three different points along a curve. The circles share a common normal with the curves at their points of intersection. Also, the center of each circle is the same as the curve's center of curvature: $(x_c, y_c) = (x_0^*, y_0^*)$. The circle is called the *osculating circle*.

The Evolute and the Osculating Circle

Associated with each point along a curve is an osculating circle and the osculating circle's center. The collection of all such centers forms another curve and this new curve defines the evolute (see Figure 4.10). The preceding sections demonstrate that the points sitting on three normals from an ellipse are on the evolute of the ellipse. Our initial evaluation of the evolute didn't even apply the evolute's definition. It was an accidental outcome, and we weren't aware that the curve of equation (4.9) satisfies the properties of the evolute. Below, we calculate the evolute of the ellipse from its definition and show that the curve is the same curve resulting from the initial approach. The calculation simplifies equations (4.13) and (4.14) to obtain the expressions (4.7) and (4.8).

---

[11] The result for the second derivative is frequently written as $y''(x) = \kappa/n_2^3$, where κ is the curvature.

We begin by calculating the unit normals to the ellipse. We have already found normal vectors by taking the gradient of the function $f(x, y) = \frac{x^2}{a^2} + \frac{y^2}{b^2}$. The gradient is $\left(\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y}\right) = \left(\frac{2x}{a^2}, \frac{2y}{b^2}\right)$. Normalizing the gradient and pointing the vectors inward yields the components of the unit normals:

$$n_1 = -\frac{x}{a^2\sqrt{\dfrac{x^2}{a^4} + \dfrac{y^2}{b^4}}}$$

$$n_2 = -\frac{y}{b^2\sqrt{\dfrac{x^2}{a^4} + \dfrac{y^2}{b^4}}}$$

Next, using equation (4.18), we obtain the following expression for the radius of curvature r^*:

$$r^* = \frac{1}{y''(x)n_2^3}$$

The derivative $y'(x) = -\frac{n_1}{n_2} = -\frac{b^2x}{a^2y}$. Differentiating this value results in the second derivative.

$$\begin{aligned}
y''(x) &= -\frac{b^2}{a^2}\left(\frac{y + \dfrac{b^2x^2}{a^2y}}{y^2}\right) \\
&= -\frac{b^2}{a^4y^3}\left(a^2y^2 + b^2x^2\right) \\
&= -\frac{b^2}{a^4y^3}\left(a^2b^2\right) \qquad \text{from the equation of an ellipse} \\
&= -\frac{b^4}{a^2y^3}
\end{aligned}$$

Placing these expressions into equations (4.16) yields the desired expression:

$$\begin{aligned}
x_0^* &= x + r^* n_1 \\
&= x + \frac{n_1}{y''(x) n_2^3} \\
&= x - \frac{x}{a^2\sqrt{\dfrac{x^2}{a^4} + \dfrac{y^2}{b^4}}} \frac{a^2 y^3}{b^4} \frac{\left(b^2\sqrt{\dfrac{x^2}{a^4} + \dfrac{y^2}{b^4}}\right)^3}{y^3} \\
&= x - b^2 x \left(\frac{x^2}{a^4} + \frac{y^2}{b^4}\right) \\
&= x - b^2 x \left(\frac{x^2}{a^4} + \frac{1}{b^2}\left(1 - \frac{x^2}{a^2}\right)\right) \\
&= x - \frac{b^2 x^3}{a^4} - x + \frac{x^3}{a^4} \\
&= \frac{a^2 - b^2}{a^4} x^3
\end{aligned}$$

A similar calculation beginning with $y_0^* = y + r^* n_2$ results in the equation $y_0^* = \frac{b^2 - a^2}{a^4} y^3$. Comparing this with equations (4.7) and (4.8), we find all the

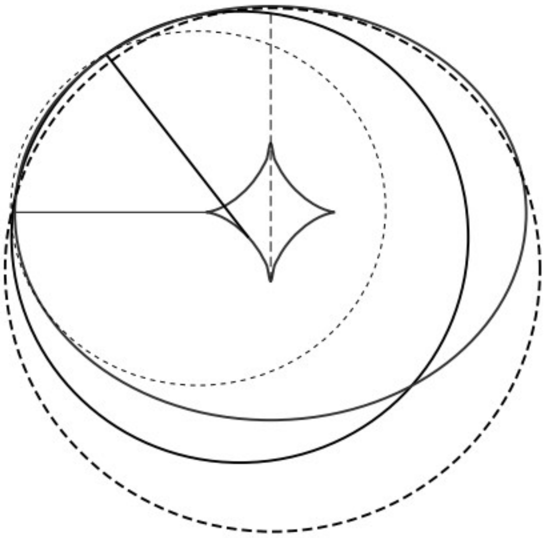

Figure 4.10. The evolute constructed from the centers of the osculating circles.

points (x_0, y_0) coincide with (x_0^*, y_0^*), affirming that the curve of expression 4.9, $(ax_0)^{2/3} + (by_0)^{2/3} = \left(a^2 - b^2\right)^{2/3}$ is, indeed, the evolute.

Figure 4.10 illustrates the construction of an ellipse's evolute using the family of osculating circles.

FUN'S HARVEST

An unanswered question is Apollonius' path to the evolute for the ellipse. Did he utilize the tangent hyperbola as in our initial approach, unaware of the osculating circle; discover and utilize the osculating as in our latter approach; or come to it through some other process? If Apollonius was aware of the osculating circle and its radius of curvature, he did not present its properties in his manuscript *On Conics*, but he most certainly motivated others to pursue it.

Christiaan Huygens (1629–1695) explicitly defines the radius of curvature and the osculating circle for for general curves. Leibniz applies his methods of calculus to determine the radius of curvature. Gauss (1777–1855), Riemann (1826–1866), and Ricci-Curbastro (1853–1925) create a general setting for non-Euclidean geometry in which the curvature is central. Then Einstein (1879–1955) incorporates curvature into his field equations of general relativity. Mathematics is fun, but not frivolous.

Three consecutive oppositions.

Note that the equations yield real values as long as $d < 1$, meaning that the distance of the deferent's center from Earth is smaller than the deferent's radius.[15]

The equation for Mars' actual coordinates [eq. (5.2)] is correct if one uses the values m_1 and m_2 of equations (5.6) and (5.7).

Before we continue, one feature of the model is noteworthy. As the longitudinal angle θ is not centered at the center of Mars' deferent, the speed of Mars' mean about the deferent is not uniform. Figure 5.9 illustrates the manner in which the speed varies. The equant-centered angles A and B are equal, so Mars' mean travels along each segment embraced by the angles' arms in an equal time. Because the segment embraced by B is longer than that embraced by A, the speed of Mars' mean is faster along the segment embraced by B. In general, the speed of Mars' mean decreases as Mars' mean approaches the equant and increases as Mars' mean recedes from the equant. As we will see in the next chapter, Copernicus found this feature most distasteful, desiring instead uniform circular motion. Kepler, on the other hand, viewed this feature favorably.

The Martian Year. Ptolemy's Martian year is the time that Mars' mean requires to trot once about the deferent. This is the same as the requirement for the longitude θ to advance by 360 degrees. Ptolemy uses an ingenious relationship between his choice of angle to represent the anomaly (referencing the apogee) and the occurrence of opposition. Figure 5.10 illustrates this relationship. The

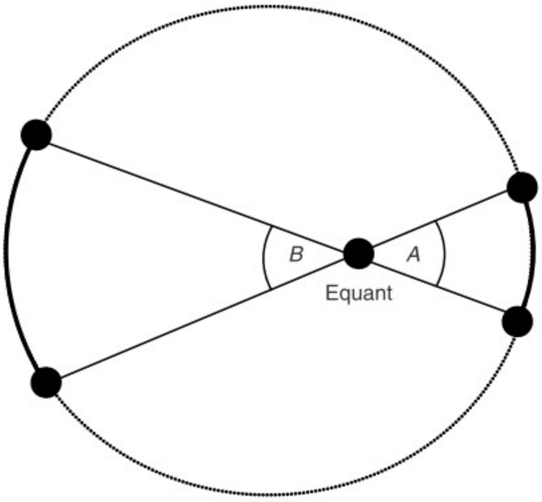

Figure 5.9. Equal angles about the equant indicate equal travel times for Mars' mean about the deferent. The size of the arc increases with distance from the equant corresponding to a higher speed.

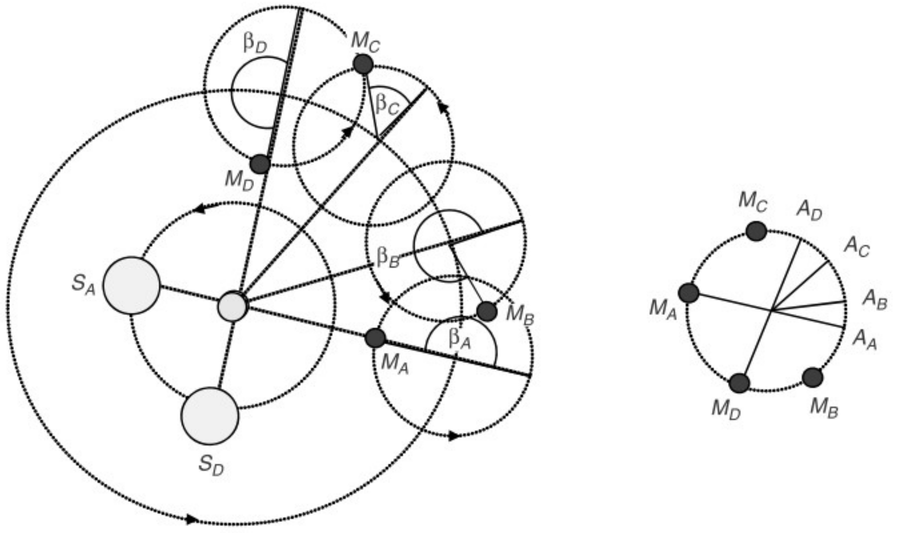
---

[15] A quadratic formula yielding two solutions arises. We choose the solution lying on the relevant ray.



(a) (b)

Figure 5.10. The change in Ptolemy's anomaly between consecutive oppositions; the anomaly completes one full circuit as both the initial and final anomalies are 180 degrees: (a) four observations; (b) corresponding positions of apogee and Mars on epicycle.

angle β is Ptolemy's measurement of the anomaly. As the figure illustrates, the angle executes one cycle between occurrences of opposition.

Because the speed of Mars' mean is not uniform about the deferent, the angle β does not vary with uniform speed. Indeed, if it did so, then the time between occurrences of central retrograde would be constant. However, Ptolemy reasoned that the rate of change in β has a long-run average. He also correctly reasoned that the long-run average of the rate of change in the angle β would be the same as the constant rate of change given by the angle β_Q of Figure 5.11:

$$\beta_Q = \alpha - \theta \tag{5.8}$$

By using a long-term historical record that provides the long-run changes in both α and β, the long-run change in θ is available. Dividing this change by the timeframe of the historical record yields the rate of change in θ. Consistent with previous notation, we indicate the rate of change in θ by ω. Once ω is known, one can calculate the Martian year. The following equations express the relevant relations:

$$\theta_0 = \alpha_0 - \beta_{Q0} \tag{5.9}$$

$$\theta_1 = \alpha_1 - \beta_{Q1} \tag{5.10}$$

$$\Delta\theta = \theta_1 - \theta_0 \tag{5.11}$$

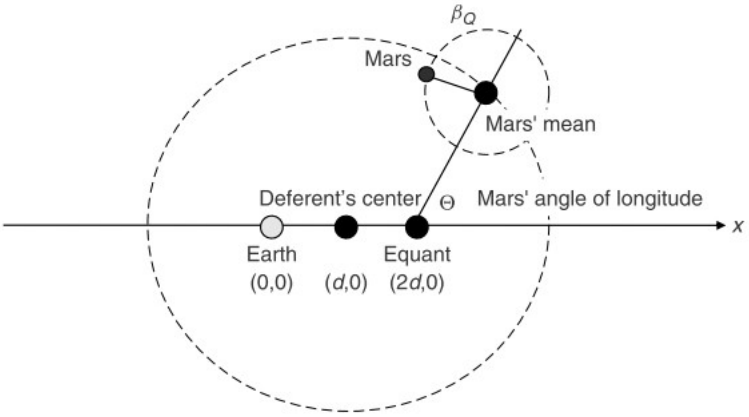


Figure 5.11. The angle β_Q.

$$= (\alpha_1 - \alpha_0) - (\beta_{Q1} - \beta_{Q0}) \tag{5.12}$$

$$\omega = \frac{\Delta\theta}{T} \tag{5.13}$$

in which the subscript 0 denotes observations at the beginning of the historical record, the subscript 1 denotes observations at the end of the historical record, and T denotes the time difference between the initial and final observations.

Ptolemy had a historical record available. Hipparchus had proposed this calculation and initiated the necessary observations. The record indicates 38 occurrences of opposition in 79.0095615[16] solar years or equivalently 37 cycles of the angle β during the timeframe $T = 79.0095615$. The angle β then changed by $37 \times 360 = 13{,}320$; that is, $\beta_{Q1} - \beta_{Q0} = 13{,}320$. We know that the angle α changes by 360 degrees in one solar year's time, so over the time range of observations, α changed by $360 \times 79.0095615 = 28{,}443.44214$ degrees; specifically, $\alpha_1 - \alpha_0$. Using equation (5.11), we find that the angle θ changed by 15,123.44214 degrees, from which one obtains the rate $\omega = \frac{15123.44214}{79.0095615} = 191.4128094$ degrees per solar year [eq. (5.12)]. With this rate of change in the equant-centered longitude, one obtains the Martian year at $\frac{360}{191.4128094} = 1.880752$ solar years.[17]

Ptolemy's Juggernaut. Ptolemy set the objective of determining all of the parameters of his model in a manner that is consistent with the observations of

---

[16] Ptolemy presents the historical record in Chapter IX of *The Almagest*. I backed into the number of years in order to match the rate of change in the Martian longitude that my translated version of *The Almagest* presents. The number of solar years differs slightly from that in the numbers I read where it sets the time frame at 79 solar years, 3 and $\frac{13}{60}$ days or equivalently, 79.008807 solar years. Confusing matters further, the translation of *The Almagest* states that the equivalent number of days is $28857\frac{53}{60}$, which is inconsistent with the number of solar years.

[17] The preceding calculation is made with a solar year equaling 365.25 days. Below, calculations are made by the year in accordance with the ancient Egyptian calendar that fixes each year at 365 days. The rate of rotation with respect to the Egyptian year is $\omega = 191.281794599$.

Table 5.1. For convenience, we once again write the full model and emphasize the variables that are time-dependent:

$$M_1(t) = m_1(t) + r_e \cos\alpha(t) \tag{5.14}$$

$$M_2(t) = m_2(t) + r_e \sin\alpha(t) \tag{5.15}$$

$$m_1(t) = \left(-d\cos\theta(t) + \sqrt{1 - d^2\sin^2\theta(t)}\right)\cos\theta(t) + 2d \tag{5.16}$$

$$m_2(t) = \left(-d\cos\theta(t) + \sqrt{1 - d^2\sin^2\theta(t)}\right)\sin\theta(t) \tag{5.17}$$

$$S_1(t) = r_S \cos\lambda(t) \tag{5.18}$$

$$S_2(t) = r_S \sin\lambda(t) \tag{5.19}$$

$$\lambda(t) = \lambda_A + \omega_\lambda t \tag{5.20}$$

$$\alpha(t) = \lambda(t) \tag{5.21}$$

$$\theta(t) = \theta_A + \omega_\theta t \tag{5.22}$$

The model variables are

t	Time measured in solar years
$(M_1(t), M_2(t))$	Coordinates of Mars
$(m_1(t), m_2(t))$	Coordinates of Mars' mean (center of Mars' epicycle)
$(S_1(t), S_2(t))$	Coordinates of the sun
$\lambda(t)$	Solar longitude
$\alpha(t)$	Mars' anomaly
$\theta(t)$	Mars' equant-centered longitude

Note that the model centers the sun's deferent on Earth.

There are eight model parameters:

r_e	Radius of Mars' epicycle
d	Distance from center of Mars' deferent to Earth, which is also half the distance from Mars' equant to Earth
r_S	Radius of the sun's deferent
λ_A	Initial solar longitude, which is also Mars' initial anomaly
θ_A	Initial longitude of Mars' mean
ω_λ	Angular speed of the sun's longitude
ω_θ	Angular speed of Mars' equant-centered longitude

An additional parameter has already been set; the radius of Mars' deferent is 1.

Ptolemy must find values for all of the parameters that ensure coincidence between the model and the observations. Aside from the radius of the deferent of Mars', two others have been set: the angular speed of the sun's longitude,

$\omega_\lambda = 360$ degrees per solar year and the angular speed of Mars' equant-centered longitude, which was found above to be 191.281794599 degrees per year. The values of the solar radius and the radius of Mars' epicycle do not impact the observations of Table 5.1. Table 5.1 gives observations of opposition, and only the sun's longitude along with Mars' mean and Mars' anomaly matter; the observations would occur with the correct solar longitude, location of Mars' mean, and anomaly regardless of the solar and epicyclic radii[18]. Accordingly, we will not consider the solar radius or the radius of Mars' epicycle. There are only three remaining parameters to specify: d, the distance from the center of Mars' deferent to Earth; λ_A, the initial solar longitude, which is also Mars' initial anomaly; and θ_A, the initial longitude of Mars' mean. Following Ptolemy, we enforce consistency between the observations and the model by selecting appropriate values for the undetermined parameters.

Figure 5.12 illustrates the model parameters and notation. The figure places Mars' mean at several observations of central retrograde; the mean lies on the line that passes through the sun, Earth, and Mars with the sun and Mars in opposition from Earth. The figure illustrates the notation that is used below. A variable with a letter as a subscript indicates the observation associated with that variable. For example, the figure illustrates Mars' mean longitude at the second observation θ_B and the sun's longitude at the third observation λ_C. With this notation, the parameters that we must determine are θ_A, Mars' initial longitude λ_A, and d.

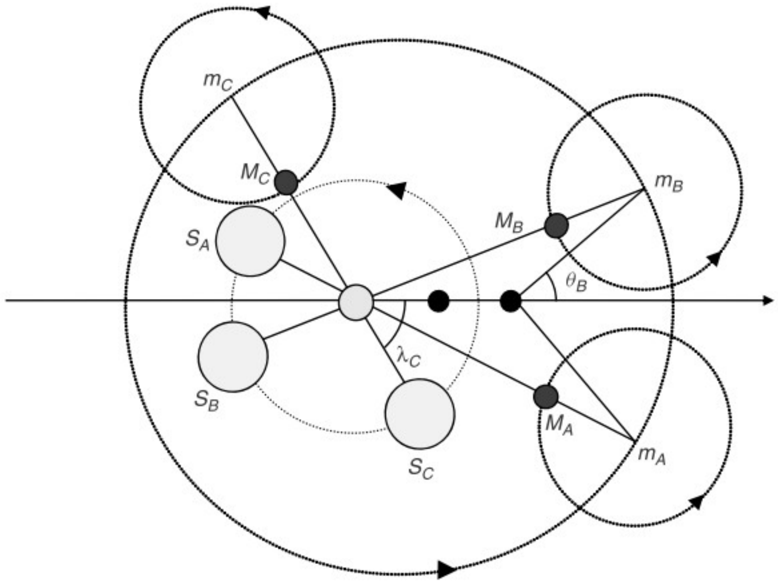

Figure 5.12. Three consecutive oppositions. Angles θ_B and λ_C are displayed.

---

[18] The radii could not be too big. The sun always remains the closest body to Earth.

Coincidence of the model and observations requires that the model's time lapse between occurrences of opposition is in agreement with the observed elapsed times of Table 5.1. Ptolemy requires a solution method to determine the parameters that ensure coincidence. Before continuing we remark on the number of free parameters. While there appear to be three free parameters, there are in fact only two, either d and λ_A or d and θ_A. To see this, let us assume that the two parameters d and λ_A are determined. Then the remaining angle θ_A is not free, but must be set by the condition that the observations are in opposition and only one value for θ_A modulo 360 degrees meets the requirement. Using a similar argument, one notes that a determination of the parameters d and θ_A sets the parameter λ_A.

As noted below, only two data points are used to determine two free parameters, the time interval between the first and second observations, and then the time interval between the first and third observations. Three observations are necessary to gather these two data points. Note that once the position of the sun and Mars' mean are correctly determined, one reconciles Mars' actual position by setting the initial value of Mars' anomaly equal to the initial value of the solar longitude, $\alpha_A = \lambda_A$. Accordingly, in the calculations below we need not further consider Mars' actual position, only its mean position.[19]

Table 5.2 gives the difference in the equant-centered Martian longitude $\Delta\theta$, where the difference is with respect to the first observation. This value is determined by multiplying the rate of change in θ (i.e., ω_θ) by the elapsed time between the observations. An equivalent calculation is made for the difference in solar longitude: $\Delta\lambda = \Delta\alpha$. Table 5.2 also displays the reduced angles, whereby the corresponding angle is reset to zero whenever it surpasses a multiple of 360 degrees. As noted above, the table gives two data points: the time interval between the first and second observations, and then the time interval between the first and third observations.

We begin by establishing a relation between the distance from Earth to the equant $2d$ and the remaining parameters. At central retrograde, when Mars' mean is in opposition to the sun, the coordinates of Mars' mean with reference to the

TABLE 5.2. Differences in Critical Angles

Observation	Year	Years Elapsed	$\Delta\lambda = \Delta\alpha$	$\Delta\theta$
A	15 of Hadrian	—	—	—

C	2 of Antonine	8.454452	3041.57 → 161.57	1617.20 → 177.20

---

[19] The reader should note that none of the calculations that follow utilize the radius of the epicycle r_e. As described above, this means that coincidence between the observations of the table and the model is independent of the radius. Ptolemy then has one extra parameter that he may freely choose to match additional observations, separate from Table 5.1. The reader may consult Ptolemy's *Almagest* for details.

solar longitude are

$$m_1 = -h\cos\lambda$$
$$m_2 = -h\sin\lambda$$

where h is the distance between Earth and Mars' mean, $h = \sqrt{m_1^2 + m_2^2}$.

Equations (5.15) and (5.16) are used to determine the following expression for h:

$$h = \left\{\left[\left(-d\cos\theta + \sqrt{1 - d^2\sin^2\theta}\right)\cos\theta + 2d\right]^2 + \left(-d\cos\theta + \sqrt{1 - d^2\sin^2\theta}\right)^2\sin^2\theta\right\}^{1/2} \tag{5.23}$$

Mars' mean resides on the line $m_1 = m_2\cot\theta + 2d$, where $2d$ is the distance from Earth to the equant.

Substituting the expressions for Mars' mean coordinates into the line and simplifying yields the relation for $2d$ that we are seeking:

$$\begin{aligned}
-h\cos\lambda &= -h\sin\lambda\cot\theta + 2d \\
2d &= h(\sin\lambda\cot\theta - \cos\lambda) \\
2d\sin\theta &= h(\sin\lambda\cos\theta - \cos\lambda\sin\theta) \\
2d\sin\theta &= h\sin(\lambda - \theta) \\
2d &= \frac{h\sin(\lambda - \theta)}{\sin\theta}
\end{aligned} \tag{5.24}$$

Equation (5.24) is valid at all three observation points. Equating the result at the first observation A with the result at either of the other observations and simplifying yields an expression relating the angle $\lambda_A - \theta_A$ with remaining parameters:

$$\begin{aligned}
\frac{h_A\sin(\lambda_A - \theta_A)}{\sin\theta_A} &= \frac{h\sin(\lambda - \theta)}{\sin\theta} \\
\frac{h_A\sin(\lambda_A - \theta_A)}{\sin\theta_A} &= \frac{h\sin(\lambda_A - \theta_A + \Delta\lambda - \Delta\theta)}{\sin(\theta_A + \Delta\theta)} \\
\frac{h_A\sin(\lambda_A - \theta_A)\sin(\theta_A + \Delta\theta)}{h\sin(\theta_A)} &= \sin(\lambda_A - \theta_A + \Delta\lambda - \Delta\theta) \\
\frac{h_A\sin(\lambda_A - \theta_A)\sin(\theta_A + \Delta\theta)}{h\sin(\theta_A)} &= \sin(\lambda_A - \theta_A)\cos(\Delta\lambda - \Delta\theta) \\
&\quad + \cos(\lambda_A - \theta_A)\sin(\Delta\lambda - \Delta\theta)
\end{aligned}$$

$$\begin{aligned}
\frac{h_A \sin(\theta_A + \Delta\theta)}{h \sin\theta_A} &= \cos(\Delta\lambda - \Delta\theta) + \cot(\lambda_A - \theta_A)\sin(\Delta\lambda - \Delta\theta) \\
\cot(\lambda_A - \theta_A)\sin(\Delta\lambda - \Delta\theta) &= \frac{h_A \sin(\theta_A + \Delta\theta)}{h \sin\theta_A} - \cos(\Delta\lambda - \Delta\theta) \\
\cot(\lambda_A - \theta_A) &= \frac{h_A \sin(\theta_A + \Delta\theta)}{h \sin\theta_A \sin(\Delta\lambda - \Delta\theta)} - \cot(\Delta\lambda - \Delta\theta)
\end{aligned} \tag{5.25}$$

As noted above, the final expression holds with the right-hand side (RHS) evaluated at either the second or third observation. Equating the RHS at the second and third observations and simplifying results in an expression for θ_A:

$$\begin{aligned}
&\frac{h_A \sin(\theta_A + \Delta\theta_B)}{h_B \sin\theta_A \sin(\Delta\lambda_B - \Delta\theta_B)} - \cot(\Delta\lambda_B - \Delta\theta_B) = \frac{h_A \sin(\theta_A + \Delta\theta_C)}{h_C \sin\theta_A \sin(\Delta\lambda_C - \Delta\theta_C)} \\
&\qquad - \cot(\Delta\lambda_C - \Delta\theta_C) \\
&\frac{h_A [\sin\theta_A \cos\Delta\theta_B + \cos\theta_A \sin\Delta\theta_B)]}{h_B \sin\theta_A \sin(\Delta\lambda_B - \Delta\theta_B)} - \cot(\Delta\lambda_B - \Delta\theta_B) \\
&\quad = \frac{h_A [\sin\theta_A \cos\Delta\theta_C + \cos\theta_A \sin\Delta\theta_C)]}{h_C \sin\theta_A \sin(\Delta\lambda_C - \Delta\theta_C)} - \cot(\Delta\lambda_C - \Delta\theta_C) \\
&\frac{h_A [\cos\Delta\theta_B + \cot\theta_A \sin\Delta\theta_B)]}{h_B \sin(\Delta\lambda_B - \Delta\theta_B)} - \cot(\Delta\lambda_B - \Delta\theta_B) \\
&\quad = \frac{h_A [\cos\Delta\theta_C + \cot\theta_A \sin\Delta\theta_C)]}{h_C \sin(\Delta\lambda_C - \Delta\theta_C)} - \cot(\Delta\lambda_C - \Delta\theta_C) \\
&\left[\frac{h_A \sin\Delta\theta_B}{h_B \sin(\Delta\lambda_B - \Delta\theta_B)} - \frac{h_A \sin\Delta\theta_C}{h_C \sin(\Delta\lambda_C - \Delta\theta_C)}\right]\cot\theta_A \\
&\quad = \frac{h_A \cos\Delta\theta_C}{h_C \sin(\Delta\lambda_C - \Delta\theta_C)} - \frac{h_A \cos\Delta\theta_B}{h_B \sin(\Delta\lambda_B - \Delta\theta_B)} \\
&\qquad + \cot(\Delta\lambda_B - \Delta\theta_B) - \cot(\Delta\lambda_C - \Delta\theta_C)
\end{aligned}$$

The result for $\cot\theta_A$ is the following.

$$\begin{aligned}
\cot\theta_A = &\left[\frac{h_A \cos\Delta\theta_C}{h_C \sin(\Delta\lambda_C - \Delta\theta_C)} - \frac{h_A \cos\Delta\theta_B}{h_B \sin(\Delta\lambda_B - \Delta\theta_B)}\right. \\
&\left. + \cot(\Delta\lambda_B - \Delta\theta_B) - \cot(\Delta\lambda_C - \Delta\theta_C)\right] \\
&\div \left[\frac{h_A \sin\Delta\theta_B}{h_B \sin(\Delta\lambda_B - \Delta\theta_B)} - \frac{h_A \sin\Delta\theta_C}{h_C \sin(\Delta\lambda_C - \Delta\theta_C)}\right]
\end{aligned} \tag{5.26}$$

If only we knew the factors h, we would have a solution. Placing the values from Table 5.2 into the RHS of equation (5.26) yields the value of θ_A. With θ_A

available, equation (5.25) yields the value of λ_A. Finally using both θ_A and λ_A in equation (5.24), one obtains the value of $2d$. However, we don't know a priori the values of h.

In *The Almagest*, Ptolemy, using far more geometric methods, confronts a similar problem. He then reveals a solution. Using an initial guess for the unknown factors that are akin to our values of h, Ptolemy establishes an initial estimate of the undetermined parameters. Then, using the estimate of the undetermined parameters, he updates the unknown factors. With the updated factors, Ptolemy once again refines his estimate of the undetermined parameters and continues in iterative fashion. We formalize and execute this iterative process.

Step 0. Choose initial values for h_A, h_B, and h_C.

Step 1. Place the latest value of h_A, h_B, and h_C in equations (5.26), (5.25), and (5.24), respectively, to determine estimates for θ_A, λ_A, and d.

Step 2. Using the latest values of θ_A, λ_A, and d, determine the longitude of Mars' mean and solar longitude at each observed position. Then use these values in equation (5.23), to update the current estimates of h_A, h_B, and h_C. If the updated estimates change materially from the previous estimates, return to step 1. Otherwise accept the estimates as the model parameters.

We perform one iterate of the algorithm and then present results in a table.

Step 0. Choose an initial values for h_A, h_B, and h_C.

If the value of d is small, then the values for h are all nearly one. Hoping that this is the case, we take $h = 1$ at each observation as the initial choice.

Step 1. Use the latest value of h_A, h_B, and h_C in equations (5.26), (5.25), and (5.24), respectively, to determine estimates for θ_A, λ_A, and d.
Equation (5.26) yields the estimate for θ_A:

$$\begin{aligned}
\cot\theta_A &= \left[\frac{h_A\cos\Delta\theta_C}{h_C\sin(\Delta\lambda_C-\Delta\theta_C)} - \frac{h_A\cos\Delta\theta_B}{h_B\sin(\Delta\lambda_B-\Delta\theta_B)}\right.\\
&\qquad \left. + \cot(\Delta\lambda_B-\Delta\theta_B) - \cot(\Delta\lambda_C-\Delta\theta_C)\right]\\
&\qquad \div\left[\frac{h_A\sin\Delta\theta_B}{h_B\sin(\Delta\lambda_B-\Delta\theta_B)} - \frac{h_A\sin\Delta\theta_C}{h_C\sin(\Delta\lambda_C-\Delta\theta_C)}\right]\\
\cot\theta_A &= \left[-\frac{\cos 177.2}{\sin 15.63} + \frac{\cos 81.73}{\sin 13.9} - \cot 13.9 + \cot 15.63\right]\\
&\qquad \div\left[-\frac{\sin 81.73}{\sin 13.9} + \frac{\sin 177.2}{\sin 15.63}\right]\\
&= -0.97448\\
\theta_A &= -45.740429
\end{aligned}$$

Equation (5.25) yields the estimate for λ_A:

$$\begin{aligned}
\cot(\lambda_A - \theta_A) &= \frac{h_A \sin(\theta_A + \Delta\theta_B)}{h_B \sin\theta_A \sin(\Delta\lambda_B - \Delta\theta_B)} - \cot(\Delta\lambda_B - \Delta\theta_B) \\
&= \frac{\sin 36.0}{\sin 45.7 \sin 13.9} + \cot 13.9 \\
&= 0.133313 \\
\lambda_A - \theta_A &= 7.638289 + 180 \\
\lambda_A &= 7.638289 - 45.740429 + 180 \\
&= 141.897860
\end{aligned}$$

Equation (5.24) yields the estimate for d:

$$\begin{aligned}
d &= \frac{h_A \sin(\lambda_A - \theta_A)}{2 \sin\theta_A} \\
&= -\frac{\sin 187.6}{2 \sin 45.7} \\
&= 0.092796
\end{aligned}$$

Step 2. Using the latest values of θ_A, λ_A, and d, determine the longitude of Mars' mean and solar longitude at each observed position. Then use these values in equations (5.23) to update the current estimates of h_A, h_B, and h_C. If the updated estimates change materially from the previous estimates, return to step 1. Otherwise accept the estimates as the model parameters.

We provide the calculation for h_A only. The other factors h_B, and h_C, follow in an identical manner:

$$\begin{aligned}
h_A &= \sqrt{m_1^2 + m_2^2} \\
m_1 &= \left(-d \cos\theta_A + \sqrt{1 - d^2 \sin^2\theta_A}\right) \cos\theta_A + 2d \\
&= \left(-0.09 \cos 45.7 + \sqrt{1 - 0.09^2 \sin^2 45.7}\right) \cos 45.7 + .18 \\
m_2 &= \left(-d \cos\theta_A + \sqrt{1 - d^2 \sin^2\theta_A}\right) \sin\theta_A \\
&= \left(-0.09 \cos 45.7 + \sqrt{1 - 0.09^2 \sin^2 45.7}\right) \sin 45.7 \\
h_A &= 1.070834 \\
h_B &= 1.079119 \\
h_C &= 0.946415
\end{aligned}$$

TABLE 5.3. Results

Using a computer, the iteration method has been programmed to generate the results of Table 5.3.

INSPIRATION

Using his more geometric method, Ptolemy passes through three iterations and finds the values $\theta_A = -41.55$, $\lambda_A = 145.5$, and $d = 0.1$. With these values, the model and the observations coincide to a remarkable degree of accuracy. The discrepancies between Ptolemy's values and the final result of Table 5.3 are immaterial and well within the tolerance of rounding error. For all intents and purposes Ptolemy, hits the mark.

The difficulties that Ptolemy had to overcome stymied Ptolemy's predecessors. Ptolemy derived his method prior to the advent of elementary algebra and Cartesian coordinates. He carried out exceedingly difficult calculations without the use of a computer, calculator, or even pencil and paper. After my own battles using a computer, I am dumbfounded and cannot imagine performing this feat under the conditions of Ptolemy's times. Not only did Ptolemy carry out his method for Mars; he also carried out similar calculations for Jupiter and Saturn. In addition, he used different but equally, if not more, complex methods for Mercury and Venus.

Let us jump briefly ahead to Kepler, whose remark concerning a similar calculation of his own is a testimony to Ptolemy. Initially, Kepler didn't buy into Ptolemy's midway compromise that fixes Mars' deferent's center at half the distance to the equant. He believed that data would show that the Ptolemaic system requires seating the equant at a different location. Kepler considered the position of the equant as another parameter and set about finding this parameter in addition to the other undetermined parameters. As he adds an additional free parameter, he requires an additional data point from an additional observation at opposition. After devising an iteration scheme inspired by, but more complicated than, Ptolemy's, Kepler calculates. More than 70 iterations later, Kepler arrives at the answer. In his book *New Astronomy*, Kepler describes the toll it has taken on him:

> If this wearisome method has filled you with loathing, it should more properly fill you with compassion for me, as I have gone through it at least seventy times at the expense of a great deal of time, and you will cease to wonder that the fifth year has gone by since I took up Mars . . . .

In performing his own calculation, Kepler found sympathy for Ptolemy, who, as noted above, carried out his calculations for all the planets. What did Ptolemy receive in return for his efforts? *The Almagest* is foundational; Ptolemy leaves a legacy that both Copernicus and Kepler require for their works. One imagines that Ptolemy believed he had crossed the divide between mathematics and theology and found perfection.

Projective Algebraic Curves

One of the main functions of this book is to place algebraic curves in a natural setting (the complex projective plane) where they can be studied easily. For some readers, particularly those whose background is not in mathematics, this may prove to be a psychological barrier. I can only assure them that the reward is much greater than the mental effort involved. History has shown that placing algebraic curves in a natural setting provides a flood of illumination, enabling one much better to comprehend the features one meets in everyday applications.

Let me motivate this by looking briefly at the important question of understanding how two curves intersect each other. The simplest situation is provided by two lines. In general, you expect two distinct lines to meet in a single point. But there are lines ($x = 0$ and $x = 1$ for instance) which do not intersect. This really is a nuisance. It would be much nicer to say that these lines intersect at a single point, namely a 'point at infinity'. In this chapter, we will extend the ordinary affine plane to a 'projective plane' by adding points at infinity, and gain much as a result.

9.1 The Projective Plane

The construction is based on the following intuition. Think of the affine plane $\mathbb{K}^2$ as a plane L in $\mathbb{K}^3$ which does not pass through the origin O, and let L_0 be the parallel plane through O. Then we have a natural one-to-one correspondence between points in $\mathbb{K}^2$, and lines through the origin O in $\mathbb{K}^3$ not in L_0. To a point in L we assign the unique line through O and that point, and conversely, to a line through O not in L_0 we assign the point where it meets L. (Figure 9.1.) In this way, we conceive of lines through O in $\mathbb{K}^3$ in L_0 as in some sense 'points at infinity' in $\mathbb{K}^2$. That motivates the following formal definitions.

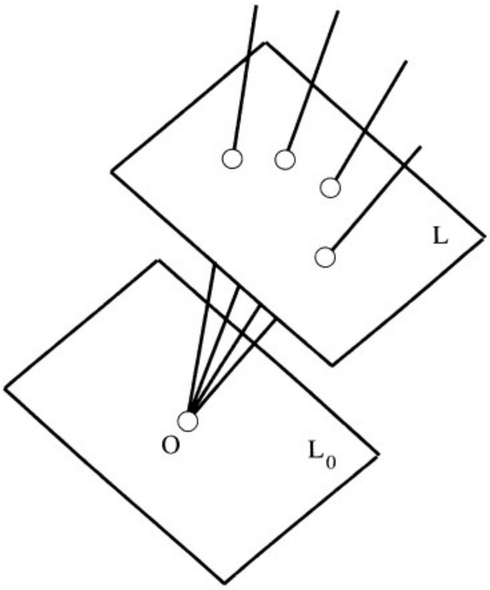

Fig. 9.1. Affine plane in 3-space

The *projective plane* $\mathbb{PK}^2$ is the set of lines through the origin O in $\mathbb{K}^3$. These lines are called the *points* of $\mathbb{PK}^2$. Given a non-zero vector $X = (x_1, x_2, x_3)$ in $\mathbb{K}^3$ there is a unique line through X, O determining a unique point in $\mathbb{PK}^2$, denoted by $(x_1 : x_2 : x_3)$. Beware, there is no point $(0 : 0 : 0)$! We call X a *representative*, and x_1, x_2, x_3 *homogeneous coordinates* for the point. Homogeneous coordinates are not unique; for any non-zero scalar λ, the vector λX represents the *same* point in $\mathbb{PK}^2$. Thus, given two points $A = (a_1 : a_2 : a_3)$, $B = (b_1 : b_2 : b_3)$ in $\mathbb{PK}^2$ the relation $A = B$ means that there exists a scalar $\lambda \neq 0$ for which $b_1 = \lambda a_1$, $b_2 = \lambda a_2$, $b_3 = \lambda a_3$. For many practical purposes we will use homogeneous coordinates labelled x, y and z.

Example 9.1 The *sphere model* of $\mathbb{PR}^2$. Each line through the origin in $\mathbb{R}^3$ meets the unit sphere $x^2 + y^2 + z^2 = 1$ in two diametrically opposite points: so $\mathbb{PR}^2$ can be thought of as a sphere, with diametrically opposite points identified. We will expand on this model of the real projective plane as we proceed.

Exercises

9.1.1 The *complex conjugate* point associated to a point $P = (a : b : c)$ in $\mathrm{P}\mathbb{C}^2$ is defined to be the point $\bar{P} = (\bar{a} : \bar{b} : \bar{c})$ where $\bar{a}$, $\bar{b}$, $\bar{c}$ are the complex conjugates of a, b, c. Show that this concept is well-defined, i.e. that the point $\bar{P}$ does not depend on the representative chosen for the point P. The point P is said to be *real* when $P = \bar{P}$. Show that P is real if and only if P has a representative with real homogeneous coordinates.

9.2 Projective Lines

Now consider any plane U through the origin in $\mathbb{K}^3$, so necessarily having an equation $ax + by + cz = 0$, where a, b, c are scalars, not all zero. Every line through the origin in U represents a point in $\mathrm{P}\mathbb{K}^2$. The resulting set of points in $\mathrm{P}\mathbb{K}^2$ is called the *line* in $\mathrm{P}\mathbb{K}^2$ with equation $ax + by + cz = 0$. Examples are the *coordinate lines* $x = 0$, $y = 0$ and $z = 0$. In the spherical model of the real projective plane, lines correspond to intersections of the unit sphere $x^2 + y^2 + z^2 = 1$ with planes through the origin, hence to great circles.

Example 9.2 A set of points in $\mathrm{P}\mathbb{K}^2$ is *collinear* when they all lie on one line. The condition for three points $P_1 = (x_1 : y_1 : z_1)$, $P_2 = (x_2 : y_2 : z_2)$, $P_3 = (x_3 : y_3 : z_3)$ to be collinear is easily obtained. It is the condition for the non-zero vectors P_1, P_2, P_3 in $\mathbb{K}^3$ to lie on a single plane through the origin, i.e. for those vectors to be linearly dependent, i.e. for the determinant

$$\begin{vmatrix} x_1 & y_1 & z_1 \\ x_2 & y_2 & z_2 \\ x_3 & y_3 & z_3 \end{vmatrix} = 0.$$

Example 9.3 Through any two distinct points in $\mathrm{P}\mathbb{K}^2$ there is a unique line. That is simply the statement that through two distinct lines through the origin in $\mathbb{K}^3$ there is a unique plane through the origin. To find the equation of the line through two distinct points with representatives $P_1 = (x_1, y_1, z_1)$, $P_2 = (x_2, y_2, z_2)$ we proceed as follows. We seek all representatives $P = (x, y, z)$ for which P_1, P_2, P are coplanar; by Example 9.2 the condition is

$$\begin{vmatrix} x_1 & y_1 & z_1 \\ x_2 & y_2 & z_2 \\ x & y & z \end{vmatrix} = 0.$$

For instance, if $P_1 = (0 : 0 : 1)$, $P_2 = (1 : 0 : 1)$ then the line joining P_1, P_2 is $y = 0$.

The next example describes the crucial property which distinguishes the affine from the projective plane.

Example 9.4 Any two distinct lines in $\mathbb{PK}^2$ intersect in a unique point. Indeed, two distinct lines in $\mathbb{PK}^2$ correspond to two distinct planes through the origin in $\mathbb{K}^3$, so intersect in a unique line through the origin in $\mathbb{K}^3$, i.e. in a unique point in $\mathbb{PK}^2$. It is this property which marks the fundamental difference between the affine plane and the projective plane. A practical question is to find the point of intersection of two distinct lines $ax+by+cz = 0$ and $a'x+b'y+c'z = 0$. By linear algebra, a solution of these equations is (X, Y, Z) where

$$X = \begin{vmatrix} b & c \\ b' & c' \end{vmatrix}, \quad Y = -\begin{vmatrix} a & c \\ a' & c' \end{vmatrix}, \quad Z = \begin{vmatrix} a & b \\ a' & b' \end{vmatrix}.$$

Note that at least one of X, Y, Z is $\neq 0$, else (by linear algebra) the vectors (a, b, c), (a', b', c') are linearly dependent, and the lines coincide.

At this point, it is worth pointing out that $\mathbb{PK}^2$ is a 'projective plane' in the sense of Section 2.3. The three points $(1 : 0 : 0)$, $(0 : 1 : 0)$, $(0 : 0 : 1)$ are not collinear; Example 9.3 tells us that through any two distinct points there is a unique line, and Example 9.4 tells us that any two lines intersect in at least one point.

Example 9.5 Any projective line $ax + by + cz = 0$ in $\mathbb{PK}^2$ can be 'rationally parametrized'. (A formal treatment of these ideas will be given in Chapter 18.) Recall that a line in $\mathbb{PK}^2$ corresponds to a plane through the origin in $\mathbb{K}^3$, and that any two *distinct* points A, B on the line correspond to basis vectors for that plane. It follows that any point on the plane has the form $X = sA + tB$ for some scalars s, t. Writing $A = (a_1, a_2, a_3)$, $B = (b_1, b_2, b_3)$, $X = (x, y, z)$ that means we can write $x = sa_1 + tb_1$, $y = sa_2 + tb_2$, $z = sa_3 + tb_3$ for some ratio $(s : t)$. For instance, the line $z = 0$ passes through the points $A = (1 : 0 : 0)$, $B = (0 : 1 : 0)$ yielding the parametrization $x = s$, $y = t$, $z = 0$. As in the affine case, the parametrization is not unique, it depends on the choice of A, B.

A few words are in order on the question of 'visualizing' the zero set of a projective line. Recall first the affine case. In the real case, we have the familiar lines in the $\mathbb{R}^2$; and in the complex case, we saw in Example 2.13

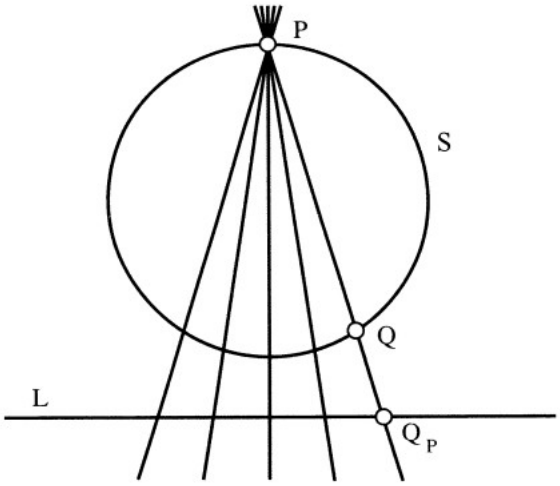

Fig. 9.2. Real projective line as a circle

that a line in $\mathbb{C}^2$ could be thought of as a real plane. Consider now the projective case, where a line is defined by a plane through the origin in $\mathbb{K}^3$. It will be no restriction to take the plane $z = 0$, so that the points of the (projective) line correspond to the (affine) lines through the origin in the (x, y)-plane, and are determined by the ratio $(x : y)$. Provided $x \neq 0$ we can identify the ratio with the quotient y/x in $\mathbb{K}$. Thus we can view the points of the projective line as the elements of $\mathbb{K}$ plus an extra element ∞. In the real and complex cases, this gives rise to simple visualizations.

Example 9.6 In the real affine plane, let S be a circle, let P be a point on S, and let L be a line not passing through P. We think of L as a copy of $\mathbb{R}$. Define *stereographic projection* to be the natural mapping $S - \{P\} \to L$, which takes a point $Q \neq P$ on S to the point on L where it meets the line through P, Q. (Figure 9.2.) Under this mapping the points of $S - \{P\}$ correspond one-to-one with the elements of $\mathbb{R}$, and we can extend the bijection to the whole of S by mapping P itself to the element ∞. Thus *we can think of a real projective line as a circle.*

Example 9.7 In real affine space, let S be a sphere, let P be a point on S, and let L be a plane not passing through P. We think of L as a copy of $\mathbb{C}$. Here too we can define *stereographic projection* to be the natural mapping $S - \{P\} \to L$, which takes a point $Q \neq P$ on S to the point on

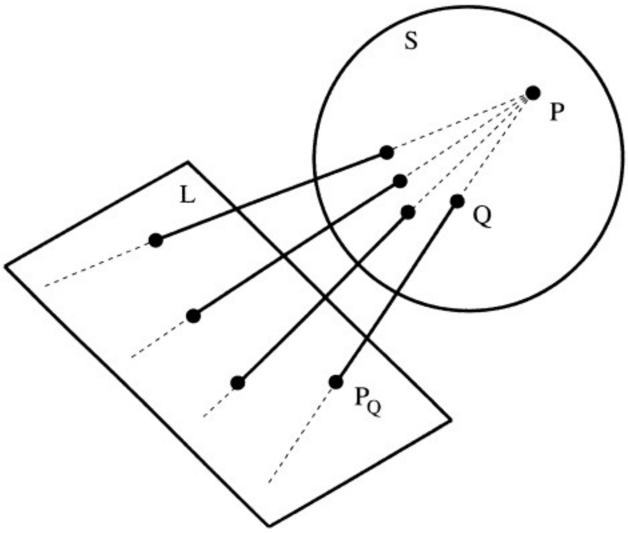

Fig. 9.3. Complex projective line as a sphere

L where it meets the line through P, Q. (Figure 9.3.) Under this mapping the points of $S - \{P\}$ correspond one-to-one with the elements of $\mathbb{C}$, and we can extend the bijection to the whole of S by mapping P itself to the element ∞. Thus *we can think of a complex projective line as a sphere.* This continues the train of thought begun in Example 2.13, namely that *'curves' in the complex projective plane can be thought of as real surfaces.*

Example 9.8 Just for the fun of it, consider the projective plane $P\mathbb{Z}_2^2$ over the field $\mathbb{Z}_2$ with two elements 0, 1. There are seven points: $(0:0:1)$, $(1:0:1)$, $(0:1:1)$, $(1:1:1)$, $(1:0:0)$, $(0:1:0)$, $(1:1:0)$. And there are seven lines: $x = 0$, $y = 0$, $z = 0$, $x = y$, $y = z$, $z = x$, $z = x + y$. Think of it as in Figure 9.4.

Exercises

9.2.1 In each of the following cases, find the equation of the line joining the points A, B in $P\mathbb{C}^2$.

(i) $A = (1:0:-1)$ $B = (1:1:-2)$
(ii) $A = (1:0:0)$ $B = (1:2:3)$
(iii) $A = (-1:1:1)$ $B = (2:3:3)$
(iv) $A = (1:i:0)$ $B = (1:-i:0)$.

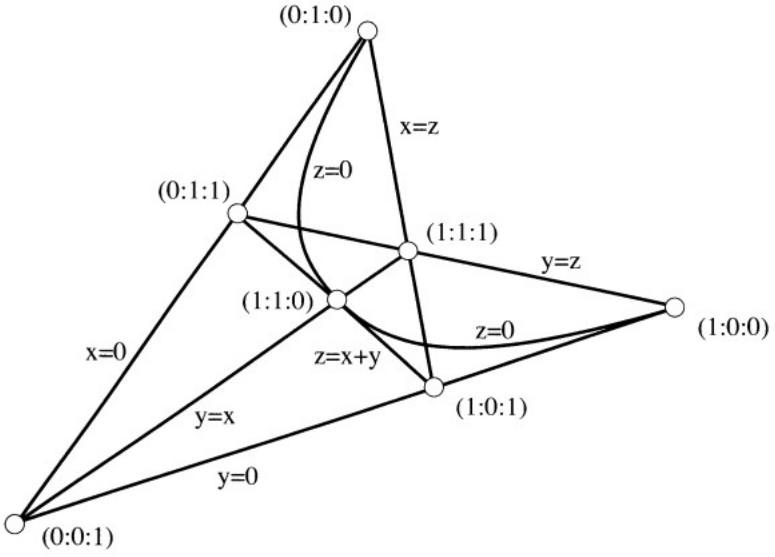

Fig. 9.4. The projective plane over $\mathbb{Z}_2$

9.2.2 In each of the following cases find the point of intersection of the two given lines in $\mathrm{P}\mathbb{C}^2$.

(i) $2x + 3y + z = 0, \quad x - y + 2z = 0$
(ii) $x + y + z = 0, \quad x + y + 2z = 0$
(iii) $x + 3y - 2z = 0, \quad y + z = 0.$

9.2.3 The *complex conjugate* line associated to a line $L = ax + by + cz$ in $\mathrm{P}\mathbb{C}^2$ is the line $\bar{L} = \bar{a}x + \bar{b}y + \bar{c}z$. Show that this concept is well-defined, i.e. that the line $\bar{L}$ does not depend on the equation of L. L is said to be *real* when $L = \bar{L}$. Show that L is real if and only if it has a defining equation with real coefficients.

9.2.4 Let P be a non-real point in $\mathrm{P}\mathbb{C}^2$. Show that the line joining P, $\bar{P}$ is real. Let L be a non-real line in $\mathrm{P}\mathbb{C}^2$. Show that the point of intersection of L, $\bar{L}$ is real.

9.2.5 Nine points P_{ij} in $\mathrm{P}\mathbb{C}^2$ are defined as follows, where ω is a primitive complex cube root of unity. (These points will arise naturally in a geometric context in Example 13.6.)

$$\begin{array}{lll} P_{00} = (0 : -1 : 1) & P_{01} = (0 : -\omega : 1) & P_{02} = (0 : -\omega^2 : 1) \\ P_{10} = (1 : 0 : -1) & P_{11} = (1 : 0 : -\omega) & P_{12} = (1 : 0 : -\omega^2) \\ P_{20} = (-1 : 1 : 0) & P_{21} = (-\omega : 1 : 0) & P_{22} = (-\omega^2 : 1 : 0). \end{array}$$

Any two of these points determine a line. Show that in total there are twelve such lines, and that each one passes through exactly three of the points P_{ij}. You might find it interesting to form a diagram of these nine points and twelve lines, and then compare it with that in Figure 2.2.

9.2.6 Show that the projective plane $\mathrm{P}\mathbb{Z}_3^2$ has precisely 13 points, and precisely 13 lines. How many points lie on a line? And how many lines pass through a point?

9.3 Affine Planes in the Projective Plane

We need to say something about the fundamental matter of how affine planes 'sit' in projective planes. To this end, we return to the basic intuition of Section 9.1. We start from an arbitrary affine plane L in $\mathbb{K}^3$, not through the origin O, and denote by L_0 the parallel plane through O. That gave us a natural one-to-one correspondence between points in L, and lines in $\mathbb{K}^3$ through O not lying in the plane L_0. In the language of the preceding section, L_0 defines a line in $\mathrm{P}\mathbb{K}^2$, the *line at infinity* associated to L, whose points are the *points at infinity*; explicitly, if L has equation $ax + by + cz = d$ then L_0 has equation $ax + by + cz = 0$. Thus we obtain a natural one-to-one correspondence between points in L and points in $\mathrm{P}\mathbb{K}^2$ not lying on the line L_0. In other words, we can think of the projective plane $\mathrm{P}\mathbb{K}^2$ as the 'affine' plane L, plus an associated 'line at infinity' L_0. That is the underlying geometric picture. The reader should bear in mind that the 'line at infinity' depends on a choice of plane L, there is nothing unique about it.

For practical purposes, we need to be more explicit about exactly how we identify L with the affine plane $\mathbb{K}^2$. The idea is that, provided L is not parallel to a given coordinate axis, we can identify L with the corresponding coordinate plane (obtained by setting the coordinate equal to zero) by projection onto that plane, in the direction of the axis. The correspondence could be written down quite explicitly, by solving the equation $ax + by + cz = d$ for one of x, y, z in terms of the other two. For instance the affine plane L defined by $x + y + z = 1$ is not parallel to the z-axis, and can be identified with the coordinate plane $z = 0$ via $(x, y) \sim (x, y, 1 - x - y)$. For most practical purposes, it will be sufficient to take L to be one of the planes $x = 1$, $y = 1$, $z = 1$, with associated lines at infinity $x = 0$, $y = 0$, $z = 0$. These choices give rise to three basic identifications:

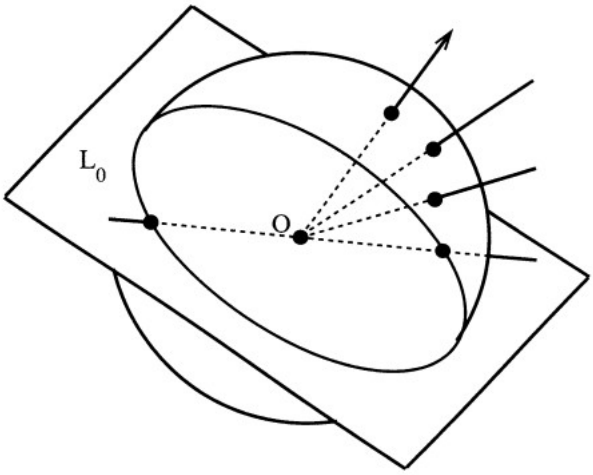

Fig. 9.5. Hemisphere model of $P\mathbb{R}^2$

choice	identification
$x = 1$	$(y, z) \sim (1 : y : z)$
$y = 1$	$(z, x) \sim (x : 1 : z)$
$z = 1$	$(x, y) \sim (x : y : 1)$

Example 9.9 The hemisphere model of $P\mathbb{R}^2$. Suppose we are given a plane L_0 through the origin O in $\mathbb{R}^3$. Each line through O meets the closed unit hemisphere $x^2 + y^2 + z^2 = 1$, $L_0 \geq 0$, with boundary a great circle, at least once. More precisely, every line through O meets the open hemisphere $x^2 + y^2 + z^2 = 1$, $L_0 > 0$ just *once*, whilst lines which meet the boundary great circle $x^2 + y^2 + z^2 = 1$, $L_0 = 0$ do so *twice*. Thus, in contrast to the sphere model, we have only to identify diametrically opposite points *on the boundary*. Perhaps this represents the best visualization of $P\mathbb{R}^2$, with the open hemisphere corresponding to $\mathbb{R}^2$, and the boundary circle to a line. Looking at the hemisphere from a distant point on the line perpendicular to L_0 through O one 'sees' the projective plane as a disc. (Figure 9.5.) Points in the interior correspond one-to-one with points in the real affine plane $\mathbb{R}^2$; the boundary circle corresponds to a line, but 'opposite' points have to be identified. It is conceptually important to realize that, whereas the sphere model provides

us with a *single* representation of the real projective plane, the hemisphere model provides a whole *family* of representations, one for each choice of the plane L_0.

9.4 Projective Curves

In this section we will work in the projective plane $\mathrm{P}\mathbb{K}^2$, with homogeneous coordinates x, y, z. By a *projective algebraic curve* of degree d in $\mathrm{P}\mathbb{K}^2$ we mean a non-zero form $F(x, y, z)$ of degree d, *up to multiplication by a non-zero scalar*. As in the affine case, we will abbreviate the term 'algebraic curve' to 'curve'. Projective curves of degree 1, 2, 3, … are called *lines*, *conics*, *cubics*, and so on. Over the real field we refer to *real* projective curves, and over the complex field to *complex* projective curves. Given a curve F we can associate to it the set

$$C(F) = \{(x, y, z) \in \mathbb{K}^3 : F(x, y, z) = 0\}.$$

This set has the crucial property of being a *cone*, meaning that if (x, y, z) is a point in $C(F)$ then so too is (tx, ty, tz), for any choice of scalar t; that is immediate from the defining property $F(tx, ty, tz) = t^d F(x, y, z)$ of forms. (Lemma 3.12.) In view of this fact, it makes sense to define the *zero set* of F to be the set $V(F)$ defined below; the key fact is that whether a point belongs to $V(F)$ does not depend on the choice of representative for that point.

$$V(F) = \{(x : y : z) \in \mathrm{P}\mathbb{K}^2 : F(x, y, z) = 0\}.$$

Recall from Section 3.4 that any form F over the field $\mathbb{K}$ admits a unique factorization $F = cF_1^{r_1} \dots F_s^{r_s}$ with $c \neq 0$ in $\mathbb{K}$, and the F_i irreducible forms such that F_j is not a factor of F_k for $j \neq k$. When F is a projective curve, we refer to $F_1, \dots, F_s$ as the *irreducible components* of F. And, as in the affine case, the zero set of F is the union of the zero sets of $F_1, \dots, F_s$.

Example 9.10 Let F be a curve in the real projective plane $\mathrm{P}\mathbb{R}^2$. We can think of the zero set in terms of the sphere model of the projective plane. Since the set $C(F)$ is a cone, the zero set is completely determined by the 'curve' of intersection with the sphere $x^2 + y^2 + z^2 = 1$. Thus we can think of the zero set as a 'curve' on the sphere, with diametrically opposite points identified. (Figure 9.6.) For instance, when F is a line the cone is a plane through the origin, intersecting the sphere in a great circle. Likewise, we can think of the zero set in terms of the hemisphere

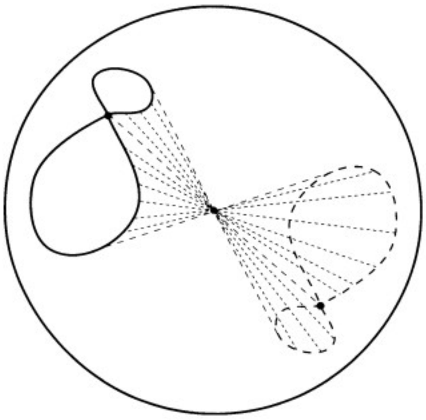

Fig. 9.6. Projective curve in the spherical model

model, where it is completely determined by the 'curve' of intersection with the hemisphere $x^2 + y^2 + z^2 = 1$, $z \geq 0$. Thus we can think of the zero set as a 'curve' on the hemisphere, with diametrically opposite points on the boundary great circle identified. For instance, when F is a line the resulting cone intersects the hemisphere in a great semicircle, and we identify the two end points.

9.5 Affine Views of Projective Curves

The object of this section is to establish the basic relations between affine and projective curves. Suppose we have a projective curve F, and make a choice of affine plane L with equation $ax + by + cz = d$. Then by eliminating one of the variables x, y, z between the relations $F(x, y, z) = 0$, $ax + by + cz = d$ we obtain an affine curve f in the (y, z)-plane, the (x, z)-plane or the (x, y)-plane. We assume here that the coefficient of the variable in the equation of L is non-zero. We refer to f as an *affine view* of F. Thus, to any projective curve F, we associate a family of affine views f, one for each choice of affine plane L and each choice of variable.

Example 9.11 Consider the real projective conic $F = x^2 + y^2 - z^2$. The affine views of F corresponding to the planes $z = 1$, $x + z = 1$ and $x + y + z = 1$ are the real ellipse $x^2 + y^2 = 1$, the parabola $y^2 = 1 - 2x$, and the hyperbola $2xy = 2x + 2y - 1$. This example makes the point

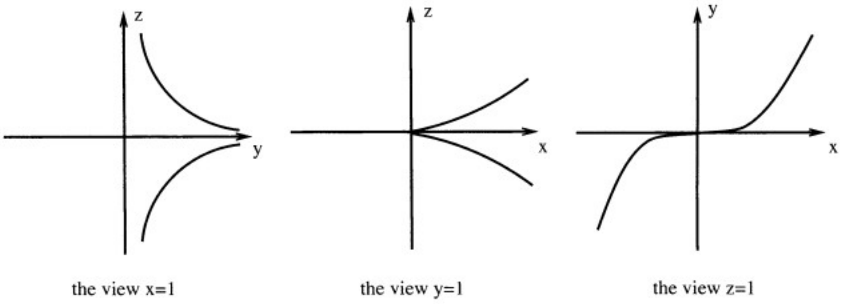

Fig. 9.7. Three affine views of a cubic curve

that different affine views of a projective curve may well fail to be affine equivalent.

Perhaps the best mental picture is to start from the spherical model of the real projective plane, with F defining a 'curve' on the surface of the unit sphere. An affine view is then determined by an affine plane L, with L_0 the parallel plane through O. The plane L_0 then determines a hemispherical model of the real projective plane, with the curve on the sphere giving a curve on the open hemisphere, and opposite points of intersection with the great circle $L_0 = 0$ identified. For instance, when F is a line, the intersection with the sphere is a great circle, intersecting the hemisphere in 'half' a great circle, with its end points identified. As L_0 changes, so the view of the 'curve' will change. In practice, we will work with the three *principal* affine views, meaning those associated to the affine planes $x = 1$, $y = 1$, $z = 1$. (Note that *any* point in the projective plane has a representative with either $x = 1$, $y = 1$ or $z = 1$ so these views cover the whole plane.) The process of obtaining the equation for f by substituting $x = 1$, $y = 1$ or $z = 1$ in $F(x, y, z)$ is known as *dehomogenization*, since it destroys the homogeneity of F.

Example 9.12 Consider, for instance, the projective cubic $F = yz^2 - x^3$ in $P\mathbb{R}^2$. Dehomogenizing with respect to x, y, z we obtain the three affine views of Figure 9.7, namely $f = y - x^3$ in the (x, y)-plane, $g = yz^2 - 1$ in the (y, z)-plane, and $h = z^2 - x^3$ in the (z, x)-plane. No two of these affine views are affine equivalent.

It is illuminating to think of Example 9.12 in terms of hemispherical models. If we take the hemispheres resulting from the planes $x = 0$,

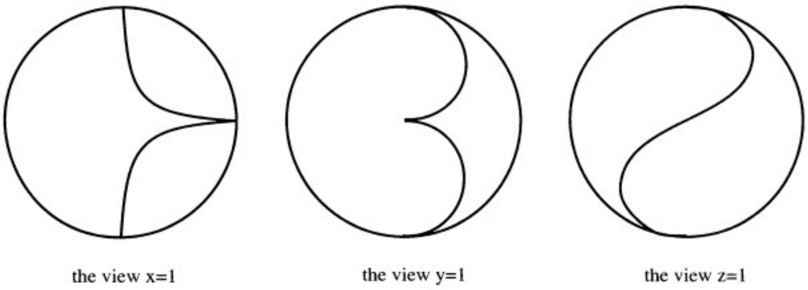

Fig. 9.8. Three hemispherical views of a cubic curve

$y = 0$, $z = 0$ in $\mathbb{R}^3$, we obtain the three pictures in Figure 9.8 which make it more plausible that they are different 'views' of the same curve F.

That brings us to one of the key constructions in this book, namely that of reversing the above process. More precisely, given any affine curve $f(x, y)$ of degree d in $\mathbb{K}^2$, and any affine plane L in $\mathbb{K}^3$ not through the origin, and not parallel to the z-axis, there exists a projective curve $F(x, y, z)$ of degree d in $P\mathbb{K}^2$ with the property that $F(x, y, z) = f(x, y)$ for every point (x, y, z) in L. Indeed, if L is defined by an equation $l = 1$, where $l = ax + by + cz$ with $c \neq 0$, and $f(x, y) = \sum a_{ij}x^i y^j$, we have only to observe that we can take

$$F(x, y, z) = l^d f\left(\frac{x}{l}, \frac{y}{l}\right) = \sum a_{ij}x^i y^j l^{d-i-j}.$$

Note that the condition $c \neq 0$ ensures that F has a term of degree d with non-zero coefficient. This is the process of *homogenization* with respect to the form l, you homogenize f by multiplying each monomial by that power of l necessary to bring the degree up to d. In practice, the only case of this construction we will meet is when L is the plane $z = 1$, so

$$F(x, y, z) = z^d f\left(\frac{x}{z}, \frac{y}{z}\right) = \sum a_{ij}x^i y^j z^{d-i-j}.$$

For instance, to the affine line $f = ax + by + c$ we associate the projective line $F = ax + by + cz$. Note that f itself is one of the family of affine views provided by F; indeed, if we homogenize f to obtain F, and then dehomogenize using z again, we are back to f. However, beware! That can fail when the order of the processes is reversed. For instance, if we dehomogenize the projective curve $F = z^2(x^2 + z^2)$, we obtain the affine curve $f = x^2 + 1$, and then homogenization with respect to z yields a *different* projective curve $G = x^2 + z^2$. Of course the process of homogenization applies equally well when the variables in the affine

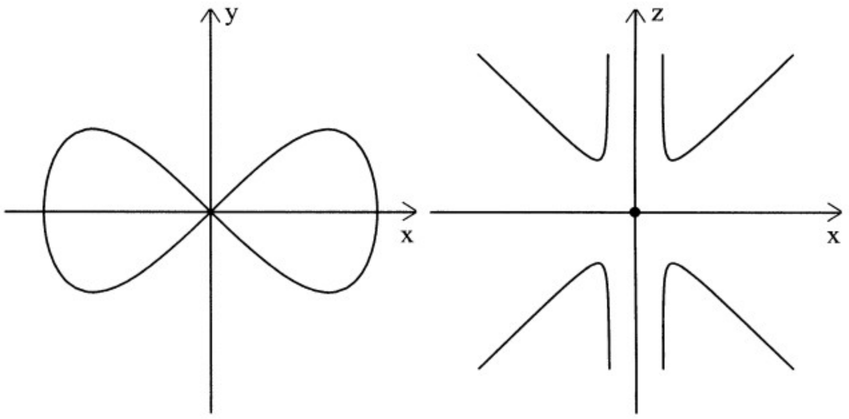

Fig. 9.9. Two affine views of the eight-curve

plane are labelled as x, z (when we homogenize with respect to y) or as y, z (when we homogenize with respect to x).

Example 9.13 Consider the cubic $f = y - x^3$ in $\mathbb{PR}^2$. The associated projective curve is $F = yz^2 - x^3$. But, as we saw in Example 9.12, the zero sets of the principal affine views $f = y - x^3$, $g = z^2 - x^3$ and $h = yz^2 - 1$ are visually quite different. At first sight it is difficult to imagine that the views g, h have any connexion with the original curve f. In particular, the view g shows that there is a 'cusp' at infinity on f, something that one might not have expected.

This example makes a very fundamental conceptual point. An affine curve f is simply one out of a very large family of affine views of the associated projective curve F. By working solely in the affine case, we deny ourselves the rich geometry provided by the projective situation. It is virtually impossible to get a genuine understanding of the geometry of an affine curve without moving into the projective situation. Here is another illuminating illustration.

Example 9.14 The projective curve in $\mathbb{PR}^2$ associated to the eight-curve $f = y^2 - x^2 + x^4$ is $F = y^2z^2 - x^2z^2 + x^4$. This meets the line at infinity $z = 0$ when $x^4 = 0$, yielding the point at infinity $Y = (0 : 1 : 0)$ on the y-axis. The affine view given by $y = 1$ is $g = z^2 - x^2z^2 + x^4$, and in that view Y corresponds to the origin in the (z, x)-plane. The zero set of g is easily sketched, by writing $g = 0$ in the form $z^2 = x^4/(x^2-1)$, and reveals that the origin is an isolated point on the zero set of g. (Figure 9.9.) Thus Y is an 'isolated' point on the projective curve – another unexpected revelation.

There is a very simple relationship between the zero sets of an affine curve f and its homogenization F with respect to z. Since $F(x, y, 1) = f(x, y)$ we have $f(x, y) = 0$ if and only if $F(x, y, 1) = 0$. Identifying the point (x, y) in $\mathbb{K}^2$ with the point $(x : y : 1)$ in $P\mathbb{K}^2$ (as above), we see that the zero set of F can be thought of as the zero set of f, plus the points at infinity $(x : y : 0)$ satisfying $F(x, y, 0) = 0$. Note that $F(x, y, 0)$ is a binary form in x, y, so finding the points at infinity on the curve is tantamount to finding the linear factors of that form.

Example 9.15 Any projective curve F in $P\mathbb{C}^2$ has an infinite zero set. Indeed the zero set of F 'contains' the zero set of any affine curve f in $\mathbb{C}^2$ obtained by dehomogenization, so is infinite by Lemma 2.1.

Example 9.16 To any line $ax + by + c$ in $\mathbb{K}^2$ we can associate a line $ax + by + cz$ in $P\mathbb{K}^2$. The zero set of the projective line comprises that of the affine line together with a unique point at infinity $(x : y : 0)$ for which $ax + by = 0$, i.e. the point $(-b : a : 0)$. Note that the point at infinity on the line does not depend on the coefficient c. All lines parallel to $ax+by+c = 0$ in $\mathbb{K}^2$ have the same point at infinity. In particular, the point at infinity on the x-axis is $X = (1 : 0 : 0)$ and the point at infinity on the y-axis is $Y = (0 : 1 : 0)$.

Example 9.17 The parabola $f = y^2 - x$ in $\mathbb{R}^2$ gives rise to the conic $F = y^2-xz$ in $P\mathbb{R}^2$ which meets the line at infinity $z = 0$ when $F(x, y, 0) = y^2 = 0$, i.e. at the single point $X = (1 : 0 : 0)$.

Example 9.18 The Maltese cross (Figure 6.6) is the quartic in $\mathbb{R}^2$ defined by $f = xy(x^2 - y^2) - (x^2 + y^2)$. The associated projective curve in $P\mathbb{R}^2$ is $F = xy(x^2 - y^2) - z^2(x^2 + y^2)$, which meets the line at infinity $z = 0$ when $xy(x^2 - y^2) = 0$. Thus we obtain the points at infinity on the lines $x = 0$, $y = 0$, $y = x$ and $y = -x$, namely $(0 : 1 : 0)$, $(1 : 0 : 0)$, $(1 : 1 : 0)$ and $(1 : -1 : 0)$.

Example 9.19 The general circle in $\mathbb{R}^2$ with centre (a, b) and radius $r > 0$ is $f = (x - a)^2 + (y - b)^2 - r^2$. The associated projective curve is $F = (x-az)^2+(y-bz)^2-r^2z^2$ in $P\mathbb{R}^2$. This meets the line at infinity $z = 0$

when $x^2+y^2=0$, giving no points in $\mathrm{P}\mathbb{R}^2$. However, we can also think of F as a projective curve in $\mathrm{P}\mathbb{C}^2$, in that case the relation $x^2+y^2=0$ yields $y=\pm ix$, so there are two points at infinity in $\mathrm{P}\mathbb{C}^2$, namely the complex conjugate points $I=(1:i:0)$ and $J=(1:-i:0)$.

The points I, J in Example 9.19 play a special role in the history of curve theory; they are called the *circular points at infinity*, since any circle (thought of as a complex projective curve) passes through them. The notation has its origins in the biblical names Isaak and Jakob. Real algebraic curves for which the associated complex projective curve passes through I, J are said to be *circular*, and play an important role in mechanical engineering problems. We have already met a number of circular curves, for instance, the pedal curves of the parabola and the unit circle, the three- and four-leaved clovers, and the astroid.

Exercises

9.5.1 Find the points at infinity on the projective curves in $\mathrm{P}\mathbb{R}^2$ corresponding to the following curves f in $\mathbb{R}^2$.

(i) $f=x^3-xy^2-y$
(ii) $f=(y-x^2)^2-xy^3$
(iii) $f=x^4+4xy-y^4$
(iv) $f=x^5+y^5-2xy^2$
(v) $f=x^2y^2+x^2-y^2$.

9.5.2 Find the points at infinity on the projective curves in $\mathrm{P}\mathbb{R}^2$ corresponding to the following curves f in $\mathbb{R}^2$.

(i) $f=x^5+y^5-2x^2-5xy+2y^2$
(ii) $f=x^5+y^5-5x^2y^2+3x-3y$
(iii) $f=(2x+y)(x+y)^2+(2x-y)(x+y)+(x-y)$
(iv) $f=x^4y+x^2y^3+x^4-y^3+1$.

9.5.3 Let $f=cf_1^{r_1}\dots f_s^{r_s}$ be the unique factorization of the polynomial f into irreducible factors, and let $F, F_1, \dots, F_s$ be the forms obtained from $f, f_1, \dots, f_s$ by homogenization. Show that $F=cF_1^{r_1}\dots F_s^{r_s}$ is the unique factorization of the form F into irreducible forms.

9.5.4 Let h be any irreducible conic in $\mathbb{R}^2$ having at least one real point and let H be the corresponding projective conic in $\mathrm{P}\mathbb{C}^2$. Show that if H passes through the circular points at infinity I, J then

h is a circle. (Point out *precisely* where you use the hypothesis that h is irreducible, and where you use the hypothesis that h has a real point.)

9.5.5 Let $f(x, y)$ be a curve of degree d in $\mathbb{R}^2$, and let $F(x, y, z)$ be the corresponding projective curve in $P\mathbb{C}^2$. Show that $f(x, y)$ is circular if and only if its HOT are divisible by $x^2 + y^2$. Use this characterization to verify that the pedal curves of the parabola and the unit circle, the three- and four-leaved clovers, and the astroid are all circular curves.

9.5.6 Let F, G be two curves in $P\mathbb{R}^2$ intersecting in finitely many points. Show that the intersections are either real, or occur in complex conjugate pairs.

10

Singularities of Projective Curves

The next step in our development is to extend the concept of 'singularity' from the affine to the projective situation. We will follow the same pattern as in the affine case. The starting point is to extend the idea of intersection number (of a line with a curve at some point) to the projective situation; we can then define the 'multiplicity' of a point on a projective curve, and use this to introduce 'singular' points. As an application of these ideas, we return to conics, and show that by thinking of conics in the projective (rather than the affine) plane we can gain geometric insight into the delta invariants of Chapter 5.

10.1 Intersection Numbers

For projective curves we can mimic what we did in Chapter 6 for affine curves. Let $F(x, y, z)$ be a curve of degree d in $\mathbb{PK}^2$. And let L be a line. L is determined by any two distinct points, say $A = (a_1 : a_2 : a_3)$ and $B = (b_1 : b_2 : b_3)$: then, as in Example 9.5, the line L can be parametrized as $x_1 = sa_1 + tb_1$, $x_2 = sa_2 + tb_2$, $x_3 = sa_3 + tb_3$. The intersections of F with L are given by $\Phi(s, t) = 0$, where Φ is defined by

$$\Phi(s,t) = F(sa_1 + tb_1, sa_2 + tb_2, sa_3 + tb_3).$$

Since $F(x, y, z)$ is a form of degree d we have $\Phi(\lambda s, \lambda t) = \lambda^d \Phi(s, t)$ for any scalar λ, so $\Phi(s, t)$ is a binary form of degree d, the *intersection form*. Of course, Φ may be identically zero. It is worth comparing this with the situation in the affine case where an intersection polynomial $\phi(t)$, associated to an affine curve f of degree d and a line l, is only known to be of degree $\leq d$. Concerning the generalities of how lines intersect projective curves, we have the following analogue of Lemma 4.4.

Lemma 10.1 *Let F be a curve of degree d in $\mathrm{P}\mathbb{K}^2$, and let L be a line. Then either L meets F in $\leq d$ points, or L is a component of F. Thus, for a curve F with no line components, the degree d is an upper bound for the number of intersections of F with any line L.*

Proof As above, we can associate an intersection form Φ of degree d to the (parametrized) line L and the curve F. Provided Φ is not identically zero, the equation $\Phi(s,t) = 0$ has $\leq d$ roots, and there are $\leq d$ points of intersection. Suppose now that Φ is identically zero, so F vanishes at every point on L. Let L have equation $ax + by + cz = 0$. It is no restriction to suppose that $c \neq 0$, so $X = x$, $Y = y$, $Z = ax + by + cz$ is an invertible linear mapping. Then $F(X, Y, Z)$ vanishes at every point of $Z = 0$, so the binary form $F(X, Y, 0)$ is identically zero, and Z must be a factor of $F(X, Y, Z)$. In terms of the variables x, y, z that means that L is a factor of $F(x, y, z)$, as required. □

Next, let us look in more detail at the way in which a line L intersects a projective curve F of degree d. Assume L is not a component of F. Let P be a point on L corresponding to the ratio $(s_0 : t_0)$, in some parametrization of L. We define the *intersection number* $I(P, F, L)$ to be the multiplicity of $(s_0 : t_0)$ as a root of the equation $\Phi(s,t) = 0$; that means that $\Phi(s,t)$ has a factor $(t_0 s - s_0 t)^m$ for some integer $m \geq 0$, and that $I(P, F, L) = m$. Clearly $I(P, F, L)$ is an integer ≥ 0, and vanishes if and only if P is not an intersection of F, L. It is a convention that $I(P, F, L) = \infty$ when L is a component of F.

Example 10.1 The projective curve corresponding to the eight-curve $f = y^2 - x^2 + x^4$ in $\mathbb{R}^2$ is $F = y^2z^2 - x^2z^2 + x^4$ in $\mathrm{P}\mathbb{R}^2$. Let L be the line $x = 0$. Then L is the line through $P = (0 : 0 : 1)$, $Q = (0 : 1 : 0)$ and parametrized as $x = 0$, $y = t$, $z = s$. The resulting intersection form is $\Phi(s,t) = s^2t^2$, having roots $(1 : 0)$ and $(0 : 1)$ both of multiplicity 2; the root $(1 : 0)$ corresponds to P, whilst $(0 : 1)$ corresponds to Q. Since both roots have multiplicity 2 the intersection numbers are $I(P, F, L) = 2$, $I(Q, F, L) = 2$.

The next step in our development is to establish that $I(P, F, L)$ does not depend on the chosen parametrization of the line L. We follow the paradigm of the affine case, by establishing a preliminary lemma. By a projective *change of parameter* we mean an invertible linear map $U(s,t) = (u, v)$ where $u = \alpha s + \gamma t$, $v = \beta s + \delta t$ and α, β, γ, δ are scalars with $\alpha\delta - \beta\gamma \neq 0$. We now have

Lemma 10.2 *Suppose that two forms* $\Phi(s,t)$, $\Psi(u,v)$ *are related by a projective change of parameter, i.e.* $\Phi(s,t) = \Psi(U(s,t))$ *for some projective change of parameter* $U(s,t)$. *Then* (s_0, t_0) *is a zero of multiplicity* m *of* $\Phi(s,t)$ *if and only if* $U(s_0,t_0)$ *is a zero of multiplicity* m *of* $\Psi(u,v)$.

Proof Write $U(s_0,t_0) = (u_0, v_0)$. Observe (using the Factor Theorem) that $-t_0 s + s_0 t$ is a factor of $\Phi(t)$ if and only if (s_0, t_0) is a zero of $\Phi(t)$, if and only if $U(s_0,t_0)$ is a zero of $\Psi(U(s,t))$, if and only if $-v_0 u + u_0 v$ is a factor of $\Psi(u,v)$. However, by Lemma 4.6 corresponding factors $t - t_0$, $u - u(t_0)$ have the same multiplicity, as required. □

Lemma 10.3 $I(P,F,L)$ *depends only on* P, F, L, *it does not depend on the choice of parametrization of* L.

Proof This follows exactly the same lines as the corresponding result (Lemma 6.3) in the affine case. Consider two parametrizations of L, the first via distinct points A, B with parameter the ratio $(s:t)$, yielding the intersection form $\Phi(s,t) = F(sA + tB)$, and the second via distinct points C, D with parameter the ratio $(u:v)$, yielding the intersection form $\Psi(u,v) = F(uC + vD)$. The connexion between $\Phi(s,t)$, $\Psi(u,v)$ is easily established. Let $A = \alpha C + \beta D$, $B = \gamma C + \delta D$. Then, by direct calculation

$$\Phi(s,t) = F(sA + tB) = F(u(s,t)C + v(s,t)D) = \Psi(u(s,t), v(s,t))$$

where $u(s,t) = \alpha s + \gamma t$, $v(s,t) = \beta s + \delta t$. Thus $\Phi(s,t)$ is obtained from $\Psi(u,v)$ by the projective change of parameter $U(s,t) = (u(s,t), v(s,t))$. (Note that $\alpha\delta - \beta\gamma \neq 0$ else A, B coincide.) Then $(s_0 : t_0)$ is a zero of $\Phi(s,t)$ if and only if $U(s_0,t_0)$ is a zero of $\Psi(u,v)$, and it follows from Lemma 10.2 that the multiplicities of the zeros coincide. The result follows from the definition of $I(P,F,L)$. □

The *total number* of intersections of F with L (counted properly) is the sum of the intersection numbers $I(P,F,L)$ with P on F. As the sum of the multiplicities of the roots of $\Phi(s,t)$ is $\leq d$, we deduce that the total number of intersections of a curve F of degree d with a line L is $\leq d$. Over the complex field the intersection form Φ has exactly d zeros, counted with multiplicities, so the total number of intersections (counted properly) is *precisely* d, in particular Φ has at least one zero. Thus we have established

Lemma 10.4 *Let F be a curve of degree d in* $\mathbb{PC}^2$, *and let L be a line which is not a component of F. Then L meets F in exactly d points, counted properly. In particular, L meets F in at least one point.*

Lemma 10.4 is a special case of a celebrated result in the theory of algebraic curves, namely Bézout's Theorem. Roughly speaking, this says the following. Any two curves F, G in $\mathbb{PC}^2$ with no common component intersect in only finitely many points P. Moreover, it is possible to associate an 'intersection number' $I(P, F, G)$ to any such curves F, G, and any point P, in such a way that the sum of the intersection numbers at all points of intersection is de, where $d = \deg F$, $e = \deg G$. And in the special case when G is a line L, this 'intersection number' agrees with the number $I(P, F, L)$ defined above. The proof of Bézout's Theorem is presented in Chapter 14, together with the algebraic ideas on which it depends.

It is worth remarking at this stage that the definition of $I(P, F, L)$ has a fatal limitation. We used the fact that L can be parametrized globally by parameters s, t. In principle, one could extend the idea by replacing L by any curve G which can be globally parametrized. However, this approach founders on the fundamental fact that rather few algebraic curves have this property. (We will have more to say about this matter in the final chapter.) In practice you can reduce the computation of intersection numbers in the projective plane to one in an affine plane, via the following result.

Lemma 10.5 *Let P be an intersection point of a curve F of degree d with a line L in the projective plane* $\mathbb{PK}^2$. *Dehomogenize with respect to one of the variables x, y, z to obtain a point p, a curve f, and a line l in the affine plane* $\mathbb{K}^2$. *Then $I(P, F, L) = I(p, f, l)$.*

Proof At least one of the homogeneous coordinates of P is non-zero. Without loss of generality, assume it is z. Let $B = (b_1 : b_2 : 0)$ be the unique point where $z = 0$ meets L, and let $A = (a_1 : a_2 : 1)$ be any point on L distinct from B. Then the projective line L is parametrized as $sA + tB$, with $s = 0$ corresponding to B, and gives rise to an intersection form $\Phi(s, t) = F(sA + tB)$. Likewise, the affine line l is parametrized as $a + tb$, where $a = (a_1, a_2)$, $b = (b_1, b_2)$, and gives rise to an intersection polynomial $\phi(t) = f(a + tb)$. Moreover, under the identification $(x, y) \sim (x : y : 1)$ the point on l with parameter t_0 corresponds to the point on

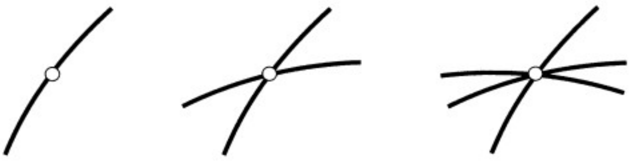

Fig. 10.1. Simple, double and triple points

L with parameter $s = 1$, $t = t_0$. For $s \neq 0$ we have

$$\Phi(s,t) = F(sA + tB) = s^d f(a + ub) = s^d \phi(u)$$

where $u = t/s$. Thus the zeros (s_0, t_0) of $\Phi(s,t)$ with $s_0 \neq 0$ correspond to zeros t_0 of $\phi(t)$, and have the same multiplicity. The result follows from the definitions of $I(P,F,L)$, $I(p,f,l)$. □

Example 10.2 Consider the curve $F = y^2z^2 - x^2z^2 + x^4$ in $\mathbb{PR}^2$, the line L given by $x = 0$, and the point $P = (0:0:1)$. Dehomogenizing with respect to z, we obtain the affine curve $f = y^2 - x^2 + x^4$, the line l given by $x = 0$, and the point $p = (0,0)$. We can parametrize l as $x = 0$, $y = t$ with p corresponding to the value $t = 0$ of the parameter. Then the intersection polynomial is $\phi(t) = t^2$, and $I(p,f,l) = 2$, agreeing with the result of Example 10.1.

10.2 Multiplicity of a Point on a Curve

Let P be a point on a curve F in $\mathbb{PK}^2$. Consider the pencil of all lines L through P. By the *multiplicity* of P on F we mean the minimal value m of the intersection number $I(P,F,L)$ as L varies over the pencil, i.e. $I(P,F,L) \geq m$ for *every* line L through P, and there exist lines L for which $I(P,F,L) = m$. Points of multiplicity 1, 2, 3, 4, … are said to be *simple*, *double*, *triple*, *quadruple*, … points of F. A crude mental picture for a point P of multiplicity m is that there are m 'branches' of the curve self-intersecting at P. (Figure 10.1.) But, as in the affine case, that is not the whole story.

In view of Lemma 10.5, we have the following result, which allows us to compute multiplicities via the technique of Lemma 6.4.

Lemma 10.6 *Let P be a point on a curve F in $\mathbb{PK}^2$. Dehomogenize with* *respect to one of the variables x, y, z to obtain a point p on a curve f in $\mathbb{K}^2$. Then the multiplicity of P on F coincides with that of p on f.*

Example 10.3 The eight-curve gives rise to the projective curve $F = y^2z^2 - x^2(z^2 - x^2)$ in $P\mathbb{R}^2$, intersecting the line at infinity at the unique point $Q = (0 : 1 : 0)$. To find the multiplicity of Q we dehomogenize with respect to y to obtain the affine curve $f = z^2 - x^2(z^2 - x^2)$ and the point $q = (0, 0)$ in the (x, z)-plane. Here the LOT are z^2, so q has multiplicity 2 on f, and hence Q has multiplicity 2 on F.

Exercises

10.2.1 Let F be an irreducible quartic curve in $P\mathbb{C}^2$. Show that F cannot have a point P of multiplicity ≥ 4. Show also that if F has a triple point P then P is the only point on F of multiplicity ≥ 2.

10.2.2 Let P be a point on a projective curve F in $P\mathbb{K}^2$ of multiplicity $\geq m$. Show that P is a point on the projective curve F_z of multiplicity $\geq (m - 1)$. And show, by means of an example, that P could have multiplicity $> m - 1$.

10.3 Singular Points

A point P on a projective curve F is *singular* when it has multiplicity ≥ 2. The curve F itself is *singular* when it has at least one singular point, otherwise it is *non-singular*. We will see in Chapter 18 that an irreducible curve F has at most finitely many singular points.

Example 10.4 A cubic curve F in $P\mathbb{K}^2$ with two singular points P, Q necessarily reduces to a conic, and the line L joining P, Q. Indeed, since P, Q are singular, we have $I(P, F, L) \geq 2$, $I(Q, F, L) \geq 2$ so the total number of intersections of L with F is ≥ 4, contradicting Lemma 10.1 unless L is a component of F.

Here is a simple criterion for a point to be singular on a curve F, analogous to Lemma 6.6 in the affine case.

Lemma 10.7 *A point P is a singular point on a curve F if and only if $F(P) = 0$ and $F_x(P) = F_y(P) = F_z(P) = 0$.*

Proof The condition for $P = (p_1 : p_2 : p_3)$ to be singular is that $I(P, F, L) \geq 2$ for *every* line L through P. We need to interpret this in detail. Let L be any line through P, and let $Q = (q_1 : q_2 : q_3)$ be another point on L. Recall that the intersection form $\Phi(s,t) = F(sP + tQ)$ is a form of degree d in s, t so has the form

$$\Phi(s,t) = s^d F_0(P,Q) + s^{d-1}tF_1(P,Q) + \cdots + t^d F_d(P,Q)$$

where each $F_k(P,Q)$ is a polynomial in the entries of P, Q. The point P corresponds to the ratio $(1 : 0)$ and the condition $I(P,F,L) \geq 2$ is that $(1 : 0)$ should have multiplicity ≥ 2 as a root of $\Phi(s,t) = 0$, i.e. that $\Phi(s,t)$ has t^2 as a factor, i.e. that $F_0(P,Q) = 0$, $F_1(P,Q) = 0$. The condition $F_0(P,Q) = 0$ holds automatically, as P lies on F, so it remains to interpret the condition $F_1(P,Q) = 0$. Write

$$\phi(t) = F(P + tQ) = tF_1(P,Q) + \cdots + t^d F_d(P,Q)$$

so $F_1(P,Q) = \phi'(0)$. The Chain Rule gives $\phi'(t) = q_1F_x + q_2F_y + q_3F_z$, where the partials are evaluated at $P + tQ$; setting $t = 0$ yields

$$F_1(P,Q) = q_1F_x(P) + q_2F_y(P) + q_3F_z(P).$$

This expression is zero for all choices of q_1, q_2, q_3 if and only if $F_x(P) = F_y(P) = F_z(P) = 0$, as required. □

Example 10.5 A point R of intersection of two projective curves F, G is necessarily a singular point of $H = FG$. The point R satisfies the relations $F(R) = 0$, $G(R) = 0$ and hence $H(R) = 0$. Moreover, the rule for differentiating a product gives

$$H_x = F_xG + FG_x, \quad H_y = F_yG + FG_y, \quad H_z = F_zG + FG_z$$

so R also satisfies the relations $H_x(R) = 0$, $H_y(R) = 0$, $H_z(R) = 0$ and is therefore singular on H.

The labour involved in finding singular points in practice can be reduced via the following useful little result about forms, known as the Euler Lemma.

Lemma 10.8 *Let $F(x_1,\ldots,x_n)$ be a form of degree d over a field $\mathbb{K}$, then we have the Euler relation*

$$dF = \sum x_kF_{x_k}.$$

Proof Recall first (Lemma 3.12) that a form $F(x_1,\ldots,x_n)$ of degree d satisfies the following identity, for all $t \in \mathbb{K}$

$$F(tx_1,\ldots,tx_n) = t^dF(x_1,\ldots,x_n).$$

Differentiating both sides of this relation with respect to t, using the Chain Rule, we get the following relation. The required result then follows on setting $t = 1$.

$$\sum x_k F_{x_k}(tx_1, \ldots, tx_n) = dt^{d-1} F(tx_1, \ldots, tx_n).$$

□

The point of the Euler Lemma is that if all the partials F_x, F_y, F_z of a projective curve F vanish at a point P then *automatically* F itself vanishes at P. Thus *the singular points of a projective curve F are obtained by solving the equations*

$$0 = F_x = F_y = F_z.$$

Many of the classical affine curves turn out to have singularities 'at infinity', helping to explain their geometry.

Example 10.6 Agnesi's versiera (Example 2.8) is the real affine cubic $f = x^2y - 4a^2(2a - y)$ with $a > 0$. Although it has no singularities in $\mathbb{R}^2$, the corresponding projective curve $F = x^2y - 4a^2z^2(2az - yz)$ does have a singularity at infinity. Singularities are given by $0 = F_x = 2xy$, $0 = F_y = x^2 + 4a^2z^2$, $0 = F_z = -8a^2z(3az - y)$. The first relation gives $x = 0$ or $y = 0$; $x = 0$ leads to the singularity $P = (0 : 1 : 0)$, the point at infinity on the y-axis, whilst $y = 0$ produces only the trivial solution. The nature of the singularity at P is revealed by setting $y = 1$ in F, yielding the affine curve

$$g = x^2 - 4a^2z^2(2az - 1) = x^2 + 4a^2z^2 + \text{HOT}$$

having a singularity at the origin in the (x, z)-plane, namely an acnode. In particular, this explains why all the 'vertical' lines in the (x, y)-plane only meet the curve once – they meet the curve twice more at the point P.

Example 10.7 The eight-curve gives rise to the projective curve $F = y^2z^2 - x^2(z^2 - x^2)$ in $\mathbb{PR}^2$. Singular points require $0 = F_x = 2x(2x^2 - z^2)$, $0 = F_y = 2yz^2$, $0 = F_z = 2z(y^2 - x^2)$. Clearly, $y = 0$ or $z = 0$: $y = 0$ gives $P = (0 : 0 : 1)$ and $z = 0$ gives $Q = (0 : 1 : 0)$. This throws light on Example 10.1; there we saw that the line $x = 0$ meets the curve solely at P, Q with intersection number 2 in each case. Since Q is a singular point of the curve, that is no longer too surprising.

Example 10.8 Consider the family of *Steiner* cubics in $\mathbb{PC}^2$ given by the formulas

$$F = \mu(x^3 + y^3 + z^3) + 3\lambda xyz.$$

We claim that F is singular if and only if $\mu = 0$ or $\lambda^3 = -1$, and that in each of these four cases F reduces to a triangle. (By a *triangle* we mean a projective cubic which reduces to three non-concurrent lines, known as the *sides*; the three points of intersection of the sides are the *vertices* of the triangle.) When $\mu = 0$, the cubic is $F = xyz$, a triangle with singular points at the vertices $(1 : 0 : 0)$, $(0 : 1 : 0)$, $(0 : 0 : 1)$. When $\mu \neq 0$ we can assume that $\mu = 1$, by multiplying the equation through by a scalar. Then singular points are given by $F_x = 0$, $F_y = 0$, $F_z = 0$, i.e. by

$$x^2 = -\lambda yz, \qquad y^2 = -\lambda zx, \qquad z^2 = -\lambda xy.$$

Note that if one of x, y, z is $= 0$ then all are $= 0$, so we can assume x, y, z are all $\neq 0$. Equating the product of the three left-hand sides, with the product of the three right-hand sides, we get $(1 + \lambda^3)x^2y^2z^2 = 0$. When $\lambda^3 \neq -1$, one of x, y, z must be $= 0$, a contradiction, so in that case F is non-singular. Suppose $\lambda^3 = -1$. Multiplying the three relations by x, y, z respectively yields $x^3 = y^3 = z^3 = -\lambda xyz$. Let 1, ω, ω^2 be the three complex cube roots of 1. Then λ is one of -1, $-\omega$, $-\omega^2$; moreover it is no restriction to suppose that $x = 1$ so y, z must each be one of 1, ω, ω^2. That yields the following singular points.

$$\begin{cases} \lambda = -1 & (1 : 1 : 1) \quad (1 : \omega : \omega^2) \quad (1 : \omega^2 : \omega) \\ \lambda = -\omega & (1 : 1 : \omega^2) \quad (1 : \omega : \omega) \quad (1 : \omega^2 : 1) \\ \lambda = -\omega^2 & (1 : 1 : \omega) \quad (1 : \omega : 1) \quad (1 : \omega^2 : \omega^2). \end{cases}$$

In each case, we have three non-collinear points; the lines joining any two of these points meet F in ≥ 4 points, so must be components, and the cubic reduces to a triangle, with vertices the given singular points.

Exercises

10.3.1 Find the singular points of the quartic curve in $\mathbb{PC}^2$ given by $F = x^2y^2 + y^2z^2 + z^2x^2$, and determine their multiplicities.

10.3.2 Find the singular points of the quartic curve in $\mathbb{PC}^2$ given by $F = (x^2 - z^2)^2 - y^2z(2y + 3z)$, and determine their multiplicities.

10.3.3 Show that the quartic curve $F = (x^2 + y^2 - zx)^2 - z^2(x^2 + y^2)$ in $\mathbb{PC}^2$ has exactly three singular points.

10.3.4 Let λ be a complex number and let F_λ be the quartic curve in $P\mathbb{C}^2$ given by $F_\lambda = x^4 + xy^3 + y^4 - \lambda zy^3 - 2x^2yz - xy^2z + y^2z^2$. Show that $O = (0 : 0 : 1)$ is singular on F_λ. Further, show that there are exactly two values of λ for which F_λ has a second singular point.

10.3.5 Show that the quintic $F = (x^2 - a^2z^2)^2y - (y^2 - b^2z^2)^2x$ in $P\mathbb{C}^2$ has exactly four singular points. ($a \neq 0$, $b \neq 0$.)

10.3.6 Show that the sextic curve $F = (z^2 - x^2 - y^2)^3 - 27x^2y^2z^2$ in $P\mathbb{C}^2$ has exactly ten singular points. (This is the complex projective version of the astroid.)

10.3.7 Show that the sextic curve $F = (x^2 + y^2)^3 - 4x^2y^2z^2$ in $P\mathbb{C}^2$ has exactly three singular points, namely a quadruple point P, and two double points at the circular points at infinity I, J.

10.3.8 The Euler Lemma expresses a form F of degree d in terms of the first order partials of F. Extend this to second order partials by showing that

$$d(d-1)F = \sum x_i x_j F_{x_i x_j}.$$

10.3.9 Let $f(x, y)$ be a polynomial over the field $\mathbb{K}$ which can be written in the form $f = F + G$ where F, G are forms of different degrees $d, e \geq 2$. Use the Euler Lemma to show that the singular points of f in $\mathbb{K}^2$ satisfy the relations $F = 0$, $G = 0$. If, in addition, F, G have no common factors, deduce that $(0, 0)$ is the only singularity of f. Deduce that the Maltese cross curve in $\mathbb{R}^2$ defined by $f = xy(x^2 - y^2) - (x^2 + y^2)$ has just one singularity, namely a double point at $(0, 0)$.

10.3.10 Let $p(x)$ be a complex polynomial of degree $d \geq 3$, let f be the affine curve in $\mathbb{C}^2$ defined by $f = y^2 - p(x)$, and let F be the corresponding projective curve in $P\mathbb{C}^2$. Show that F meets the line at infinity at a unique point P, of multiplicity $(d - 2)$. (The singular points of f were determined in Exercise 6.3.9.)

10.4 Delta Invariants viewed Projectively

In this section we will consolidate our account of affine conics in Chapter 5 by showing that the projective viewpoint gives considerable geometric insight into the delta invariants δ, Δ of that chapter. Recall that a general conic in $\mathbb{K}^2$ has the shape

$$q = ax^2 + 2hxy + by^2 + 2gx + 2fy + c \qquad (\star)$$

where the coefficients a, b, c, f, g, h lie in $\mathbb{K}$, and at least one of a, b, h is non-zero. The corresponding projective curve in $P\mathbb{K}^2$ is

$$Q = ax^2 + by^2 + cz^2 + 2hxy + 2fyz + 2gzx \qquad (\star\star)$$

The first thing to ask is how the conic meets the line at infinity. Setting $z = 0$ in $(\star\star)$ gives a binary quadratic equation $ax^2 + 2hxy + by^2 = 0$. Over the complex field this has two roots (giving two points at infinity on the conic) with coincidence if and only if the discriminant vanishes. The discriminant is $-4(ab - h^2) = -4\delta$, where δ is the affine invariant we met in Chapter 5, thus the geometric significance of the relation $\delta = 0$ is that the associated projective conic meets the line at infinity at a single point with intersection number 2. Over the real field we can say more. When $\delta < 0$, the binary quadratic has two real roots (and the conic has two real points at infinity), and when $\delta > 0$ the binary quadratic has no real roots (and the conic has no real points at infinity). Thus in the real case, the conditions $\delta < 0$, $\delta = 0$, $\delta > 0$ correspond to the projective conic Q having two, one or no points at infinity. Looking at Table 5.4 we see that for an *irreducible* real conic these conditions characterize respectively the hyperbola, the parabola and the two types of ellipse.

A geometric understanding of the invariant Δ is based on the following elementary result.

Lemma 10.9 *The conic $(\star\star)$ is singular if and only the matrix A below is singular.*

$$A = \begin{pmatrix} a & h & g \\ h & b & f \\ g & f & c \end{pmatrix}$$

Proof Q is singular if and only if there exists a non-trivial solution (x, y, z) for the following system of linear equations: and by linear algebra that is the case if and only if the matrix A of coefficients is singular.

$$\begin{aligned} Q_x &= 2(ax + hy + gz) = 0 \\ Q_y &= 2(hx + by + fz) = 0 \\ Q_z &= 2(gx + fy + cz) = 0. \end{aligned}$$

□

Recall from linear algebra that a matrix A is singular if and only if its determinant is zero. However the determinant of A is precisely the invariant Δ of Chapter 5, so the geometric interpretation of the condition $\Delta = 0$ is that the associated projective conic Q has a singular point.

Example 10.9 The conic $Q(x, y, z) = xy + yz + zx$ in $P\mathbb{K}^2$ is non-singular because its matrix A (below) has non-zero determinant.

$$A = \frac{1}{2}\begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}.$$

Lemma 10.10 *A reducible conic Q is necessarily singular. And a singular conic Q with at least two points is reducible. Over the complex field a conic is singular if and only if it is reducible.*

Proof Suppose Q reduces, necessarily, to two lines L, M. These lines intersect in at least one point R which is singular on Q, by Example 10.5. Conversely, suppose Q is singular, with at least two points. Let R be a singular point of Q, and let S be a point on Q distinct from R. Then the line joining R, S meets Q in ≥ 3 points, so by Lemma 10.1 is a component, and Q is reducible. The final statement is immediate from the fact that any curve in $P\mathbb{C}^2$ has an infinite zero set. □

Over the real field, a singular conic may fail to be reducible; for instance, although the conic $Q = x^2 + y^2$ in $P\mathbb{R}^2$ is irreducible, the zero set contains only one point $P = (0 : 0 : 1)$, which is singular on Q. Finally, it is instructive to look again at the lists of normal forms for real affine conics in Table 5.4. All the normal forms with $\Delta = 0$ do indeed exhibit a singular point in the projective plane, though in the 'parallel lines' cases that point is 'at infinity'.

Curvature

The (signed) curvature of a curve parametrised by its arc-length is the rate of change of direction of the tangent vector. The absolute value of the curvature is a measure of how sharply the curve bends. Curves which bend sharply will have a large absolute curvature. Curves which bend slowly, which are almost straight lines, will have a small absolute curvature. Straight lines themselves have zero curvature. Curves which swing to the left have positive curvature and curves which swing to the right have negative curvature. The curvature of the direction of a road will affect the maximum speed at which vehicles can travel without skidding, and the curvature in the trajectory of an aeroplane will affect whether the pilot will suffer "blackout" as a result of the g–forces involved. In this chapter we give the basic definitions and properties of curvature. In Chapter 8 we consider some applications of the curvature of parametrised curves, and in Chapter 9 we consider the circle of curvature.

7.1 Cartesian coordinates

7.1.1 General parameters

Let $t \mapsto \mathbf{r}(t)$ be a regular smooth parametrised curve[†]. The parameter t will not in general be arc-length. Since the curve is regular and smooth, the parametrisation will determine a direction along the curve as t increases. An *oriented curve* is a curve with such a direction along it. We wish to measure the rate of change of direction of the tangent vector in a way which is intrinsic to curve, that is, in a way which is not dependent on a particular parametrisation of the curve, but only on the orientation of the curve (direction along the curve) determined by the parametrisation. We measure this rate of change of direction with respect to the arc-length s. Let ψ be the angle measured counter-clockwise from the direction of the initial half-line (the positive x-axis) to the tangent vector (see Figure 7.1). Notice that[†]

[†] Often we use t as parameter. The reader should however become familiar with the use of other parameters such as s, usually the arc-length, and φ, often used in case the parameter is an angle.

$$\frac{d\mathbf{r}}{ds} = (\cos\psi, \sin\psi).$$

We assume in general that the direction of the positive y–axis is given by a counter-clockwise rotation through an angle $\frac{\pi}{2}$ from the direction of the positive x–axis.

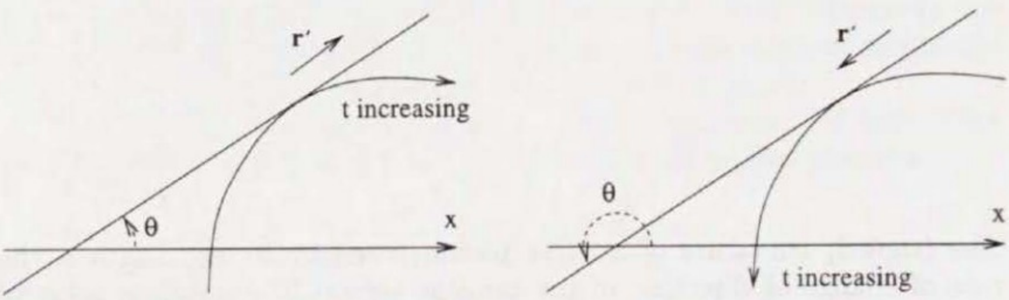

Figure 7.1 *Curvature.*

Definition 7.1. The *curvature* or *signed curvature* κ of a smooth curve $t \mapsto \mathbf{r}(t)$ at a regular point is the rate of change of direction at that point of the tangent line with respect to arc-length, that is

$$\boxed{\kappa = \frac{d\psi}{ds}\ ,}$$

where arc-length $t \mapsto s(t)$ is measured along the curve so that s increases as t increases. The *absolute curvature* of the curve at a point is the absolute value $|\kappa|$ of the curvature at that point.

In general the arc-length parametrisation of the curves we consider is not given by a simple formula and, in order to calculate the curvature of a specific parametrised curve, we need to determine a formula for curvature in terms of the given parameter. As a first step to this we give in the following lemma a formula for curvature in terms of the rate of change of direction of the tangent vector with respect to the parameter t by which the curve is described.

[†] We use ψ for the polar angle of $\mathbf{r}'$, and generally use θ or φ when considering the polar angle of $\mathbf{r}$.

Lemma 7.2. *The curvature of a curve $t \mapsto \mathbf{r}(t)$ at a regular point is*

$$\kappa = \kappa(t) = \frac{d\psi}{dt}\Big/\left|\frac{d\mathbf{r}}{dt}\right| = \frac{\dfrac{d\psi}{dt}}{\sqrt{\left(\dfrac{dx}{dt}\right)^2 + \left(\dfrac{dy}{dt}\right)^2}} = \frac{d\psi}{dt}\Big/\frac{ds}{dt} = \frac{d\psi}{ds}\,,$$

where arc-length $t \mapsto s(t)$ is measured in the direction given by t increasing.

*Solution**. We need to prove the last of the equalities. Since the arc-length is measured in terms of t increasing, we have at regular points $\dfrac{ds}{dt} > 0$ and therefore $\dfrac{ds}{dt} = |\mathbf{r}'|$. For a regular (smooth) curve $t \mapsto \mathbf{r}(t)$, we also have that $t \mapsto s(t)$ is smooth (see §4.6.2). By the inverse function theorem (see §4.7), in this case of a regular smooth curve, the function $t \mapsto s(t)$ has an inverse $s \mapsto t(s)$ which is also smooth. Therefore ψ can be regarded as a function of s by $s \mapsto \psi(t(s))$. The last of the equalities in the definition now follows from the chain rule $\dfrac{d\psi}{dt} = \dfrac{d\psi}{ds}\dfrac{ds}{dt}$, on regarding ψ as a function of s on the one hand and as a function of t on the other, where $s = s(t)$. □

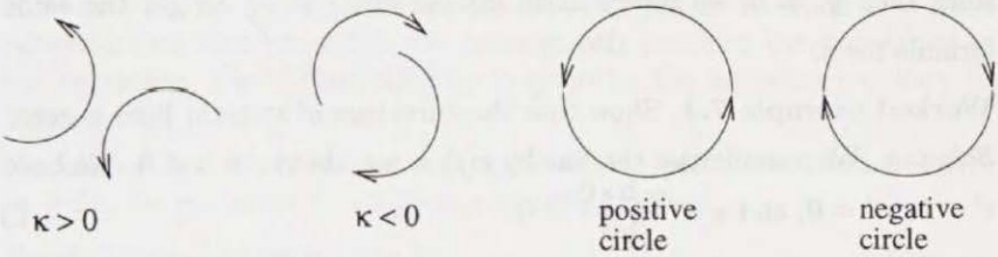

Figure 7.2 *Sign of the curvature.*

The curvature can be positive, negative or zero. The angle ψ is measured counterclockwise. Therefore the curvature of a parametrised curve is *positive* $\left(\kappa = \dfrac{d\psi}{ds} > 0\right)$ if the curve swings to the left as t increases, that is ψ increases as s increases. Similarly the curvature is *negative* $\left(\kappa = \dfrac{d\psi}{ds} < 0\right)$ if the curve swings to the right as t increases, that is ψ decreases as s increases (see Figure 7.2). Thus the *sign* of the curvature at a point depends on the direction along which the curve is parametrised at the point. If the curve is reparametrised in the opposite direction then the sign of the curvature becomes the opposite of what it had been.

---

* For the meaning of * see the preface.

Mnemonic

$$\boxed{\text{A curve with positive curvature swings to the left.}}$$

We next give a formula for curvature which is the one normally used in calculations.

Theorem 7.3. *At a regular point of a smooth curve* $t \mapsto \mathbf{r}(t)$, *the curvature satisfies*

$$\boxed{\kappa = \frac{x'\,y'' - y'\,x''}{((x')^2 + (y')^2)^{\frac{3}{2}}} = \frac{x'\,y'' - y'\,x''}{|\mathbf{r}'|^3} = -\,\frac{\mathbf{r}'\,.\,(-y'', x'')}{|\mathbf{r}'|^3}\,.}$$

Proof. Differentiating $\tan\psi = \dfrac{y'}{x'}$ with respect to t, we have, for $x' \neq 0$,

$$\frac{x'\,y'' - y'\,x''}{(x')^2} = \sec^2\psi \cdot \psi' = (1 + \tan^2\psi) \cdot \psi' = \left(1 + \left(\frac{y'}{x'}\right)^2\right) \cdot \psi',$$

and the result follows easily on multiplying each side by $(x')^2$. At any (regular) point at which $x' = 0$, we cannot use the above argument, but, since then $y' \neq 0$, we differentiate instead $\cot\psi = \dfrac{x'}{y'}$ to get the same formula for κ. □

Worked example 7.4. Show that the curvature of straight lines is zero.

Solution. We parametrise the line by $\mathbf{r}(t) = \mathbf{a} + t\mathbf{b}$ where $\mathbf{b} \neq \mathbf{0}$. We have $\mathbf{r}' = \mathbf{b}$, $\mathbf{r}'' = \mathbf{0}$, and $\kappa = \dfrac{-\mathbf{b}\cdot\mathbf{0}}{|\mathbf{b}|^3} = 0$. □

Worked example 7.5. Show that the curvature of a positively described (counter-clockwise) circle of radius R is $\dfrac{1}{R}$, and that the curvature of a negatively described (clockwise) circle of radius R is $-\dfrac{1}{R}$.

Solution. We parametrise the circle having centre $\mathbf{a}$ and radius R in the counter-clockwise direction by $\mathbf{r}(t) = \mathbf{a} + R(\cos t, \sin t)$. Therefore we have $\mathbf{r}' = R(-\sin t, \cos t)$, and $\mathbf{r}'' = -R(\cos t, \sin t)$. Therefore

$$\kappa = \frac{x'\,y'' - y'\,x''}{((x')^2 + (y')^2)^{\frac{3}{2}}} = \frac{R^2(\sin^2 t + \cos^2 t)}{(R^2\sin^2 t + R^2\cos^2 t)^{\frac{3}{2}}} = \frac{1}{R}\,.$$

If the circle is oriented in the clockwise direction, by

$$\mathbf{r}(t) = \mathbf{a} + R(\cos t, -\sin t)$$

for example, we obtain in a similar way that the curvature is $-\dfrac{1}{R}$. □

By Example 7.5, we have the following memory-aid for the sign of the curvature of a curve.

Mnemonic

A positively (counter-clockwise) described circle has positive curvature.

Worked example 7.6. Find the curvature of the curve $x = t^3 - t, y = t^2$.

Solution. We have $\mathbf{r}' = (3t^2 - 1, 2t)$, and $\mathbf{r}'' = (6t, 2)$. Therefore

$$\kappa = \frac{x'\,y'' - y'\,x''}{((x')^2 + (y')^2)^{\frac{3}{2}}} = \frac{(3t^2 - 1).2 - 2t.6t}{((3t^2 - 1)^2 + (2t)^2)^{\frac{3}{2}}} = -\frac{6t^2 + 2}{(9t^4 - 2t^2 + 1)^{\frac{3}{2}}}\,.$$

□

Notice that Theorem 7.3 tells us that

$$\frac{x'\,y'' - y'\,x''}{((x')^2 + (y')^2)^{\frac{3}{2}}}$$

is invariant under change of rectangular axes (rotation and/or translation), since the curvature $\dfrac{d\psi}{ds}$ is clearly invariant under such a change. If the axes are changed by a reflexion, the curvature simply changes sign. The curvature is also independent of the choice of parametrisation in a fixed direction (see Exercise 7.20). We subsequently consider the derivatives of the curvature. The differentiability is given by the following corollary to Theorem 7.3.

Corollary 7.7. *At a regular point of a smooth parametrisation* $t \mapsto \mathbf{r}(t)$ $(n \geq 2)$, *the curvature* $t \mapsto \kappa(t)$ *is a smooth function.*

Proof. The curvature is given by

$$\kappa = \frac{x'\,y'' - y'\,x''}{((x')^2 + (y')^2)^{\frac{3}{2}}}\,.$$

The numerator is a polynomial in the smooth functions x', y', x'', and y'', and therefore is a smooth function; similarly $(x')^2 + (y')^2$ is smooth. Also $X \to X^{\frac{3}{2}}$ is a smooth function of X at points for which $X > 0$. The result follows since the composite of two smooth functions is smooth, and the quotient of a smooth function by a non-zero smooth function is also smooth. □

7.1.2 Coordinates as parameter

An important special case of Theorem 7.3 is the formula for the curvature of a graph. The graph of a function $y = g(x)$ is usually assumed to be parametrised using x as parameter, that is by $\mathbf{r}(x) = (x, g(x))$. With this parametrisation the graph of $y = g(x)$ has the orientation given by x increasing. Similarly the curve given by $x = h(y)$ is usually assumed to be parametrised using y as parameter, that is by $\mathbf{r}(y) = (h(y), y)$, and has then the orientation given by y increasing.

Corollary 7.8. *The graph, parametrised by the coordinate x, of a smooth function $y = g(x)$ has curvature*

$$\boxed{\kappa(x) = \frac{\dfrac{d^2y}{dx^2}}{\left(1 + \left(\dfrac{dy}{dx}\right)^2\right)^{\frac{3}{2}}} = \frac{g''(x)}{(1 + (g'(x))^2)^{\frac{3}{2}}} \,.}$$

Proof. We have $\mathbf{r}' = (1, g'(x))$ and $\mathbf{r}'' = (0, g''(x))$. Thus

$$\kappa = \frac{x'\,y'' - y'\,x''}{|\mathbf{r}'|^3} = \frac{1\,.\,g''(x) - g'(x)\,.\,0}{(1 + (g'(x))^2)^{\frac{3}{2}}} \,.$$

☐

For a curve parametrised by the x–coordinate, the curvature is positive where the concavity of the curve is "upward", and is negative where the concavity is "downward"; moreover, in this case of a curve parametrised by the x–coordinate, the curvature has the same sign as $\dfrac{d^2y}{dx^2}$ by Corollary 7.8.

Compare the formula of Corollary 7.8 carefully with the formula for the curvature for general parametrisations. Of course, by Theorem 4.22, any algebraic curve may be parametrised locally, near a non-singular point, by either the x or the y coordinate, or by both. Each such local parametrisation will give a local orientation along the curve, determined by x increasing or y increasing respectively, and hence will determine a sign for the curvature. For some curves the curvature will have the opposite sign and the curve will have the opposite local orientation for increasing x to those given by increasing y.

Worked example 7.9. Find the curvature of the graph of $y = x^3$ parametrised by x.

Solution. We have $\dfrac{dy}{dx} = 3x^2$, and $\dfrac{d^2y}{dx^2} = 6x$. Therefore

$$\kappa = \frac{6x}{(1 + 9x^4)^{\frac{3}{2}}} \,.$$

☐

Worked example 7.10. Find the point of greatest absolute curvature of the graph of $y = \log x$.

Solution. The domain of parametrisation is $x > 0$. We have

$$\frac{dy}{dx} = \frac{1}{x}, \quad \text{and}$$
$$\frac{d^2y}{dx^2} = -\frac{1}{x^2}.$$

Therefore

$$\kappa = -\frac{x}{(1+x^2)^{\frac{3}{2}}}, \quad \text{and}$$

$$\frac{d\kappa}{dx} = \frac{2x^2-1}{(1+x^2)^{\frac{5}{2}}} = \frac{2\left(x-\frac{1}{\sqrt{2}}\right)\left(x+\frac{1}{\sqrt{2}}\right)}{(1+x^2)^{\frac{5}{2}}}.$$

The critical point is at $x = \frac{1}{\sqrt{2}}$, and the required point, which gives a minimum value of the signed curvature corresponding to the parametrisation by x and a maximum value of the absolute curvature, is $\left(\frac{1}{\sqrt{2}}, -\frac{1}{2}\log 2\right)$. The curve is not defined at $x = -\frac{1}{\sqrt{2}}$. □

7.1.3 A short cut

We note the following technique which is sometimes useful in shortening the calculation of curvature and in determining whether or not a cusp is ordinary. Recall that $(-v', u')$ is obtained by rotating (u', v') counter-clockwise through the angle $\frac{\pi}{2}$, in the case where $(u', v') \neq 0$. Let $\mathbf{Z}(t) = (X(t), Y(t))$ satisfy $\mathbf{Z}' = f(t).(u(t), v(t))$. Suppose we wish to calculate

$$\mathbf{Z}' \cdot (-Y'', X'').$$

We have

$$\mathbf{Z}'' = f'(t).(u(t), v(t)) + f(t).(u'(t), v'(t)).$$

Therefore

$$\mathbf{Z}' \cdot (-Y'', X'') = \mathbf{Z}' \cdot (f(t).(-v'(t), u'(t))),$$

since $(u'(t), v'(t)) \cdot (-v'(t), u'(t)) = 0$.

Notice that we have differentiated

$$f(t).(u(t), v(t))$$

as a product of a scalar function and a vector function, rather than writing it in the form $(f(t).u(t), f(t).v(t))$.

Exercises

7.1. Find the curvature at regular points of the following curves:

a) The rectangular hyperbola $t \mapsto \mathbf{r}(t) = \left(at, \frac{a}{t}\right)$.

$$\left[\frac{2a^2t^4}{a^3(1+t^4)^{\frac{3}{2}}};\ \text{none, none}\right]$$

b) The cuspidal cubic $t \mapsto \mathbf{r}(t) = (t^2, t^3)$.

c) The crunodal cubic $t \mapsto \mathbf{r}(t) = (t^2-1, t(t^2-1))$.

$$\left[\frac{6t^2+2}{(9t^4-2t^2+1)^{\frac{3}{2}}};\ \text{none, none}\right]$$

d) The acnodal cubic $t \mapsto \mathbf{r}(t) = (1+t^2, t(1+t^2))$.

In each case find the non-regular points and the points at which the curvature is zero.

7.2. Prove that the ellipse $x = a\cos\varphi, y = b\sin\varphi$ $(0 < b < a)$ has curvature

$$\kappa = \frac{ab}{(a^2\sin^2\varphi + b^2\cos^2\varphi)^{\frac{3}{2}}}.$$

7.3. Show that the right-hand branch $x = a\sec\varphi, y = b\tan\varphi$ of the hyperbola $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ has curvature

$$\kappa = -\frac{ab}{(a^2\tan^2\varphi + b^2\sec^2\varphi)^{\frac{3}{2}}}.$$

Find the curvature on the left-hand branch $x = -a\sec\varphi, y = b\tan\varphi$.

7.4. Show that the parabola $x = at^2, y = 2at$ has curvature

$$\kappa = -\frac{1}{2a\,(1+t^2)^{\frac{3}{2}}}.$$

7.5. Show that the curvature of the cycloid $x = a(t - \sin t)$, $y = a(1-\cos t)$ is

$$-\frac{1}{4a\left|\sin\frac{t}{2}\right|}.$$

7.6. Show that the curvature of the curve

$$t \mapsto \mathbf{r}(t) = (a\sin 2t\,(1+\cos 2t), a\cos 2t\,(1-\cos 2t))$$

is $4a\cos 3t$.

7.7. The curvature of the ellipse given by $x = a\cos\varphi, y = b\sin\varphi$ $(0 < b < a)$ is

$$\kappa = \frac{ab}{(a^2\sin^2\varphi + b^2\cos^2\varphi)^{\frac{3}{2}}}.$$

Show that

$$a^2 \sin^2 \varphi + b^2 \cos^2 \varphi = (a^2 - b^2) \sin^2 \varphi + b^2$$

is strictly monotone increasing in the interval $0 \le \varphi \le \frac{\pi}{2}$ and hence deduce that there are precisely four points on the ellipse at which the curvature of the ellipse is $\frac{1}{a}$. (This is the curvature of the circle of radius a which has, as a diameter, the major axis of the ellipse.)

7.8. Show that the curve $\mathbf{r}(t) = a(\sin 2bt, \sin bt)$ is regular and that its tangent is parallel to the y–axis if, and only if, $bt = \pm\frac{\pi}{4}$ or $\pm\frac{3\pi}{4}$. Find the point where the tangent is parallel to the x–axis. Determine the curvature at those points where the tangent is parallel to either axis.

7.9. Find the curvature at the origin of the curve $y = \sin ax^2$ parametrised by the x coordinate. $[\kappa = a]$

7.10. Find the curvature at the origin of the curve $y = x^2 - x^3$ parametrised by the x coordinate.

7.11. Show that the curvature of the catenary $y = a \cosh \frac{x}{a}$ parametrised by the x coordinate is $\frac{a}{y^2}$.

7.12. Find the curvature of a curve given by $x = h(y)$ and parametrised by the y–coordinate.

7.13. A curve which can be parametrised near the origin by a smooth function $y = f(x)$ has the x–axis as tangent at the origin. Prove that the curvature at the origin is given by Newton's formula:

$$\kappa(0) = \lim_{x \to 0} \frac{2y}{x^2}.$$

Obtain a similar formula in case the curve is parametrised near the origin by a smooth function $x = g(y)$ and has the y–axis as tangent at the origin. (*Hint:* Use L'Hôpital's theorem – see §4.7.5.)

$$\left[\kappa(0) = -\lim_{y \to 0} \frac{2x}{y^2}\right]$$

7.14. Find the curvature at the origin of the quartic curve

$$3x^4 + 2y^4 + 4xy^2 + xy - x^2 + 2y = 0.$$

(*Hint:* Use the local parametrisation theorem (Theorem 4.22) to show that there is a local parametrisation $y = f(x)$ near the origin, divide the algebraic equation by x^2, and use Exercise 7.13.) $[\kappa = 1]$

7.15. Show that the curvature of the ellipse $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$ parametrised locally by x is $\kappa = \pm \frac{ab}{(a^2 - e^2x^2)^{\frac{3}{2}}}$, where e is the eccentricity. Indicate on a diagram which parts of the ellipse have positive curvature in this case and which have negative curvature.

7.16. Find the maximum distance from the origin of points on the curve

$$t \mapsto \mathbf{r}(t) = \left(a\sin t - b\sin\frac{at}{b}\, , a\cos t - b\cos\frac{at}{b}\right) .$$

Show that the curvature at such a point of maximum distance is $\dfrac{a+b}{4ab}$.

7.17. Show that the curvature of the hyperbola $\dfrac{x^2}{a^2} - \dfrac{y^2}{b^2} = 1$ parametrised by x is $\kappa = \pm\dfrac{ab}{(e^2x^2 - a^2)^{\frac{3}{2}}}$, where e is the eccentricity. Indicate on a diagram which parts of the hyperbola have positive curvature in this case and which have negative curvature.

7.18. Show that the curvature of a general curve satisfies

$$\kappa = \frac{\mathbf{r}''\,.\,\mathbf{n}}{|\mathbf{r}'|^3} ,$$

where $\mathbf{n} = (-y', x')$ is the (usual) normal.

7.19. Let $s \mapsto \mathbf{r}(s)$ be a curve parametrised by arc-length. Prove that $\mathbf{r}'$ and $(-y'', x'')$ are parallel. Deduce that $|\kappa(s)| = |\mathbf{r}''(s)|$. Prove further that $\mathbf{r}'' \cdot \mathbf{r}'' + \mathbf{r}' \cdot \mathbf{r}''' = 0$ and deduce that $\kappa(s)^3 = x''\,y''' - y''\,x'''$.

7.20. Show that the curvature of a curve $t \mapsto \mathbf{r}(t)$ is unchanged by rotation or translation of the coordinate axes. Prove that it is also left unchanged by a change of parameter given by $t = g(\tau)$ where g is a smooth function and $g'(\tau) > 0$ for all relevant values of τ.

7.21. Let $t \to \mathbf{r}(t)$ be a regular parametrised curve and let $t \to \mathbf{n}(t)$ be a smooth function such that $\mathbf{n}(t)$ is one of the two unit normals to the curve at $\mathbf{r}(t)$. Let the curvature, for this choice of normal, be defined by

$$\mathbf{n}'(t) + \kappa(t)\mathbf{r}'(t) = \mathbf{0}.$$

Deduce that $\mathbf{n} \cdot \mathbf{r}'' = \kappa\mathbf{r}' \cdot \mathbf{r}'$ for each value of t, and that $\mathbf{n} \cdot \mathbf{r}''' = 3\kappa\mathbf{r}' \cdot \mathbf{r}''$ at t if, and only if, $\kappa'(t) = 0$. Prove also that if $\mathbf{n}' \cdot \mathbf{n}' = 1$ for all t, then $\kappa'(t) = 0$ if, and only if, $\mathbf{r}' \cdot \mathbf{r}'' = 0$.

7.2 Curves given by polar equation

We now develop a technique which we can use to find the curvature of curves given by a polar equation. Let

$$\mathbf{w} = (\cos\varphi, \sin\varphi),$$

be the parametrisation of the unit circle $x^2 + y^2 = 1$ where the parameter φ in this case is the polar angle θ, then we have

$$\begin{aligned}\mathbf{w}' &= (-\sin\varphi, \cos\varphi), \text{ and}\\ \mathbf{w}'' &= -(\cos\varphi, \sin\varphi).\end{aligned}$$

The vectors $(\cos\varphi, \sin\varphi)$ and $(-\sin\varphi, \cos\varphi)$ satisfy

$$\begin{aligned}(\cos\varphi, \sin\varphi)\cdot(\cos\varphi, \sin\varphi) &= 1,\\ (-\sin\varphi, \cos\varphi)\cdot(-\sin\varphi, \cos\varphi) &= 1, \text{ and}\\ (\cos\varphi, \sin\varphi)\cdot(-\sin\varphi, \cos\varphi) &= 0,\end{aligned} \tag{7.1}$$

that is they are orthogonal unit vectors or orthonormal vectors.

A curve given by a polar equation $r = r(\theta)$, has the parametric equation

$$\mathbf{r} = r(\varphi)(\cos\varphi, \sin\varphi),$$

according to our convention of replacing θ, the polar angle, by φ. Then we have by the chain rule

$$\begin{aligned}\mathbf{r}' &= r'(\varphi)(\cos\varphi, \sin\varphi) + r(\varphi)(-\sin\varphi, \cos\varphi),\\ \mathbf{r}'' &= r''(\varphi)(\cos\varphi, \sin\varphi) + 2r'(\varphi)(-\sin\varphi, \cos\varphi) - r(\varphi)(\cos\varphi, \sin\varphi),\end{aligned}$$

and

$$\begin{aligned}(-y'', x'') = r''(\varphi)(-\sin\varphi, \cos\varphi) &- \\ &2r'(\varphi)(\cos\varphi, \sin\varphi) - r(\varphi)(-\sin\varphi, \cos\varphi).\end{aligned}$$

Notice how $\mathbf{r}$, $\mathbf{r}'$, $\mathbf{r}''$, and $(-y'', x'')$ are expressed as linear combinations of the two orthogonal unit vectors $(\cos\varphi, \sin\varphi)$ and $(-\sin\varphi, \cos\varphi)$. These two vectors vary by rotating as φ increases. The above technique of writing the successive derivatives of $\mathbf{r}$ as linear combinations of these two rotating orthogonal vectors considerably shortens and simplifies the calculation needed to determine the curvature of curves given by their polar equation. We now have easily, on using Equations 7.1,

$$\begin{aligned}|\mathbf{r}'|^2 &= \{r'(\varphi)\}^2 + \{r(\varphi)\}^2, \text{ and}\\ -\mathbf{r}'\cdot(-y'', x'') &= r^2 + 2(r')^2 - r\,r''.\end{aligned}$$

The following theorem is obtained by substituting these into the formula for curvature given in Theorem 7.3.

Theorem 7.11. *The curvature of a curve given by a polar equation $r = r(\theta)$ is*

$$\kappa(\theta) = \frac{r^2 + 2\left(\dfrac{dr}{d\theta}\right)^2 - r\dfrac{d^2r}{d\theta^2}}{\left(r^2 + \left(\dfrac{dr}{d\theta}\right)^2\right)^{\frac{3}{2}}}.$$

The parameter used for this result is θ and therefore the curve has the orientation given by increasing θ. As usual the sign of the curvature is positive if the curve turns to the left as θ increases. Notice that the formula for $\kappa(\theta)$ is unchanged when r is replaced by $-r$ and θ is replaced by $\theta + \pi$. Therefore the formula is valid where $r = r(\theta)$ is given by the polar equation, and is equally valid where r is the polar coordinate ($r \geq 0$) of the point given by the polar equation; recall that the polar coordinates are either $(r(\theta), \theta)$ or $(-r(\theta), \theta + \pi)$, where r is given by the polar equation.

We now use the above technique as a model for calculating the curvature in a specific example. It is suggested that the reader calculate the curvature of curves given by their polar equation directly in this way rather than by learning and using the formula of Theorem 7.11. We stress that direct calculations are far more complicated if the above technique involving orthogonal vectors is not used.

Worked example 7.12. Find the curvature of the equi-angular spiral

$$\mathbf{r}(\varphi) = e^{a\varphi}(\cos\varphi, \sin\varphi),$$

where a is a real number.

Solution. We have

$$\begin{aligned}\mathbf{r}' &= ae^{a\varphi}(\cos\varphi, \sin\varphi) + e^{a\varphi}(-\sin\varphi, \cos\varphi),\\ \mathbf{r}'' &= a^2e^{a\varphi}(\cos\varphi, \sin\varphi) + 2ae^{a\varphi}(-\sin\varphi, \cos\varphi) - e^{a\varphi}(\cos\varphi, \sin\varphi),\end{aligned}$$

and

$$(-y'', x'') = a^2e^{a\varphi}(-\sin\varphi, \cos\varphi) - 2ae^{a\varphi}(\cos\varphi, \sin\varphi) - e^{a\varphi}(-\sin\varphi, \cos\varphi).$$

Therefore $\mathbf{r}' \cdot (-y'', x'') = -2a^2e^{2a\varphi} + a^2e^{2a\varphi} - e^{2a\varphi}$ (deduce this directly using the fact that $(\cos\varphi, \sin\varphi)$ and $(-\sin\varphi, \cos\varphi)$ are orthogonal unit vectors). Hence the curvature is

$$\kappa = \frac{(1+a^2)e^{2a\varphi}}{(1+a^2)^{\frac{3}{2}}e^{3a\varphi}} = \frac{e^{-a\varphi}}{\sqrt{1+a^2}}.$$

□

Exercises

7.22. For the following curves use the technique described in this section to show that the curvature is as given:

a) The circle $r = a\cos\theta$, $\kappa = \dfrac{2}{a}$.

b) The Archimedean spiral $r = a\theta$, $\kappa = \dfrac{2a^2 + r^2}{(a^2 + r^2)^{\frac{3}{2}}}$.

c) The cardioid $r = a(1 + \cos\theta)$, $\kappa = \dfrac{3}{4a}\left|\sec\dfrac{\theta}{2}\right|$.

7.23. Calculate the curvature of the curves of Exercise 7.22 by using the formula of Theorem 7.11.

7.24. Show that the astroid $\varphi \mapsto \mathbf{r}(\varphi) = (a\cos^3\varphi, a\sin^3\varphi)$ has curvature at regular points given by

$$\kappa = -\frac{2}{3a|\sin 2\varphi|}.$$

7.25. Show that the curvature of $r = a\cos 2\theta$ is

$$\frac{3\sin^2 2\theta + 5}{a(3\sin^2 2\theta + 1)^{\frac{3}{2}}}.$$

7.26. Show that the curvature of the curve

$$x(t) = \int_0^t \frac{\cos u}{\sqrt{u}}\,du\,, \quad y(t) = \int_0^t \frac{\sin u}{\sqrt{u}}\,du$$

is $\kappa = -\sqrt{t}$. Sketch the curve.

7.27. Show that the curvature of $r\cos 2\theta = a$ at $r = a$ is

$$\kappa = -\frac{3}{a}.$$

7.28. Show that the curvature of $r^2 = a^2(1 + \cos\theta)$ at $\theta = 0$ is

$$\kappa = \frac{5}{4\sqrt{2}\,a}.$$

7.29. For the sinusoidal spirals $r^m = a^m \cos m\theta$, prove that

$$\frac{dr}{d\theta} = -r\tan m\theta, \text{ and that } \frac{d^2r}{d\theta^2} = r(\tan^2 m\theta - m\sec^2 m\theta).$$

Deduce that

$$\kappa = \frac{(m+1)|r|^{m-1}}{a^m}.$$

(Special cases of this general curve for various values of rational m include the line ($m = -1$), the circle ($m = 1$), the parabola $\left(m = -\frac{1}{2}\right)$, the cardioid $\left(m = \frac{1}{2}\right)$, the rectangular hyperbola ($m = -2$), and Bernoulli's lemniscate ($m = 2$).)

7.3 Curves in the Argand diagram

For certain curves, especially ones given by a polar equation, the representation of points $\mathbf{r} = (x, y)$ of the plane by the complex number $z = x + iy$ can very considerably shorten and simplify the calculation of the curvature of the curve.

Let the parametrised curve $J \mapsto \mathbf{C}$ in the Argand diagram be given by $t \mapsto z(t) = x(t) + iy(t)$. Recall that multiplying by i in the Argand diagram corresponds to rotating counter-clockwise through an angle $\frac{\pi}{2}$. The next theorem, which is is equivalent to Theorem 7.3, follows on using the bijection between the plane $\mathbf{R}^2$ and the Argand diagram $\mathbf{C}$ which associates the vector $\mathbf{r} = (x, y)$ in the plane to the vector $z = x + iy$ in the Argand diagram: we simply replace the vector $\mathbf{r}$ in the formula for curvature in Theorem 7.3 by the vector z, and recall that the scalar product in $\mathbf{C}$ of z and $w = u + iv$ is given by $(z, w) \mapsto \operatorname{re}(z\overline{w})$, and thus the scalar product of z and iw is $-\operatorname{im}(z\overline{w})$.

Theorem 7.13. *At a regular point of a smooth parametrisation the curvature satisfies*

$$\boxed{\kappa = -\frac{\operatorname{im}\left(z'\,\overline{z''}\right)}{|z'|^3}\,.}$$

Note especially the negative signs which occur in the last formulae of Theorem 7.3 and in Theorem 7.13. Also when calculating curvature we use the formula $|z'|^2 = z' \,.\, \overline{z'}$, which again can shorten the calculations for curves related to circles.

The technique we use in calculations is similar to that given in §7.2. Let

$$w(\varphi) = e^{i\varphi},$$

be the parametrisation of the unit circle $|z| = 1$ where the parameter φ is the polar angle θ, then we have

$$w' = ie^{i\varphi}, \text{ and}$$
$$w'' = -e^{i\varphi}.$$

The vectors $e^{i\varphi}$ and $ie^{i\varphi}$ are orthogonal unit vectors, or orthonormal vectors, in the Argand diagram, that is they satisfy $|e^{i\varphi}| = 1$, $|ie^{i\varphi}| = 1$, and

$$\operatorname{re}\left(e^{i\varphi}.\overline{ie^{i\varphi}}\right) = \operatorname{re}(-i) = 0.$$

The condition for complex numbers z and w to be orthogonal is that $\operatorname{re}(z.\overline{w}) = 0$, or, equivalently, that multiplying one by i gives a scalar (i.e., real) multiple of the second. A curve given by a polar equation $r = r(\theta)$, has the parametric equation

$$z(\varphi) = r(\varphi)e^{i\varphi}$$

according to our convention of replacing θ by φ. Then we have

$$z' = r'e^{i\varphi} + rie^{i\varphi},$$
$$z'' = (r'' - r)e^{i\varphi} + 2r'ie^{i\varphi}.$$

Notice how z, z', and z'' are expressed as linear combinations of the two orthogonal unit vectors $e^{i\varphi}$ and $ie^{i\varphi}$, which rotate as φ increases. We now have easily

$$|z'|^2 = \{r'(\varphi)\}^2 + \{r(\varphi)\}^2, \text{ and}$$
$$-\text{im}\,(z'\,\overline{z''}) = r^2 + 2(r')^2 - r\,r''.$$

Theorem 7.11 again follows from Theorem 7.13 and these last two equations. However, we use the above technique, which is similar to that of §7.2, for calculating the curvature in specific examples.

Worked example 7.14. Show that the equi-angular spiral $z = e^{(a+i)\varphi}$, where a is real, has curvature $\kappa = \dfrac{e^{-a\varphi}}{\sqrt{1+a^2}}$.

Solution. We have

$$\begin{aligned} z' &= (a+i)e^{(a+i)\varphi}, \\ z'' &= (a+i)^2 e^{(a+i)\varphi}, \\ |z'| &= |(a+i)e^{i\varphi}e^{a\varphi}| = \sqrt{1+a^2}e^{a\varphi}, \\ z'\,\overline{z''} &= (a+i)e^{(a+i)\varphi}\,\overline{(a+i)^2 e^{(a+i)\varphi}} \\ &= (a+i)e^{(a+i)\varphi}\,(a-i)^2 e^{(a-i)\varphi} = (a-i)(1+a^2)e^{2a\varphi}, \text{ and} \\ -\text{im}\,(z'\,\overline{z''}) &= (1+a^2)e^{2a\varphi}. \end{aligned}$$

Hence the curvature $\kappa = \dfrac{(1+a^2)e^{2a\varphi}}{(1+a^2)^{\frac{3}{2}}e^{3a\varphi}} = \dfrac{e^{-a\varphi}}{\sqrt{1+a^2}}$. ☐

Exercises

7.30. Use the technique of this section to show that the curvature is as given for the following curves (in each case a is a real number):

a) The circle $z = (a\cos\varphi)\,e^{i\varphi}$, $\kappa = \dfrac{2}{a}$.

b) The Archimedean spiral $z = a\varphi e^{i\varphi}$, $\kappa = \dfrac{2+\varphi^2}{a(1+\varphi^2)^{\frac{3}{2}}}$.

c) The cardioid $z = a(1+\cos\varphi)e^{i\varphi}$, $\kappa = \dfrac{3}{4a}\left|\sec\dfrac{\varphi}{2}\right|$.

7.4 An alternative formula

As well as being an important theoretical result which we shall use later, the following theorem gives a useful alternative way of calculating the curvature, especially where points of the plane are represented by complex numbers in the Argand diagram.

Theorem 7.15. *At a regular point of smooth parametrised curve in the Argand diagram we have*

$$\boxed{\frac{d}{dt}\left(\frac{z'(t)}{|z'(t)|}\right) = i\kappa z'(t).}$$

In particular, in the case where the parametrisation is by the arc-length s, we have

$$\boxed{z''(s) = i\kappa z'(s).}$$

Proof. Since $z' = |z'|e^{i\psi}$, where $\psi = \psi(t)$ as in §7.1.1 is the angle measured counter-clockwise from the initial half-line to the tangent vector $z' = z'(t)$ or equivalently is the polar angle of z', we have, on using Lemma 7.2,

$$\frac{d}{dt}\left(\frac{z'}{|z'|}\right) = \frac{d}{dt}\left(e^{i\psi}\right) = ie^{i\psi}\psi' = ie^{i\psi}|z'|\kappa = i\kappa z',$$

as required. □

Notice that $\dfrac{z'(t)}{|z'(t)|}$ is the unit (length) tangent vector, and that iz' is a normal vector. The derivative of the unit tangent vector is therefore orthogonal to the tangent vector provided that the curvature is not zero. In the case of arc-length parametrisation, $z'(s)$ is already a unit tangent vector for each s and $iz'(s)$ is the corresponding unit normal vector.

Worked example 7.16. Use Theorem 7.15 to show that the curvature at all points of a circle of radius R is either $\dfrac{1}{R}$ or $-\dfrac{1}{R}$, depending on the orientation.

Solution. Consider the circle oriented counter-clockwise by the parametrisation $z = z_0 + Re^{it}$ $(0 \le t \le 2\pi)$. This has centre $z_0 = x_0 + iy_0$ and radius R. We have

$$z' = iRe^{it}, \quad \frac{z'}{|z'|} = ie^{it}, \quad \text{and} \quad \frac{d}{dt}\left(\frac{z'}{|z'|}\right) = -e^{it} = \frac{1}{R}iz'.$$

Thus, by Theorem 7.15, the curvature at all points of this circle of radius R (which is oriented counter-clockwise) is $\dfrac{1}{R}$. Similarly for circles

$$z = z_0 + Re^{-it} \quad (0 \le t \le 2\pi)$$

oriented clockwise the curvature is $-\dfrac{1}{R}$ at all points. □

The equivalent of Theorem 7.15 for curves in $\mathbf{R}^2$ is the following corollary.

Corollary 7.17. *At a regular point of a smooth parametrised curve in* $\mathbf{R}^2$ *we have*

$$\boxed{\frac{d}{dt}\left(\frac{1}{|\mathbf{r}'(t)|}\,\mathbf{r}'(t)\right) = \kappa\,.\,(-y'(t), x'(t)).}$$

In particular, in the case where the parametrisation is by the arc-length s, *we have*

$$\boxed{\mathbf{r}''(s) = \kappa\,(-y'(s), x'(s)) \quad \textit{and} \quad (-y''(s), x''(s)) = -\kappa\mathbf{r}'(s).}$$

Note that in the latter case, $\mathbf{r}'(s)$ is a unit tangent vector for each s and $(-y'(s), x'(s))$ is the corresponding unit normal vector.

It is not necessary to calculate the curvature itself to find points at which the curvature is zero. The following corollary can save unnecessary calculation.

Corollary 7.18. *At a regular point of a smooth parametrisation the curvature is zero if, and only if,*

$$x'y'' - y'x'' = \mathbf{r}' \cdot (-y'', x'') = -\mathrm{im}\,\left(z'\,\overline{z''}\right) = 0.$$

Equivalently the curvature is zero if, and only if,

$$\frac{d}{dt}\left(\frac{1}{|\mathbf{r}'|}\,\mathbf{r}'\right) = \frac{d}{dt}\left(\frac{z'}{|z'|}\right) = 0\,.$$

In order to use this result to find points at which the curvature is zero, we must check that the points we find are regular points. The curvature is not normally defined at non-regular points.

Exercises

7.31. Use Theorem 7.13 to show that the Archimedean spiral $z = a\varphi e^{i\varphi}$ has curvature $\kappa = \dfrac{\varphi^2 + 2}{a(\varphi^2 + 1)^{\frac{3}{2}}}$.

7.32. Use Theorem 7.15 to show that the equi-angular spiral $z = e^{(a+i)t}$ has curvature $\dfrac{e^{-at}}{\sqrt{1 + a^2}}$.

7.33. Let $\mathbf{n} = \dfrac{1}{|\mathbf{r}'|}(-y', x')$ be the standard unit normal vector. Show that

$$\mathbf{n}' = -\kappa\mathbf{r}'.$$

7.34. Show that the line $z = z_0 + tw$ $(w \neq 0)$ has curvature $\kappa = 0$.

Curvature: applications

In this chapter we give applications of the curvature of parametrised curves. First we show how the curvature and its derivatives can be used to determine inflexions, vertices, and undulations. Then we show how the curvature of algebraic curves can be determined. Finally we show how cusps can be classified by considering the limiting curvature at the cusp, together with the sign of the curvature at points on each side of the cusp.

8.1 Inflexions of parametric curves at regular points

We defined a point of simple inflexion at a regular point of a parametrised curve to be a point at which the tangent has three-point contact, or, equivalently, a point at which $\mathbf{r}''$ is parallel to $\mathbf{r}'$ and $\mathbf{r}'''$ is not parallel to $\mathbf{r}'$ (see §5.3.1). Recall that $\mathbf{r}''$ is 'parallel to $\mathbf{r}'$ includes the possibility that $\mathbf{r}'' = \mathbf{0}$. We now give a criterion for determining inflexions using the curvature and its derivatives.

Criterion 8.1. *A regular point of a twice differentiable parametrisation is a point of simple inflexion if, and only if,* $\kappa = 0$ *and* $\kappa' \neq 0$.

Proof. This result follows easily from Theorem 7.3. First $(-y'', x'')$ is obtained from $\mathbf{r}''$ by a counter-clockwise rotation through the angle $\frac{\pi}{2}$. We have $\kappa = 0$ if, and only if, $\mathbf{r}' \cdot (-y'', x'') = 0$, that is if, and only if, $\mathbf{r}''$ is a parallel to $\mathbf{r}'$. Also

$$\begin{aligned}\kappa' &= \frac{d}{dt}\left(-\frac{\mathbf{r}' \cdot (-y'', x'')}{|\mathbf{r}'|^3}\right)\\ &= -\frac{\mathbf{r}'' \cdot (-y'', x'')}{|\mathbf{r}'|^3} - \frac{\mathbf{r}' \cdot (-y''', x''')}{|\mathbf{r}'|^3} - \mathbf{r}' \cdot (-y'', x'')\frac{d}{dt}\left(\frac{1}{|\mathbf{r}'|^3}\right).\end{aligned}$$

The first term on the right is always 0, the third term is 0 whenever κ is 0, and the second term is 0, if, and only if, $\mathbf{r}'''$ is a parallel to $\mathbf{r}'$. □

More generally a point of inflexion is a point (a, b) where $\kappa = 0$ and where κ has opposite signs on the curve close to (a, b) on either side of (a, b), that is it is positive along the curve on one side of (a, b) and negative along the curve on the other side of (a, b).

Example 8.2. On the line $\mathbf{r} = (a, b) + t(p, q)$ we have $\mathbf{r}' = (p, q)$ and $\mathbf{r}'' = \mathbf{0}$. Thus $\kappa = \kappa' = 0$ at all points on the line. Therefore at every point on a line we have $\kappa = 0$; but no point on a line is a point of simple inflexion, since κ' is zero at all such points.

Worked example 8.3. Prove that the acnodal cubic $y^2 = x^3 - x^2$ has precisely two points of simple inflexion and find them.

Solution. We parametrise the curve excluding its isolated point, by

$$\mathbf{r} = (x, y) = (t^2 + 1,\ t(t^2 + 1))$$

for real values of t. We have

$$\begin{aligned} \mathbf{r}' &= (2t,\ 3t^2 + 1), \\ \mathbf{r}'' &= (2,\ 6t), \\ (-y'', x'') &= (-6t,\ 2), \\ (\mathbf{r}')^2 &= 9t^4 + 10t^2 + 1, \text{ and} \\ -\mathbf{r}' \cdot (-y'', x'') &= 6t^2 - 2. \end{aligned}$$

Thus the curvature is given by

$$\kappa = \frac{6t^2 - 2}{(9t^4 + 10t^2 + 1)^{\frac{3}{2}}},$$

which is zero if, and only if, $t = \pm\frac{1}{\sqrt{3}}$. Writing

$$t^2 - \tfrac{1}{3} = \left(t - \tfrac{1}{\sqrt{3}}\right)\left(t + \tfrac{1}{\sqrt{3}}\right),$$

we have, by Lemma 8.4 below,

$$\kappa'\left(\tfrac{1}{\sqrt{3}}\right) = \left.\frac{6\left(t + \frac{1}{\sqrt{3}}\right)}{(9t^4 + 10t^2 + 1)^{\frac{3}{2}}}\right|_{t=\frac{1}{\sqrt{3}}} \neq 0,$$

Similarly $\kappa'\left(-\frac{1}{\sqrt{3}}\right) \neq 0$. Therefore the acnodal cubic has precisely two points of simple inflexion, at $t = \pm\frac{1}{\sqrt{3}}$. □

8.1.1 *A useful lemma*

The following lemma can save a great deal of work in calculating the derivative of a function at point at which the function is zero, and in determining the sign of such a derivative. One use is to show easily (in suitable cases) which inflexions are simple. Another is to determine whether a critical point is a maximum or a minimum.

Lemma 8.4. *Let $f(x) = g(x)h(x)$ where g and h are differentiable at a and $g(a) = 0$. Then $f'(a) = g'(a)h(a)$.*

By this lemma, in order to determine $f'(a)$, or simply the sign of $f'(a)$, it is not necessary to differentiate the whole of the formula for f, but simply that 'factor' which is zero at $x = a$.

Proof. We have

$$f'(a) = g'(a)h(a) + g(a)h'(a)$$

by the rule for differentiating a product, and the result is immediate. □

Example 8.5. Let $f(x) = (x-2)\tan^{-1}\left(\frac{x^2+x+1}{x^4+1}\right)$, then (immediately) we have

$$f'(2) = \tan^{-1}\left(\frac{4+2+1}{16+1}\right) = \tan^{-1}\left(\frac{7}{17}\right).$$

Exercises

8.1. Find the curvature of the following curves and determine their inflexions

a) $(\frac{1}{2}t^2, t + \frac{1}{3}t^3)$ $\left[\frac{t^2-1}{(t^4+3t^2+1)^{\frac{3}{2}}}; \pm 1, \text{ both simple}\right]$

b) $(t + \frac{1}{2}t^2, \frac{1}{3}t^3)$

8.2. Let $f(x) = g(x)h(x)$ where g and h are twice differentiable at a and $g(a) = g'(a) = 0$. Show that $f''(a) = g''(a)h(a)$.

8.3. Let $f(x) = g(x)h(x)$ where g and h are n–times differentiable at a and $g(a) = g'(a) = \cdots = g^{(n-1)}(a) = 0$. Show that $f^n(a) = g^n(a)h(a)$.

8.2 Vertices and undulations at regular points

We defined a point of simple undulation at a regular point of a parametrised curve to be a point at which the tangent has four-point contact, or, equivalently a point at which $\mathbf{r}'$, $\mathbf{r}''$, and $\mathbf{r}'''$, are parallel and $\mathbf{r}^{(4)}$ is not parallel to $\mathbf{r}'$ (see §5.3.1). We now give an alternative criterion for undulation in terms of the curvature.

Criterion 8.6. *A regular point of a three times differentiable parametrisation is a point of simple undulation if, and only if, $\kappa = \kappa' = 0$ and $\kappa'' \neq 0$.*

Proof. By Criterion 8.1 we know that $\kappa = 0$ if, and only if, $\mathbf{r}'$ and $\mathbf{r}''$ are parallel, that $\kappa = \kappa' = 0$ if, and only if, $\mathbf{r}'$, $\mathbf{r}''$, and $\mathbf{r}'''$ are parallel, and that in general

$$\kappa' = -\frac{\mathbf{r}' \cdot (-y''', x''')}{|\mathbf{r}'|^3} - (\mathbf{r}' \cdot (-y'', x''))\,\frac{d}{dt}\left(\frac{1}{|\mathbf{r}'|^3}\right).$$

At a point where $\mathbf{r}'$, $\mathbf{r}''$ and $\mathbf{r}'''$ are parallel, we have, on using Lemma 8.4,

$$\kappa'' = -\frac{\mathbf{r}' \cdot (-y^{(4)}, x^{(4)})}{|\mathbf{r}'|^3}.$$

Thus given that $\kappa = \kappa' = 0$, we have that $\kappa'' \neq 0$ if, and only if, $\mathbf{r}^{(4)}$ is not parallel to $\mathbf{r}'$. □

More generally a point of undulation is a point (a, b) where $\kappa = 0$ and where κ has the same sign on the curve on either side of (a, b), that is either it is positive along the curve on both sides of (a, b) or negative along the curve on both sides of (a, b).

Definition 8.7. A *vertex* is a (regular) point for which $\kappa' = 0$.

Thus points, at which the curvature $\kappa(t)$ has a local maximum, a local minimum or a stationary point of inflexion, are vertices.

Note carefully the difference between simple inflexion, vertex, and simple undulation using the curvature criteria. Note also the difference between vertex and corner; a vertex is a regular point and a corner is not.

Worked example 8.8. Show that, on circles and lines, all points are vertices.

Solution. For a line we have $\kappa = 0$ and for a circle we have that κ is constant. In each case $\kappa' = 0$. □

Worked example 8.9. Find the curvature of $y = x^4$. Deduce that the curve has a simple undulation at the origin, and, additionally, two vertices close to the origin. Show that there is a strict local maximum of the curvature at each of these two vertices.

Solution. We parametrise the curve by $x \mapsto (x, x^4) = \mathbf{r}(x)$. We have

$$\kappa = \frac{x'\,y'' - y'\,x''}{|\mathbf{r}'|^3} = \frac{12x^2}{(16x^6+1)^{3/2}}, \text{ and}$$
$$\kappa' = \frac{24x(1-56x^6)}{(16x^6+1)^{5/2}}.$$

Also at the point where $x = 0$, we have by Lemma 8.4,

$$\kappa''(0) = \left.\frac{24(1-56x^6)}{(16x^6+1)^{5/2}}\right|_{x=0} = 24.$$

Therefore $\kappa(0) = \kappa'(0) = 0$ and $\kappa''(0) \neq 0$. Thus there is a simple undulation at $x = 0$. Also there are two vertices and the values taken by x at these are the two real sixth roots of $\frac{1}{56}$, which are $\approx \pm .51$; thus the vertices are $\approx (\pm.51, .07)$. Using Lemma 8.4, we readily see that a strict local maximum of the curvature occurs at each of the vertex points, since, at the vertex points,

$$\kappa'' = \left.\frac{24x(-56.6x^5)}{(16x^6+1)^{5/2}}\right|_{x=\pm\frac{1}{\sqrt[6]{56}}} < 0.$$

$\square$

Worked example 8.10. Let $\mathbf{r}(t) = (3t^2-1,\, t\,(3t^2-1)\,)$. Show that the curve $t \mapsto \mathbf{r}(t)$ is regular, and find its curvature. Show that the curve has no inflexions and only one vertex. Find the points at which the tangents are horizontal and the points at which the tangents are vertical. Find the slopes of the tangent lines to the curve at the point $\mathbf{r} = \mathbf{0}$. Find the local maxima and minima of y regarded as a function of x. Write down the algebraic equation of the curve.

Solution. We have $\mathbf{r}' = (6t, 9t^2-1)$, $\mathbf{r}'' = (6, 18t)$, and $|\mathbf{r}'|^2 = (9t^2+1)^2$. The parametrisation is regular, since $\mathbf{r}' \neq \mathbf{0}$. The curvature is

$$\kappa = \frac{x'\,y'' - y'\,x''}{|\mathbf{r}'|^3} = \frac{6(9t^2+1)}{(9t^2+1)^3} = \frac{6}{(9t^2+1)^2}\ , \text{ and}$$

$$\kappa' = \frac{6.18t.(-2)}{(9t^2+1)^3}\,.$$

Thus there are no inflexions and a vertex only at $t=0$: at $t=0$ we have (using Lemma 8.4)

$$\kappa'(0) = 6.18.(-2) < 0,$$

and thus the curvature has a local maximum where $t=0$, that is at the point $(-1,0)$. The tangent is horizontal (i.e., $y'=0$ and $x'\neq 0$) if, and only if, $t = \pm\frac{1}{3}$, and is vertical (i.e., $x'=0$ and $y'\neq 0$) if, and only if, $t=0$. Also $\mathbf{r} = \mathbf{0}$ if, and only if, $t = \pm\frac{1}{\sqrt{3}}$. At $t = \pm\frac{1}{\sqrt{3}}$ we have

$$\frac{dy}{dx} = \frac{y'}{x'} = \pm\frac{1}{\sqrt{3}}.$$

Now

$$\frac{dy}{dx} = \frac{y'}{x'} = \frac{9t^2-1}{6t} = 0$$

if, and only if, $t = \pm\frac{1}{3}$. Also

$$\frac{d^2y}{dx^2}\,x' = \frac{d}{dt}\left(\frac{dy}{dx}\right),$$

and again using Lemma 8.4, we see that $\dfrac{d^2y}{dx^2} \neq 0$ at $t = \pm\frac{1}{3}$, and therefore the local maxima and minima of y, regarded as a function of x, are at $(-\frac{2}{3}, \pm\frac{2}{9})$. For large values of t, the curve is 'close' to the semi-cubical parabola $x^3 = 3y^2$ parametrised by $t \mapsto (3t^2, 3t^3)$. The algebraic equation of the curve is given by

$$y^2 = x^2t^2 = \frac{x^2(x+1)}{3},$$

that is by $3y^2 = x^2(x+1)$: so it is a cubic curve. □

Worked example 8.11. Show that the ellipse $\mathbf{r} = (a\cos t, b\sin t)$ has no inflexions and has precisely four vertices.

Solution. We have

$$\kappa = \frac{ab}{(a^2\sin^2 t + b^2\cos^2 t)^{\frac{3}{2}}}, \text{ and}$$

$$\kappa' = -\frac{3ab(a^2-b^2)\sin t\,\cos t}{(a^2\sin^2 t + b^2\cos^2 t)^{5/2}}.$$

Thus the ellipse has no inflexions and has precisely four vertices. The parameter values at which these vertices occur are $t = 0, \dfrac{\pi}{2}, \pi, \dfrac{3\pi}{2}$. Using Lemma 8.4, we readily see that $\kappa'' \neq 0$ at each of these vertices. Therefore the curvature has a local maximum or a local minimum at each vertex.

□

This example illustrates a general property of simple closed curves, that is that such curves have at least four vertices.

Theorem 8.12. *(Four-vertex theorem) A simple closed curve has at least four vertices; at least two correspond to local maximum values of κ and at least two correspond to local minimum values of κ.*

A *simple* curve here means a regular curve with no multiple points except the end points, that is $\mathbf{r}(t_0) = \mathbf{r}(T)$. The proof of this theorem is hard and beyond the scope of this book. The proof can be found in texts on algebraic curves, or algebraic geometry.

Exercises

8.4. Show that the curve $t \mapsto \mathbf{r}(t) = (t^2-1,\ t\,(t^2-1))$ is regular, and find its curvature. Show that $\kappa' = 0$ if, and only if, $9t^5 + 4t^3 - 1 = 0$, and deduce that the curve has no inflexions and precisely three vertices. Find the points at which the tangents are horizontal and the points at which the tangents are vertical. Find the slopes of the tangent lines to the curve at the point $\mathbf{r} = \mathbf{0}$. Find the local maxima and minima of y regarded as a function of x. Write down the algebraic equation of the curve.

$$\left[\frac{6t^2+2}{(9t^4-2t^2+1)^{\frac{3}{2}}}; 0, t^2 = \tfrac{1}{18}\left(\sqrt{52}-4\right); 0, \pm\tfrac{1}{\sqrt{3}}; \pm 1; \pm\tfrac{1}{\sqrt{3}}; y^2 = x^2(1+x)\right]$$

8.5. Find the curvature of $\left(t + \frac{1}{2}t^2, \frac{1}{2}t^2\right)$. Show that the curve has no inflexions and has precisely one vertex. Write down the algebraic equation of the curve.

8.6. Prove that the curvature of $r = 2 + \cos\theta$ is

$$\kappa = \frac{6(1+\cos\theta)}{(5+4\cos\theta)^{\frac{3}{2}}}.$$

Show that the curve has a simple undulation at $\theta = -\pi$, and find the vertices.

(*Hint:* Use Exercise 8.2.) $\left[0, \frac{2\pi}{3}, \pi, \frac{4\pi}{3}\right]$

8.3 Curvature of algebraic curves*

In general algebraic curves cannot be parametrised in a simple way, that is by using a simple formula which gives a parametrisation of the whole curve. Therefore the formulae for the curvature which we have considered previously cannot be used. However algebraic curves can be parametrised locally near a non-singular point, though not in general using a simple formula. We now use this result to give a parameter-free formula for the curvature of algebraic curves.

Given a polynomial $f(x,y)$ let $J = \begin{pmatrix} f_{xx} & f_{xy} \\ f_{xy} & f_{yy} \end{pmatrix}$ be the Hessian matrix.

Theorem 8.13. *The curvature of the algebraic curve $f(x,y) = 0$ at a non-singular point (x,y) on the curve is*

$$\kappa = \pm \frac{(f_y, -f_x)\, J \begin{pmatrix} f_y \\ -f_x \end{pmatrix}}{(f_x^2 + f_y^2)^{\frac{3}{2}}} = \pm \frac{f_y^2 f_{xx} - 2f_x f_y f_{xy} + f_x^2 f_{yy}}{(f_x^2 + f_y^2)^{\frac{3}{2}}}$$
$$= \pm \frac{f_y^2 f_{xx} - 2f_x f_y f_{xy} + f_x^2 f_{yy}}{|\mathbf{grad}\, f|^3},$$

where the sign $-$ is taken in case the motion along the curve is in the direction of the vector $(f_y, -f_x)$ and where the sign $+$ is taken in case the motion along the curve is in the direction of the vector $-(f_y, -f_x)$.

Proof. By Theorem 4.4, the algebraic curve can be given a regular local parametrisation near a non-singular point by $t \mapsto \mathbf{r}(t)$. Differentiating

$$f(x(t), y(t)) = 0,$$

using the chain rule, we obtain

$$\mathbf{r}' \cdot (f_x, f_y) = 0.$$

Therefore $\mathbf{r}'$ is orthogonal to (f_x, f_y), and we have $\mathbf{r}' = \lambda(f_y, -f_x)$ where $\lambda \neq 0$ is a function of t, and $(-y', x') = \lambda(f_x, f_y)$. On differentiating once more we obtain

---

* For the meaning of * see the preface.

$$\mathbf{r}'' \cdot (f_x, f_y) + (x', y')\, J \begin{pmatrix} x' \\ y' \end{pmatrix} = 0.$$

Therefore we have

$$x'\, y'' - y'\, x'' = \mathbf{r}'' \cdot (-y', x') = \lambda\, \mathbf{r}'' \cdot (f_x, f_y) = -\lambda^3 (f_y, -f_x)\, J \begin{pmatrix} f_y \\ -f_x \end{pmatrix}.$$

Since $|\mathbf{r}'| = |\lambda|\, |(f_y, -f_x)|$, the result follows. ☐

Corollary 8.14. *The algebraic curve has a point of inflexion at a non-singular point (a,b) if, and only if,*

$$f_y^2 f_{xx} - 2 f_x f_y f_{xy} + f_x^2 f_{yy}$$

is zero at (a,b) and changes sign as (x,y) moves through (a,b) along the curve.

Thus in order to find all points of inflexion of an algebraic curve we first determine the points where the curvature is zero by finding the simultaneous solutions of the equations

$$f(x,y) = 0, \text{ and}$$
$$f_y^2 f_{xx} - 2 f_x f_y f_{xy} + f_x^2 f_{yy} = 0,$$

and then find those solutions which are non-singular points. Next we determine whether the curvature changes sign as we move along the curve past the point of zero curvature. If the curvature changes sign, the point is an inflexion. If the sign of the curvature is the same immediately before and after the point, the point is an undulation. In practice we can check on the change of sign if, for example, the curve can be parametrised near the point by x, and

$$f_y^2 f_{xx} - 2 f_x f_y f_{xy} + f_x^2 f_{yy}$$

becomes a function of x after substituting from $f(x,y) = 0$. Such a local parametrisation by x exists by Theorem 4.4 provided that the tangent at the point is not parallel to the y–axis.

Worked example 8.15. Calculate the curvature of the hyperbola

$$x^2 - 3y^2 = 1$$

at $(2,1)$.

Solution. Let $f = x^2 - 3y^2 - 1$. We have $f_x = 2x$, $f_y = -6y$, $f_{xx} = 2$, $f_{xy} = 0$, and $f_{yy} = -6$. Therefore

$$\kappa = \pm \frac{(-6y)^2 . 2 + (4x)^2 . (-6)}{(4x^2 + 36y^2)^{\frac{3}{2}}} = \pm \frac{9y^2 - 12x^2}{(x^2 + 9y^2)^{\frac{3}{2}}}.$$

In particular

$$\kappa(2,1) = \pm \frac{-3}{\sqrt{13}}.$$

$\square$

Worked example 8.16. Find the points of inflexion of the acnodal cubic

$$f(x,y) = y^2 + x^2 - x^3 = 0.$$

Solution. We have $f_x = 2x - 3x^2$, $f_y = 2y$, $f_{xx} = 2 - 6x$, $f_{xy} = 0$, and $f_{yy} = 2$. Eliminating y from

$$f(x,y) = y^2 + x^2 - x^3 = 0, \text{ and}$$

$$\begin{aligned} f_y^2 f_{xx} - 2f_x f_y f_{xy} + f_x^2 f_{yy} &= 4y^2(2-6x) + 2(2x-3x^2)^2 \\ &= 8y^2 - 24xy^2 + 8x^2 - 24x^3 + 18x^4, \end{aligned}$$

we have, on the curve, that

$$f_y^2 f_{xx} - 2f_x f_y f_{xy} + f_x^2 f_{yy} = 8x^3 - 6x^4.$$

The origin is a singular point. Therefore there are precisely two points of zero curvature. They are $\left(\frac{4}{3}, \pm\frac{4}{3\sqrt{3}}\right)$. At these points

$$\mathbf{grad}\, f = (2x - 3x^2, 2y)$$

is not parallel to the y–axis, and therefore the curve can be parametrised locally by x. Also

$$8x^3 - 6x^4 = 6x^3\left(\tfrac{4}{3} - x\right)$$

changes sign as we move along the curve past each of the points and therefore the curvature also changes sign. Thus the two points are points of inflexion. (Near points of undulation the curvature does not change sign.)

$\square$

Exercises

8.7. Calculate the curvature of the ellipse $\dfrac{x^2}{4} + y^2 = 1$ at $(2,0)$ using Theorem 8.13. Compare your result with that given by using the parametrisation $t \mapsto (2\cos t, \sin t)$. $\left[\mp\frac{3}{8}\right]$

8.8. Show that the curvature of $x^4 + y^2 = 2a(x+y)$ at the origin is

$$\pm\frac{1}{2\sqrt{2a}}.$$

8.9. Show that the curvature of $y^2(a-x) = x^2(a+x)$ at $(-a,0)$ is $\pm\dfrac{4}{a}$.

8.10. Show that the curvature of $x^2y = x^2 + y^2$ at non-singular points is

$$\pm\frac{2x^3y^4(y^2-3x^2)}{(4y^6 + x^2(y^2-x^2)^2)^{\frac{3}{2}}}.$$

8.11. Show that the curvature of $x^3 - xy^2 - y = 0$ at points where y has a local maximum or minimum value is $\pm 2^{-\frac{1}{2}}3^{\frac{5}{4}}$.

8.4 Limiting curvature of algebraic curves at cusps

As a further application of curvature, we show how curvature can be used to classify the cusps of algebraic curves. We divide cusps into three types, ceratoid cusps, cusps with zero limiting curvature, and rhamphoid cusps (see Figure 8.1). Although the curvature is not defined at a cusp, in that the formula for curvature is not meaningful at a cusp, it is nevertheless useful to consider the limit of the curvature at a point as the point approaches the cusp. The following analysis of types of cusps does not extend to non-algebraic curves in general.

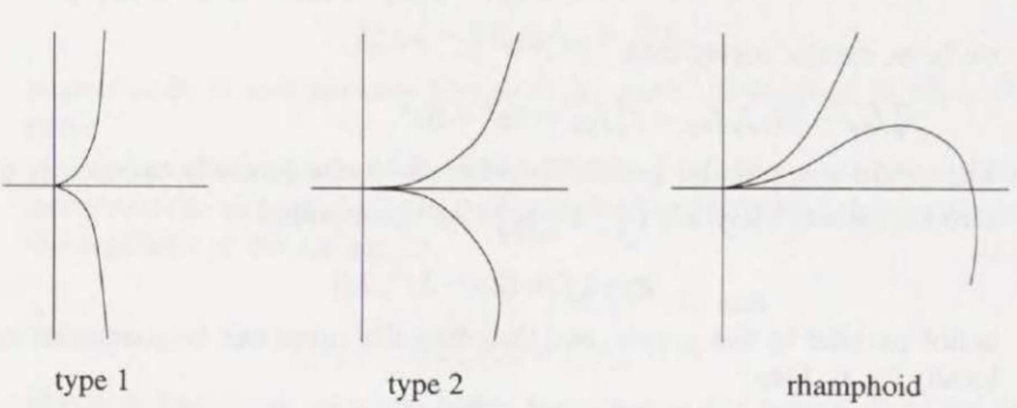

Figure 8.1 *Limiting curvature at cusps.*

8.4.1 Type 1: Ceratoid cusps (limiting radius of curvature zero).

A point $z(t_0)$ is a *ceratoid cusp* if it is a cusp for which $|\kappa(t)|$ tends to ∞ along both branches as t tends to t_0, or equivalently for which the radius of curvature tends to zero as t tends to t_0. For ceratoid cusps the curve appears to move away from the cuspidal tangent line 'fairly rapidly' as it leaves the cusp, since near the cusp the curvature is very large and therefore the curve bends sharply.

Example 8.17. For the semi-cubical parabola $x^3 = y^2$ parametrised by $t \mapsto \mathbf{r}(t) = (t^2, t^3)$ for all real t, we have

$$\begin{aligned} \mathbf{r}' &= (2t, 3t^2), \\ \mathbf{r}'' &= (2, 6t), \text{ and} \\ \mathbf{r}''' &= (0, 6). \end{aligned}$$

The curvature of the curve is given by

$$\kappa = \frac{6t^2}{(4t^2+9t^4)^{\frac{3}{2}}} = \frac{6}{|t|(4+9t^2)^{\frac{3}{2}}}.$$

In this calculation we have used the formula $\sqrt{t^2} = |t|$. We have that κ tends to ∞ as t tends to 0, and therefore the limiting radius of curvature is zero. The semi-cubical parabola has an ordinary cusp at $\mathbf{r}'(0) = \mathbf{0}$, since $\mathbf{r}''(0) = (2, 0)$ and $\mathbf{r}'''(0) = (0, 6)$ are linearly independent.

8.4.2 Type 2: limiting radius of curvature infinite

The second type of cusp is a cusp at a point $z(t_0)$ for which $\kappa(t)$ tends to 0 along both branches as t tends to t_0, or equivalently for which the limiting radius of curvature is infinite. In this case the curve appears to linger near the cuspidal tangent line as it leaves the cusp, since the curvature is close to zero near the cusp.

Example 8.18. For the curve $(2\,x)^5 = (5\,y)^2$, parametrised by

$$t \mapsto \mathbf{r}(t) = \left(\tfrac{1}{2}t^2, \tfrac{1}{5}t^5\right)$$

for all real t, we have

$$\begin{aligned} \mathbf{r}' &= (t, t^4), \\ \mathbf{r}'' &= (1, 4t^3), \text{ and} \\ \mathbf{r}''' &= (0, 12t^2). \end{aligned}$$

The curvature of the curve is given by

$$\kappa = \frac{3t^4}{(t^2 + t^8)^{\frac{3}{2}}} = \frac{3|t|}{(1 + t^6)^{\frac{3}{2}}} \; .$$

We have that κ tends to 0 as t tends to 0, and the limiting radius of curvature is infinite. This cusp is not ordinary since $\mathbf{r}'' = (1, 0)$ and $\mathbf{r}''' = (0, 0)$ are not linearly independent at it. In this calculation we have used the formula $\sqrt{t^2} = |t|$. Recall that the curvature is positive as the curve swings to the left; this is indicated in the figure.

Cusps ($\mathbf{r}'' \neq 0$), for which, in moving through the cusp, the curve crosses the cuspidal tangent line from one side to the other, are necessarily of Type 1 or of Type 2 (ie. $|\kappa| = \infty$ or $\kappa = 0$ in the limit). For Type 1 and Type 2 cusps the curvature has the same sign, close to the cusp, on each side of the cusp.

8.4.3 Type 3: Rhamphoid cusps

Rhamphoid cusps are cusps for which the curve, close to the cusp, lies on one side of the cuspidal tangent line. For such cusps the curvature has different signs, close to the cusp, on each side of the cusp. These cusps can also have limiting radii of curvature other than 0 or ∞.

Example 8.19. The curve $(y - x^2)^2 = x^5$, or $y = x^2 \pm x^{\frac{5}{2}}$, parametrised by $t \mapsto \mathbf{r}(t) = (t^2, t^4 + t^5)$ for all real t, satisfies

$$\begin{aligned} \mathbf{r}' &= (2t, 4t^3 + 5t^4), \\ \mathbf{r}'' &= (2, 12t^2 + 20t^3), \text{ and} \\ \mathbf{r}''' &= (0, 24t + 60t^2). \end{aligned}$$

The curvature of the curve is given by

$$\kappa = \frac{(16t^3 + 30t^4)}{(4t^2 + (4t^3 + 5t^4)^2)^{\frac{3}{2}}} = \frac{t}{|t|}\frac{(16 + 30t)}{(4 + (4t^2 + 5t^3)^2)^{\frac{3}{2}}} .$$

In this calculation we have used the formula $\sqrt{t^2} = |t|$. We have $|\kappa|$ tends to 2 as t tends to 0, κ tends to $+2 > 0$ as $t > 0$ tends to 0, and κ tends to $-2 < 0$ as $t < 0$ tends to 0. Also we have the slope

$$\frac{dy}{dx} = \frac{y'}{x'} = \frac{t^3(4 + 5t)}{2} .$$

This curve has a point of simple inflexion where $\kappa = 0$, that is, where $t = -\frac{8}{15}$. Also, regarded as the graph of a function of x, the curve has a horizontal tangent at $t = -\frac{4}{5}$. Again the cusp is not ordinary since $\mathbf{r}'' = (2, 0)$ and $\mathbf{r}''' = (0, 0)$ are not linearly independent at it.

Drawing cusps. Note the different shapes of these cusps depending on the different limiting radii of curvature, and on whether or not the cusp is rhamphoid.

Exercises

8.12. For each of the following curves, show that there is a cusp at the origin, and classify the cusp by finding the limiting radius of curvature and determining whether or not it is rhamphoid.

i) $(\frac{1}{2}t^2, \frac{1}{3}t^3)$, [$\infty$; type 1, ordinary]

ii) $(\frac{1}{2}t^2, \frac{1}{4}t^4 + \frac{1}{5}t^5)$,

iii) (t^2, t^5), [0; type 2]

vi) $(\frac{1}{2}t^2, \frac{1}{6}t^6 + \frac{1}{6}t^6)$.

8.13. Show that $\mathbf{r}(t) = (t^2, t^n)$ $(n \geq 7)$ has, at the origin, a type 2 cusp if n is odd.

8.14. Show that $\mathbf{r}(t) = (t^2, t^n + t^{n+1})$ $(n \geq 6)$ has, at the origin, a rhamphoid cusp if n is even.

8.15. Use L'Hôpital's theorem (see §4.7.5) to show that, at a cusp $\mathbf{r}(t_0)$ of a parametrised curve $t \mapsto \mathbf{r}(t)$,

$$\lim_{t \to t_0} \frac{x'\,y'' - y'\,x''}{(x')^2 + (y')^2} = \frac{x''\,y''' - y''\,x'''}{2(x'')^2 + 2(y'')^2} .$$

Deduce that $\lim\limits_{t \to t_0} |\kappa(t)| = \infty$ at a simple cusp.

We give here some more general exercises which can include curve sketching or plotting if desired.

8.16. Let $\mathbf{r}(t) = (\sqrt{3}(t^2 - 1),\ t\,(t^2 - 1))$. Show that the curve $t \mapsto \mathbf{r}(t)$ is regular. Prove that the curvature of $t \mapsto \mathbf{r}(t)$ at $\mathbf{r}(t)$, is given by

$$\kappa = \frac{2\sqrt{3}}{(3t^2 + 1)^2}\,,$$

and show that the curve has no inflexions and only one vertex. Show further that the curvature κ does not have an inflexion at the vertex of the curve. Find the points at which the tangents are horizontal and the points at which the tangents are vertical. Hence sketch the curve, noting the points with horizontal tangents and the points with vertical tangents, and the local maxima and minima of y. Write down the algebraic equation of the curve.

$$\left[t = 0, \kappa''(0) \neq 0 : \pm\tfrac{1}{\sqrt{3}}; 0 : 9y^2 - 3x^2 - \sqrt{3}x^3 = 0\right]$$

8.17. Show that the curve $z(t) = (\cos t, \cos t \sin t)$ is regular and has curvature

$$\kappa = \frac{\cos t\,(1 + 2\sin^2 t)}{(1 - 3\sin^2 t + 4\sin^4 t)^{\frac{3}{2}}}\,.$$

Hence find the inflexions of the curve. Show that every point of $z(t)$ belongs to the algebraic curve

$$y^2 = x^2 - x^4.$$

By writing $x^2 - x^4 = x^2(1 - x^2)$, show conversely that every point of the algebraic curve has the form $z(t)$ for some t. Show that the algebraic curve has a singular point at $(0, 0)$ and no other singular point. Sketch the curve, indicating the positions of the inflexions. $\left[n\pi + \dfrac{\pi}{2}; |x| \leq 1, \text{ thus } x = \cos t\right]$

8.18. Show that the limaçon with polar equation

$$r = \sqrt{2} + \cos\theta$$

has inflexions where $\cos\theta = -\frac{2\sqrt{2}}{3}$ and vertices where

$$\sin\theta = 0 \text{ or } \cos\theta = -\tfrac{1}{\sqrt{2}}\,.$$

Find the tangent directions at the vertices. Sketch the curve.

8.19. Show that the limaçon with polar equation

$$r = \sqrt{2} - \cos\theta$$

has inflexions where $\cos\theta = \frac{2\sqrt{2}}{3}$. By checking that the appropriate determinant is zero, or otherwise, show also that the limaçon has vertices where $\sin\theta = 0$ or $\cos\theta = \frac{1}{\sqrt{2}}$. Find the tangent directions at the vertices. Sketch the curve.

$$\left[\kappa = \frac{-3\sqrt{2}\cos\theta + 4}{(2\sqrt{2}\cos\theta - 3)^{\frac{3}{2}}} : i, i \pm 1\right]$$

8.20. State the four vertex theorem. Find the vertices of the limaçon with polar equation

$$r = 1 + 2\cos\theta\,,$$

and make a careful drawing of this curve using polar graph paper. Why does this curve not provide a counterexample to the four vertex theorem?

$$[0, \pi;\ \text{not simple}]$$

8.21. Show that the parametric curve $t \mapsto \mathbf{r}(t) = (t^2 + t^4, t^2 + t^5)$ has exactly one non-regular point and that this is a cusp but not an ordinary cusp. Write down the limiting tangent direction at the cusp. Show that $z(t)$ has zero curvature where $10t^3 + 15t - 8 = 0$. Use the intermediate value theorem and Rolle's theorem to deduce that $z(t)$ has one inflexion between $t = 0$ and $t = \frac{1}{2}$ and has no other inflexions. Show that $|\kappa(t)|$ tends to $\frac{1}{\sqrt{2}}$ as t tends to 0. Draw the curve for $-1.1 \leq t \leq 1.1$ using 5 cm as 1 unit.

$$\left[\mathbf{r}'''(0) = \mathbf{0}; (1,1);\ \text{inflexion since } \frac{d}{dt}(10t^3 + 15t - 8) \neq 0\right]$$

8.22. Show that the parametric curve $t \mapsto \mathbf{r}(t) = (\frac{1}{4}t^4, t^2 + t^3)$ has exactly one non-regular point and that this is a cusp but not an ordinary cusp. Determine the limiting tangent direction at the cusp. Find the curvature $\kappa(t)$ at a general regular point, and show that $|\kappa(t)|$ tends to $\frac{1}{2}$ at the cusp. Show that there is exactly one point P at which the curve has an inflexion. Determine the tangent direction at P. Draw the curve taking 10 cm as 1 unit. Indicate the point P and plot about 9 other points. (Use the portrait mode with the origin near the left.)

8.23. Show that the parametric curve $t \mapsto \mathbf{r}(t) = (t^2, -t^4 + t^5)$ has exactly one non-regular point and that this is a cusp but not an ordinary cusp. Determine the limiting tangent direction at the cusp. Also determine the point P on the curve, not at the cusp, at which the tangent is parallel to the x-axis. Find the curvature $\kappa(t)$ at a general regular point, and show that $|\kappa(t)|$ tends to 2 at the cusp. Show that there is exactly one point Q at which the curve has an inflexion. Draw the curve for $-1.1 \leq t \leq 1.1$ using 5 cm as 1 unit. Indicate the points P and Q and plot about 9 other points. (Use the portrait mode with the origin near the top left: first calculate $\mathbf{r}(t)$ for $t = \pm 1.1$.)

$$[\mathbf{r}'''(0) = \mathbf{0}; (1,0); \tfrac{4}{5}, \tfrac{8}{15}]$$

8.24. Show that the parametric curve $t \mapsto \mathbf{r}(t) = (t^2 - t^3, t^5)$ has exactly one non-regular point and that this is a cusp but not an ordinary cusp. Determine the cuspidal tangent line. Also determine the point P on the curve, not at the cusp, at which the tangent is parallel to the y-axis. Find the curvature $\kappa(t)$ at a general regular point. Show that there is exactly one point Q at which the curve has an inflexion. Draw the curve for $-1.1 \leq t \leq 1.1$ using 5 cm as 1 unit. Indicate the points P and Q and plot about 9 other points. (Use the landscape mode with the origin at the centre.)

Circle of curvature

We consider now the radius of curvature, the circle of curvature, and the osculating circle at regular points of parametrised curves. The *radius of curvature* is the absolute value of the reciprocal of the curvature. The *circle of curvature* at a point on the curve is the circle passing through the point and having the same curvature and same tangent direction as the curve at the point. The radius of the circle of curvature is equal to the radius of curvature. The *osculating circle* at a point on the curve is the unique circle having $\geq$ 3–point contact with the curve at the point. We show that the circle of curvature coincides with the osculating circle.

9.1 Centre of curvature and circle of curvature

In general there is a unique circle having the same curvature and same tangent direction as the curve at a common point which is regular for the curve. The centre of this circle is called the centre of curvature at the point and the radius of the circle is called the radius of curvature at the point. The centre of curvature can also be described as the limiting position of the point of intersection of 'consecutive' normals. We now define the centre of curvature and the circle of curvature.

Definition 9.1. The *standard parametrisation* of a circle having curvature $\kappa \quad (\kappa \neq 0)$, and centre z_0, is

$$\boxed{z(t) = z_0 + \frac{1}{\kappa} e^{i\kappa t} \quad \text{or} \quad \mathbf{r}(t) = \mathbf{r}_0 + \frac{1}{\kappa}(\cos \kappa t, \sin \kappa t)} \quad \left(0 \leq t \leq \frac{2\pi}{|\kappa|}\right).$$

Notice that the standard parametrisation of a circle is a unit speed (arc-length) parametrisation (i.e., $|z'| = 1$), and that t is not the argument (polar angle) of $z - z_0$. This circle is positively oriented (counter-clockwise) if $\kappa > 0$, and is negatively oriented (clockwise) if $\kappa < 0$.

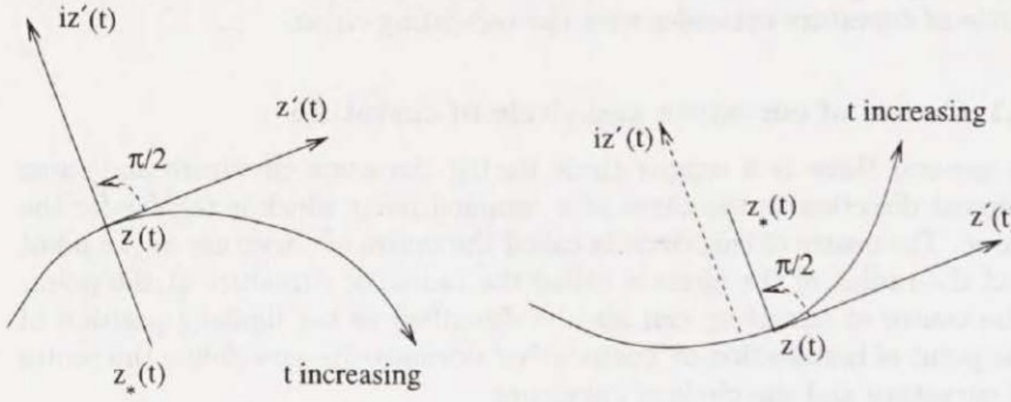
Definition 9.2. At a regular point $\mathbf{r}(t_0)$, respectively $z(t_0)$, of the curve $t \mapsto \mathbf{r}(t)$, respectively $t \mapsto z(t)$, the *centre of curvature* is

$$\boxed{\begin{aligned} &z_* = z_*(t_0) = z(t_0) + \frac{1}{\kappa}\frac{iz'(t_0)}{|z'(t_0)|}, \text{ or, equivalently,} \\ &\mathbf{r}_* = \mathbf{r}_*(t_0) = \mathbf{r}(t_0) + \frac{1}{\kappa|\mathbf{r}'(t_0)|}(-y'(t_0), x'(t_0)) . \end{aligned}}$$

Thus the centre of curvature lies along the normal to the curve at $z(t_0)$, at an 'oriented distance' $\frac{1}{\kappa}$ to the 'left' of the curve. This means that the centre of curvature lies on the 'left' if $\kappa > 0$, and lies on the 'right' if $\kappa < 0$. 'Left' and 'right' here are determined by the direction of the parametrisation. We shall use the notations $t \mapsto \mathbf{r}(t)$ and $t \mapsto z(t)$ interchangeably for a curve. Many statements, proofs, and solutions are simpler using the curve $t \mapsto z(t)$ in the Argand diagram.

Definition 9.3. At a regular point $\mathbf{r}(t_0)$ of the curve $t \mapsto \mathbf{r}(t)$ the *radius of curvature* is $\frac{1}{|\kappa|}$ for $\kappa \neq 0$, and is ∞ for $\kappa = 0$.

The centre of curvature (see Figure 9.1) can be considered as the limiting position of the point of intersection of 'consecutive' normals to the curve. Notice that the radius of curvature of a circle of radius R, whatever its orientation, is R.



negative curvature (κ < 0) positive curvature (κ > 0)

Figure 9.1 *Centre of curvature.*

Definition 9.4. The *circle of curvature* at a regular point $\mathbf{r}(t_0)$, at which the curvature is non-zero, is the circle centre $\mathbf{r}_*(t_0)$ and radius $\frac{1}{|\kappa|}$.

The equation of the circle of curvature in standard complex parametric form is

$$\boxed{Z(s) = z_*(t_0) + \frac{1}{\kappa}e^{i\kappa s}} \qquad \left(0 \le s \le \frac{2\pi}{|\kappa|}\right),$$

and the equation in standard real parametric form is

$$\boxed{\mathbf{R}(s) = \mathbf{r}_*(t_0) + \frac{1}{\kappa}(\cos\kappa s, \sin\kappa s)\,.}$$

The algebraic equation is

$$\boxed{(X - x_*)^2 + (Y - y_*)^2 = \frac{1}{\kappa^2}\,.}$$

Other forms of the equation are

$$|\, Z - z_* \,| = \frac{1}{|\kappa|} \quad \text{or} \quad (Z - z_*)(\overline{Z} - \overline{z_*}) = \frac{1}{\kappa^2}\,.$$

Here we use $Z = X + iY$ and $\mathbf{R} = (X, Y)$ rather than $z = x + iy$ and $\mathbf{r} = (x, y)$ for the variable.

Theorem 9.5. *Let $\mathbf{r}(t_0)$ be a regular point of the curve $t \mapsto \mathbf{r}(t)$. Then there is a unique standardly parametrised circle, namely the circle of curvature, which passes through $\mathbf{r}(t_0)$, and which at $\mathbf{r}(t_0)$ has the same tangent line, the same direction of tangent vector, and the same curvature as the curve. Furthermore the sign of the orientation of this circle (counterclockwise is positive) coincides with the sign of the curvature.*

Proof. From the definition of the centre of curvature, we deduce that

$$|z_* - z(t_0)| = \frac{1}{|\kappa|}.$$

Thus the circle of curvature

$$|Z - z_*| = \frac{1}{|\kappa|}$$

passes through $z(t_0)$. Let

$$Z(s) = a + \frac{1}{\kappa}e^{i\kappa s}$$

be a standardly parametrised circle which passes through $z(t_0)$, where κ is the curvature of the curve at $t = t_0$ (see Definition 9.1). Differentiating this equation gives $Z' = ie^{i\kappa s}$. This circle meets the curve at the point where $z(t_0) = Z(s)$. At this point we have

$$Z(s) - a = \frac{1}{\kappa}e^{i\kappa s} = -\frac{1}{\kappa}iZ'(s)\,, \quad \text{and,}$$

$$z(t_0) - z_*(t_0) = -\frac{1}{\kappa}i\frac{z'(t_0)}{|z'(t_0)|}\,.$$

Therefore $a = z_*(t_0)$ if, and only if,

$$Z'(s) = \frac{z'(t_0)}{|z'(t_0)|},$$

that is if, and only if, the tangent vector $z'(t_0)$ to the curve and the tangent vector $Z'(s)$ to the circle are parallel and have the same direction (recall that $s \mapsto Z(s)$ is a unit speed curve). Since $a = z(t_0)$ for the circle of curvature, the existence, and uniqueness of the required circle follows. ☐

The centre of curvature and the circle of curvature at a point lie on the 'concave side' of the curve at that point. Notice that the 'concave side' of the curve does not depend on the orientation of the curve, that is the direction of the parametrisation. The circle of curvature coincides with the osculating circle, and is often called the osculating circle. The osculating circle is the unique circle having $\geq$ 3–point contact with the curve at $\mathbf{r}(t_0)$ (see §9.2).

Mnemonic

> The circle of curvature has the same direction as the curve at their point of tangency.

Worked example 9.6. Find the centre of curvature and the circle of curvature of the curve $\mathbf{r} = (t^3 - t, t^2)$ at the origin.

Solution. The origin is given by the parameter value $t = 0$. By Example 7.6, we have that, at $t = 0$, $\kappa = -2$, and $\mathbf{r}' = (-1, 0)$. Thus the centre of curvature is

$$\mathbf{r}_* = \mathbf{r} + \frac{1}{\kappa|\mathbf{r}'|}(-y', x') = \mathbf{0} - \frac{1}{2}(0, -1) = \frac{1}{2}(0, 1).$$

The circle of curvature is

$$(X - 0)^2 + (Y - \frac{1}{2})^2 = \left(\frac{1}{2}\right)^2,$$

that is

$$X^2 + Y^2 - Y = 0.$$

☐

Worked example 9.7. Show that the circle of curvature of the curve

$$y = 2x + 3x^2 - 2xy + y^2 + 2y^3$$

at the origin is $3x^2 + 3y^2 - 5y + 10x = 0$.

Solution. Let $f = -y + 2x + 3x^2 - 2xy + y^2 + 2y^3$. We have

$$\frac{\partial f}{\partial y}(0, 0) = 1 \neq 0.$$

Therefore by Theorem 4.22, we can assume that y is given as a function of x, $y = y(x)$, near the origin. Differentiating the defining equation implicitly with respect to x we have

$$\begin{aligned} y' &= 2 + 6x - 2xy' - 2y + 2yy' + 6y^2y', \text{ and} \\ y'' &= 6 - 4y' - 2xy'' + 2(y')^2 + 2yy'' + 6y^2y'' + 12yy'y''. \end{aligned}$$

Putting $x = y = 0$ in the first gives $y' = 2$. Substituting into the second then gives $y'' = 6$. Therefore

$$\kappa = \frac{6}{(1+4)^{\frac{3}{2}}} = \frac{6\sqrt{5}}{25},$$

and $(x_*, y_*) = \frac{5}{6}(-2, 1)$. The equation of the circle of curvature is therefore

$$(x + \tfrac{5}{3})^2 + (y - \tfrac{5}{6})^2 = \tfrac{125}{36},$$

which simplifies to give

$$3x^2 + 3y^2 - 5y + 10x = 0.$$

□

Exercises

9.1. Find the circle of curvature at $t = 0$ of the following curves.

a) the crunodal cubic $\mathbf{r}(t) = (t^2 - 1, t(t^2 - 1))$.

$$\left[\left(x + \tfrac{1}{2}\right)^2 + y^2 = \tfrac{1}{4}\right]$$

b) the acnodal cubic $\mathbf{r}(t) = (t^2 + 1, t(t^2 + 1))$.

9.2. Find the coordinates of the centre of curvature of the curve $y = \cosh x$ at the point $(0, 1)$. Find the circle of curvature.
(*Hint:* Recall that the derivatives of sinh and cosh are cosh and sinh respectively.)

9.3. Find a point on the curve $y = x^2 + x - 1$ for which the centre of curvature lies on the y–axis. $[x = -1]$

9.4. Write down the formula for the centre of curvature for a curve $y = f(x)$ parametrised by its x–coordinate.

$$\left[\mathbf{r}(x) = (x, f(x)) + \frac{1 + (f'(x))^2}{f''(x)}(-f'(x), 1)\right]$$

9.5. A curve is parametrised by

$$t \mapsto \mathbf{r}(t) = \left(\frac{t^2}{1+t^2}, \frac{t^3}{1+t^2}\right).$$

Prove that the centre of curvature is $(-t^2 - \frac{1}{6}t^4, \frac{4}{3}t)$.

9.6. Show that the circles of curvature of the parabola $y^2 = 4ax$ for the ends of the latus rectum are $x^2 + y^2 - 10ax \pm 4ay - 3a^2 = 0$, and that they cut the curve again in the points $(9a, \mp 6a)$.

9.7. Prove that the curvature of the curve $y = \frac{1}{4}x^2 - \frac{1}{2}\log x$ $(x > 0)$ is

$$\frac{4x}{(1+x^2)^2}\,.$$

Find the point at which the curve is parallel to the x–axis, and prove that the circle of curvature at this point touches the y–axis.

$[(1, \frac{3}{4})]$

9.8. For the equi-angular spiral $r = ae^{m\theta}$, show that the centre of curvature is at the point where the line through the pole $r = 0$ and orthogonal to the radius vector meets the normal.

9.9. For what value of λ does the parabola $y^2 = 4\lambda x$ have the same circle of curvature as the ellipse

$$\left(\frac{x-a}{a}\right)^2 + \frac{y^2}{b^2} = 1$$

at the origin? $\left[\dfrac{b^2}{16a}\right]$

9.10. Show that the circle of curvature at the origin for the curve

$$x + y = ax^2 + by^2 + cx^3$$

is

$$(a+b)(x^2+y^2) = 2x + 2y.$$

(*Hint:* Use Theorem 8.13. Recall that

$$\mathbf{r}_* = \mathbf{r} + \frac{1}{\kappa}\mathbf{n},$$

where $\mathbf{n}$ is the unit normal vector appropriate to the choice of the sign of the curvature. Alternatively use the method of Exercise 9.7.)

9.11. Calculate the curvature of the ellipse $\dfrac{x^2}{a^2} + \dfrac{y^2}{b^2} = 1$ at the point $(a\cot t, b\sin t)$. On an ellipse with $a = 8$ cm and $b = 4$ cm, draw accurately the circle of curvature at the point $\left(\dfrac{\sqrt{3}a}{2}, \dfrac{b}{2}\right)$. On a separate copy of the ellipse draw the circles of curvature at $(a, 0)$ and at $(0, b)$. Describe the relation of the points $z(t)$ of a curve to a circle tangent to the curve at $z(t_0)$ for t sufficiently close to t_0, where the circle is not the circle of curvature at $z(t_0)$. Illustrate this by drawing two further circles tangent to the ellipse at $\left(-\dfrac{\sqrt{3}a}{2}, \dfrac{b}{2}\right)$ and noting the relevant behaviour on your diagram.

9.12. Let $y = f(x)$ be a curve whose centres of curvature all lie in the x–axis. Prove that $yy'' + (1 + (y')^2) = 0$. Hence show, by integrating this equation, that the points on the curve must satisfy an equation of the form $(x-a)^2 + y^2 = c^2$.

9.13. Show that the centre of curvature at a non-singular point (a, b) of an algebraic curve $f(x, y) = 0$ is

$$\mathbf{r}_* = (a, b) - \frac{|\mathbf{grad}\, f|^2}{f_y^2 f_{xx} - 2f_x f_y f_{xy} + f_x^2 f_{yy}}\, \mathbf{grad}\, f\ ,$$

where all partial derivatives are evaluated at (a, b).

9.2 Contact between curves and circles

We considered contact between an algebraic curve and a parametrised curve in Chapter 5. We consider here the special case where the algebraic curve is a circle that intersects a given parametric curve. We describe the significance of 1–point contact, 2–point contact and 3–point contact in this case. In general there is a unique circle having ≥ 3–point contact with a curve at a regular point. This circle is called the *osculating circle*. We show also that the osculating circle coincides with the circle of curvature at the point. This gives us an alternative way of defining the circle of curvature.

Let

$$|\mathbf{r} - (a, b)|^2 = k^2 \quad (k > 0)$$

be a fixed circle and let

$$t \mapsto \mathbf{r}(t)$$

be a parametrised curve. Define the function γ by

$$\begin{aligned}\gamma(t) = |\mathbf{r}(t) - (a, b)|^2 - k^2 &= (\mathbf{r}(t) - (a, b)) \,.\, (\mathbf{r}(t) - (a, b)) - k^2\\ &= (x(t) - a)^2 + (y(t) - b)^2 - k^2 .\end{aligned}$$

The two curves intersect where $\gamma(t) = 0$. We assume that $t \mapsto \mathbf{r}(t)$ is smooth (or, more generally, suitably differentiable). In the special case where $x(t)$ and $y(t)$ are polynomials, $\gamma(t)$ is a polynomial in t.

We now consider a number of special cases.

9.2.1 At least 1–point contact: $\gamma(t_0) = 0$

This means that the curve intersects the circle at $\mathbf{r}(t_0)$. In the case of exactly 1–point contact, the circle and the curve will not have the same tangent line at the point of intersection.

9.2.2 At least 2–point contact: $\gamma(t_0) = \gamma'(t_0) = 0$

We assume that t_0 is a regular value. The second condition is

$$\gamma'(t_0) = 2\mathbf{r}' \,.\, (\mathbf{r} - (a, b)) = 0\,. \tag{9.1}$$

Thus the curve intersects the circle at $\mathbf{r}(t_0)$ and the tangent to the curve there is orthogonal to that radius of the circle which passes through $\mathbf{r}(t_0)$,

9.13. Show that the centre of curvature at a non-singular point (a, b) of an algebraic curve $f(x, y) = 0$ is

$$\mathbf{r}_* = (a, b) - \frac{|\mathbf{grad}\, f|^2}{f_y^2 f_{xx} - 2f_x f_y f_{xy} + f_x^2 f_{yy}}\, \mathbf{grad}\, f\ ,$$

where all partial derivatives are evaluated at (a, b).

9.2 Contact between curves and circles

We considered contact between an algebraic curve and a parametrised curve in Chapter 5. We consider here the special case where the algebraic curve is a circle that intersects a given parametric curve. We describe the significance of 1–point contact, 2–point contact and 3–point contact in this case. In general there is a unique circle having $\geq$ 3–point contact with a curve at a regular point. This circle is called the *osculating circle*. We show also that the osculating circle coincides with the circle of curvature at the point. This gives us an alternative way of defining the circle of curvature.

Let

$$|\mathbf{r} - (a, b)|^2 = k^2 \quad (k > 0)$$

be a fixed circle and let

$$t \mapsto \mathbf{r}(t)$$

be a parametrised curve. Define the function γ by

$$\begin{aligned}\gamma(t) = |\mathbf{r}(t) - (a, b)|^2 - k^2 &= (\mathbf{r}(t) - (a, b)) \,.\, (\mathbf{r}(t) - (a, b)) - k^2 \\ &= (x(t) - a)^2 + (y(t) - b)^2 - k^2.\end{aligned}$$

The two curves intersect where $\gamma(t) = 0$. We assume that $t \mapsto \mathbf{r}(t)$ is smooth (or, more generally, suitably differentiable). In the special case where $x(t)$ and $y(t)$ are polynomials, $\gamma(t)$ is a polynomial in t.

We now consider a number of special cases.

9.2.1 At least 1–point contact: $\gamma(t_0) = 0$

This means that the curve intersects the circle at $\mathbf{r}(t_0)$. In the case of exactly 1–point contact, the circle and the curve will not have the same tangent line at the point of intersection.

9.2.2 At least 2–point contact: $\gamma(t_0) = \gamma'(t_0) = 0$

We assume that t_0 is a regular value. The second condition is

$$\gamma'(t_0) = 2\mathbf{r}' \,.\, (\mathbf{r} - (a, b)) = 0\,. \tag{9.1}$$

Thus the curve intersects the circle at $\mathbf{r}(t_0)$ and the tangent to the curve there is orthogonal to that radius of the circle which passes through $\mathbf{r}(t_0)$,

Ω in the family $\mathbf{F}$. For example, if $\mathbf{F}$ is the family of all lines and P is a regular/non-singular point, the osculating line at P is the tangent line to Γ at P; and if $\mathbf{F}$ is the family of all circles and P is a regular/non-singular point, the osculating circle at P is the circle of curvature of Γ at P. In each of these two cases there is a unique osculating curve.

Exercises

9.14. Show that the curve $t \mapsto \mathbf{r}(t)$ has $\geq$ 4-point contact with its osculating circle at a regular point $\mathbf{r}(t)$ if, and only if,

$$\frac{x'y'' - y'x''}{(x')^2 + (y')^2}\,(3\mathbf{r}'' \cdot \mathbf{r}') = \mathbf{r}''' \cdot (-y', x').$$

9.15. Find the points on the following curves at which the osculating circle has $\geq$ 4-point contact:

a) the ellipse $\mathbf{r}(\varphi) = (a\cos\varphi, b\sin\varphi)$ $(a \neq b)$, $[0, \tfrac{1}{2}\pi, \pi, \tfrac{3}{2}\pi]$

b) the cycloid $\mathbf{r}(\varphi) = (a\varphi - b\sin\varphi, a - b\cos\varphi)$ $(a \neq b)$.

(*Hint:* Use Exercise 9.14.)

9.16. Show that, if two curves have $\geq$ 3-point contact at a common point, then they have the same osculating circle.

(*Hint:* Use Exercise 5.6.)

Projective curves

Algebraic curves in the plane are often 'incomplete', in that certain 'points at infinity' are missing from them. We show here how plane algebraic curves can be extended to projective curves in the projective plane; any additional points obtained in the extension are the points at infinity for the original plane curve. The plane curve becomes an affine view of the projective curve. The asymptotes to the plane curve are tangents to the projective curve at the points at infinity. Different affine views of the projective curve can give further information about the original plane curve. A projective curve has many different affine views; for example, ellipses, hyperbolae, and parabolae are all affine views of the same projective curve. We give a classical definition of elements of a projective space as lines through the origin of the appropriate coordinate space. We show that points of the projective plane have a 'coordinate' representation, and use coordinates to obtain subsequent results and for solving examples. The asymptotes of the plane curve can be determined by studying the projective curve. Another application is to determine the boundedness of the plane curve.

16.1 The projective line

The projective curves we consider lie in the projective plane. The projective plane is given by adding certain points at infinity to the plane. We first consider the projective line, which is given by adding a point at infinity to the line.

Definition 16.1. The *projective line* $\mathbf{RP}^1$ is the set of lines in $\mathbf{R}^2$ which pass through the origin $(0, 0)$. A *point* in $\mathbf{RP}^1$ is a line through the origin of $\mathbf{R}^2$.

We now show that the projective line identifies with (is bijective with) any line in $\mathbf{R}^2$, not through the origin, together with the point at infinity for that line. Consider the line $\Lambda : ax + by = d$ in $\mathbf{R}^2$ which does not pass through the origin, that is $d \neq 0$; for any line we have $(a, b) \neq \mathbf{0}$. Then any point P on Λ determines a unique element L of $\mathbf{RP}^1$, where L is the line through P and $(0,0)$. Conversely any element L of $\mathbf{RP}^1$, other than the line $\Lambda_0 : ax+by=0$, determines a point P of Λ. The line $\Lambda_0 : ax+by=0$ is parallel to Λ. We thus have a bijection

$$\mathbf{RP}^1 \leftrightarrow \Lambda \ + \ \{\text{one extra point}\},$$

between $\mathbf{RP}^1$ and the union of the line Λ, which does not pass through the origin, and an extra point. The extra point corresponds to the line Λ_0 under the bijection. The extra point is called the *point at infinity* of Λ (see Figure 16.1). The line Λ is an *affine line*; it lies in the plane $\mathbf{R}^2$. Two lines $\Lambda : ax+by=d$ and $\Omega : px+qy=r$, which do not pass through the origin, will have different points at infinity (that is $ax+by=0$ and $px+qy=0$ are different lines) if they are not parallel, and will have the same point at infinity (that is $ax+by=0$ and $px+qy=0$ are the same line) if they are parallel.

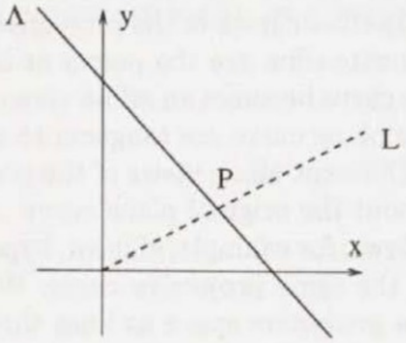

Figure 16.1 *The point at infinity of a line.*

Remark 16.2. Each element of $\mathbf{RP}^1$ determines two (opposite) points on the unit circle $x^2+y^2=1$. Indeed $\mathbf{RP}^1$ is bijective with the set[†] obtained from the upper semi-circle $\{x^2+y^2=1, y \geq 0\}$ after 'gluing together' the points $(1,0)$ and $(-1,0)$. See Figure 16.2.

16.2 The projective plane

The definition given above for the 'one-dimensional' projective line can be used as a model for defining projective spaces of 'higher dimensions'. We consider here the projective plane, which is two-dimensional projective space.

Definition 16.3. The *projective plane* $\mathbf{RP}^2$ is the set of lines in $\mathbf{R}^3$ which

---

[†] The projective line is topologically a circle, that is its shape can be deformed or stretched out to form a circle.

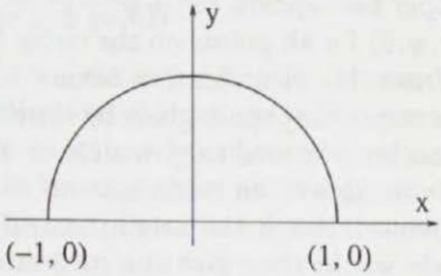

Figure 16.2 *The projective line as a circle.*

pass through the origin $(0,0,0)$. A point of $\mathbf{R}\mathrm{P}^2$ is a line passing through the origin of $\mathbf{R}^3$.

We denote by $(x:y:z)$ the element of $\mathbf{R}\mathrm{P}^2$ determined by the unique line through (x,y,z) and $(0,0,0)$ where $(x,y,z) \neq 0$. Note that

$$(\lambda x:\lambda y:\lambda z) = (x:y:z)$$

for $(x,y,z) \neq \mathbf{0}$ and $\lambda \neq 0$. The algebraic equation of the line in $\mathbf{R}^3$ corresponding to the point $(a:b:c)$ of $\mathbf{R}\mathrm{P}^2$ is

$$\frac{x}{a} = \frac{y}{b} = \frac{z}{c}.$$

This form of the equation allows up to two of a, b, c to be zero; for example if $a = 0$ the line is given by $x = 0$ and $cy = bz$. The parametric equation of the line is $(x,y,z) = \lambda(a,b,c)$. There is no point of $\mathbf{R}\mathrm{P}^2$ which corresponds to the symbol $(0:0:0)$.

Mnemonic

The projective plane is the set of points $(x:y:z)$ with $(\lambda x:\lambda y:\lambda z) = (x:y:z)$ and $(x,y,z) \neq (0,0,0)$

The coordinates x, y, z are called *homogeneous coordinates.* The numbers x, y, z are not themselves fixed for a point of the projective plane. The ratios between them are fixed for a given point.

16.2.1 Geometrical interpretation in terms of the unit sphere

Each element of $\mathbf{R}\mathrm{P}^2$, that is each line through the origin, meets the unit sphere $x^2 + y^2 + z^2 = 1$ in $\mathbf{R}^3$ in two (opposite) points. Indeed $\mathbf{R}\mathrm{P}^2$ can be considered as the space obtained from the unit sphere by identifying such pairs (x,y,z) and $-(x,y,z)$ of opposite points to give the point

$$(x:y:z).$$

(Formally $\mathbf{R}\mathrm{P}^2$ is the set of equivalence classes under the equivalence relation $(x,y,z) \sim -(x,y,z)$.) Similarly $\mathbf{R}\mathrm{P}^2$ can be considered as the space obtained from the upper hemisphere $\{x^2+y^2+z^2=1, z \geq 0\}$ by identifying $(x,y,0)$ with $-(x,y,0)$ for all points on the circle $\{x^2+y^2=1,\ z=0\}$. The space obtained from this identification cannot be deformed to give a sphere[†], unlike the corresponding space given by identifying opposite points of the circle, which can be deformed to give a circle. Rather than choosing the upper hemisphere as above, we could instead choose the hemisphere on one side of any plane through the origin; identifying opposite points on the boundary circle would then give the projective plane. A different choice of axes for $\mathbf{R}^3$ will result in different homogeneous coordinates for the projective plane.

16.2.2 Points at infinity for an affine plane in $\mathbf{R}^3$

Consider now a plane $\Pi : ax+by+cz=d$ which does not pass through the origin of $\mathbf{R}^3$ (that is $d \neq 0$). For any plane we have $(a,b,c) \neq \mathbf{0}$. Each element P of Π determines a unique element L of $\mathbf{RP}^2$ (L is the line through $(0,0,0)$ and P). Conversely each element L of $\mathbf{RP}^2$, other than those elements representing lines in the plane $\Pi_0 : ax+by+cz=0$, determines a unique element P of Π. Under this bijection, the affine plane Π can be regarded as a subset of $\mathbf{RP}^2$. The points of $\mathbf{RP}^2$ not lying in this subset are the *points at infinity* for the affine plane Π. This set of points at infinity for the affine plane $\Pi : ax+by+cz=d$ is the projective line obtained from the great circle[‡]

$$\{x^2+y^2+z^2=1,\ ax+by+cz=0\}$$

by identifying opposite points. We thus have a bijection

$$\boxed{\mathbf{RP}^2 \leftrightarrow \Pi + \text{ the projective line of points at infinity}}$$

between $\mathbf{RP}^2$ and the union of Π, which is a plane not through the origin, and the projective line of points of Π at infinity.

Mnemonic

$$\boxed{\text{The set of points at infinity for an affine plane is a projective line.}}$$

[†] Topologically, the projective plane is a non-orientable closed surface and therefore cannot be represented in three-dimensional Euclidean space without self-intersections; models can be constructed with self-intersections. In four-dimensional Euclidean space, models of the projective plane can be defined without such self-intersections.

[‡] A great circle on a sphere is the circle of intersection of the sphere and any plane through its centre.

16.2.3 Duality of lines and points

In the plane $\mathbf{R}^2$, any two distinct points determine a unique line which passes through them. However it is not generally true that any two distinct lines determine a unique common point, since parallel lines in general have no point in common. In the projective plane any two distinct lines do have a unique common point, and therefore a duality exists in the 'geometry' of the projective plane between lines and points.

Theorem 16.4. *In the projective plane*

i) two distinct lines meet in precisely one point, and

ii) there is a unique line through any two distinct points.

Proof. We give a geometric proof. Projective lines are obtained from great circles on the sphere by identifying opposite points. Two distinct great circles intersect at two opposite points, which become identified to one point of the projective plane. Two distinct points of the sphere, which are not opposite, determine a unique great circle which passes through both, and this circle becomes identified as a projective line. The result follows. ☐

16.2.4 Diagrammatic representation of the projective plane

It will sometimes be convenient to represent the projective plane diagrammatically by a portion of the plane. We represent the axes $x = 0$, $y = 0$ and $z = 0$ by 'lines' in the plane (see Figure 16.3).

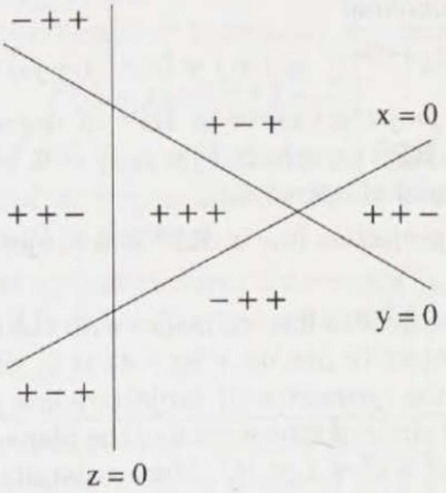

Figure 16.3 *The axes of the projective plane.*

The notation '$- + +$' for example means that the points in this region can be written $(x:y:z)$ where $x < 0$ and $y, z > 0$. The axes divide $\mathbf{RP}^2$ into four such regions. Notice that the regions determined by '$- + +$' and by '+ − −' are identical for example. The axes come from great circles, on the sphere $x^2 + y^2 + z^2 = 1$ in $\mathbf{R}^3$, given by intersection with the planes $x = 0$, $y = 0$ and $z = 0$: these great circles bound the 'first octant'

$$\{x \geq 0, y \geq 0, z \geq 0\}$$

of the sphere. The diagram should be thought of as lying within a closed curve, where 'roughly opposite' points of the closed curve are identified to give $\mathbf{RP}^2$. Care should be taken in drawing conclusions from this diagrammatic representation, particularly those relating to lines. For example there is no sense of 'parallel lines' in the projective plane; indeed, any pair of lines meet. In the affine plane given by $z = 1$, parallel lines meet on the line at infinity $z = 0$ in the projective plane. Notice in the diagram that crossing over the x–axis for example changes the sign of the x–coordinate.

16.3 Projective curves

Recall that a *homogeneous function of degree n* is a function $F : \mathbf{R}^3 \to \mathbf{R}$ which satisfies

$$F(\lambda x, \lambda y, \lambda z) = \lambda^n F(x, y, z)$$

for each real number λ and for each (x, y, z). We are especially interested in homogeneous polynomials of degree n. Such a homogeneous polynomial will have the form

$$F(x, y, z) = \sum a_{ij} x^i y^j z^{n-(i+j)}.$$

The *degree* of each monomial

$$a_{ij} x^i y^j z^{n-(i+j)} \text{ is } i + j + (n - (i + j)) = n.$$

Definition 16.5. A *projective curve* in $\mathbf{RP}^2$ of degree $n \geq 1$ is the set of points $(x : y : z)$ in $\mathbf{RP}^2$ for which $F(x, y, z) = 0$, where $F(x, y, z)$ is a homogeneous polynomial of degree n.

Definition 16.6. A *projective line* in $\mathbf{RP}^2$ is a projective curve of degree one.

This definition of 'projective line' coincides with the one defined geometrically above. The projective line $ax + by + cz = 0$, where $(x : y : z)$ lies in $\mathbf{RP}^2$, corresponds to the (geometrical) projective line given by identifying opposite points on the circle of intersection of the plane $ax + by + cz = 0$ and the unit sphere $x^2 + y^2 + z^2 = 1$ in $\mathbf{R}^3$. More generally the set of points in $\mathbf{R}^3$ satisfying $F(x, y, z) = 0$, for a homogeneous polynomial F, form a surface in $\mathbf{R}^3$. This surface is the union of the lines in a pencil of lines through the origin. Each of the lines in this pencil determines a point of $\mathbf{RP}^2$, and the set of such points in $\mathbf{RP}^2$ is the projective curve $F(x, y, z) = 0$ where $(x : y : z)$ lies in $\mathbf{RP}^2$.

Note the special case above of the projective line $ax + by + cz = 0$ of points at infinity for the affine plane $ax + by + cz = d$, considered as a subset of $\mathbf{RP}^2$.

In general a line meets a curve of degree $n \geq 2$ in the plane in $\leq n$ points. We now prove that a similar result holds in the projective plane.

Theorem 16.7. *A projective line meets a projective curve of degree n, which does not contain it, in at most n distinct points.*

Proof. We give a proof in the case where $z = 0$ is the line; the proof in the general case then follows by choosing a rotation of $\mathbf{R}^3$ which maps the plane determined by the given line to the plane $z = 0$. Let the projective curve be $F(x, y, z) = 0$. Now $F(x, y, 0)$ is the sum of the terms of $f(x, y) = 0$ of highest degree. Therefore $F(x, y, 0)$ is not identically zero. Thus $F(x, y, 0)$ is a homogeneous polynomial of degree n which factorises as

$$Ky^m \prod_{i=1}^{n-m} (x - c_i y)$$

where some c_i may not be real and some real c_i may be repeated (we are interested here only in real c_i). The only possible points of intersection are therefore the points $(c_i\!:\!1\!:\!0)$ and $(1\!:\!0\!:\!0)$. The result follows. $\square$

16.4 The projective curve determined by a plane curve

Given a plane algebraic curve of degree n with equation $f(x, y) = 0$, we define a homogeneous polynomial $F(x, y, z)$ of degree n which determines a projective curve $F(x, y, z) = 0$.

The homogeneous polynomial F is formally determined by

$$F(x, y, z) = z^n f\left(\frac{x}{z}, \frac{y}{z}\right).$$

The easiest way to find $F(x, y, z)$ is to determine the degree n of f, then to multiply each monomial in f by a suitable power of z in order to obtain, in each case, a monomial of degree n.

Definition 16.8. The projective curve *determined by* or *associated to* the plane curve $f(x, y) = 0$ in $\mathbf{R}^2$ is $F(x, y, z) = 0$ in $\mathbf{RP}^2$.

Mnemonic

A projective curve has elements $(x\!:\!y\!:\!z)$ in $\mathbf{RP}^2$.
Affine curves in $\mathbf{R}^3$ have elements (x, y, z) in $\mathbf{R}^3$.
A plane curve has elements (x, y) in $\mathbf{R}^2$.

Worked example 16.9. Find the equation of the projective curve determined by the plane curve

$$y^2 = x^3 + x.$$

Solution. The plane curve has degree 3, therefore we must multiply each monomial by a suitable power of z to give a homogeneous polynomial of degree 3. The projective curve therefore is $y^2z = x^3 + xz^2$. □

16.5 Affine views of a projective curve

Let the projective curve Γ in $\mathbf{R}\mathrm{P}^2$ be given by $F(x, y, z) = 0$; thus, the points of Γ are

$$\{(x{:}y{:}z) : F(x, y, z) = 0\}.$$

We consider the affine plane in $\mathbf{R}^3$ given by $\{(x, y, z) : ax + by + cz = d\}$ where $d \neq 0$. In this plane in $\mathbf{R}^3$, the projective curve Γ determines the affine view Π given by

$$\{(x, y, z) : F(x, y, z) = 0,\ ax + by + cz = d\} :$$

the affine curve Π is the intersection in $\mathbf{R}^3$ of the affine plane $ax+by+cz = d$ and the surface $\{(x, y, z) : F(x, y, z) = 0\}$. The projective curve can be regarded as the union of the affine curve and the set of points at infinity for the affine curve. The set of points at infinity for the affine curve in the plane $ax + by + cz = d$ is

$$\{(x{:}y{:}z) : ax + by + cz = 0,\ F(x, y, z) = 0\}.$$

Definition 16.10. The *affine view* (or *affine section*) of the projective curve

$$\{(x{:}y{:}z) : F(x, y, z) = 0\}$$

for the plane $ax + by + cz = d$ $(d \neq 0)$ is the affine curve in $\mathbf{R}^3$,

$$\{(x, y, z) : F(x, y, z) = 0,\ ax + by + cz = d\}.$$

Notice that the projective curve lies in $\mathbf{R}\mathrm{P}^2$ and the affine view lies in the plane $ax + by + cz = d$ in $\mathbf{R}^3$. This plane does not pass through the origin of $\mathbf{R}^3$.

Mnemonic

Projective curve ↔ affine view + points at infinity for affine view.

Worked example 16.11. Find the affine view for $y + z = 1$ of the projective curve

$$x^3 - y^3 - y^2z = 0.$$

Solution. Substituting $z = 1-y$ gives $x^3 = y^2$. The equation $x^3 = y^2$ in $\mathbf{R}^3$ gives the cylinder passing through the curve $x^3 = y^2$ in the xy–plane and with generators parallel to the z–axis. The affine view is the intersection of this cylinder with the plane $y + z = 1$. It has a cusp at $(0, 0, 1)$. □

16.6 Plane curves as views of a projective curve

An important case of affine views is where the affine plane is taken to be $z = 1$. The affine view in $\mathbf{R}^3$ is then

$$\{(x, y, z) : z = 1, F(x, y, 1) = 0\}$$

in the plane $z = 1$. We may identify this with the plane curve

$$F(x, y, 1) = 0$$

in $\mathbf{R}^2$. Notice that this plane curve is not given by putting $z = 0$ in $F(x, y, z) = 0$. The points at infinity for the plane curve are then

$$\{(x{:}y{:}z) : z = 0, F(x, y, 0) = 0\}$$

in $\mathbf{RP}^2$.

Theorem 16.12. *Let $F(x, y, z) = 0$ be the projective curve determined by the plane curve $f(x, y) = 0$, then the affine view for $z = 1$ of the projective curve $F(x, y, z) = 0$ is $f(x, y) = 0$. Conversely let $f(x, y) = 0$ be the affine view for $z = 1$ of a projective curve $F(x, y, z) = 0$, for which z is not a factor of $F(x, y, z)$, then the projective curve determined by $f(x, y) = 0$ is $F(x, y, z) = 0$.*

Proof. We assume that the curves are of degree $n \geq 1$.
i) We have formally

$$F(x, y, z) = z^n f\left(\frac{x}{z}, \frac{y}{z}\right).$$

The affine view for $z = 1$ is

$$F(x, y, 1) = f(x, y).$$

ii) We have $f(x, y) = F(x, y, 1)$. This determines the projective curve

$$z^n f\left(\frac{x}{z}, \frac{y}{z}\right) = z^n F(\frac{x}{z}, \frac{y}{z}, 1) = F(x, y, z).$$

□

The affine views for the planes $x = 1$ and $y = 1$ can similarly be identified with plane curves in $\mathbf{R}^2 = \{(y, z)\}$ and $\mathbf{R}^2 = \{(x, z)\}$ respectively, and a result similar to Theorem 16.12 holds.

Worked example 16.13. Determine the affine views and their points at infinity of the projective curve $y^2 z = x^3$ for the planes $x = 1$, $y = 1$, and $z = 1$.

Solution. To find the affine view for the plane $y = 1$, we put $y = 1$ in the equation $y^2 z = x^3$. The affine view is $z = x^3$. To find the point at infinity we put $y = 0$ in the equation $y^2 z = x^3$; the plane curve therefore has just one point $(0{:}0{:}1)$ at infinity. The affine view for $z = 1$ is the semi-cubical parabola $y^2 = x^3$, which also has just one point $(0{:}1{:}0)$ at infinity. The affine view for $x = 1$ is $y^2z = 1$, which has two points $(0{:}1{:}0)$ and $(0{:}0{:}1)$ at infinity. Recall that these points at infinity are in $\mathbf{RP}^2$. $\square$

We now give an example involving conic sections.

Worked example 16.14. Show that ellipses, hyperbolae, and parabolae can occur as affine views of the projective curve given by $F = x^2 + y^2 - z^2$.

Solution. The homogeneous polynomial $F = x^2 + y^2 - z^2$ determines the right circular cone

$$\{(x, y, z) \in \mathbf{R}^3 : x^2 + y^2 - z^2 = 0\},$$

which is a surface in $\mathbf{R}^3$ (see Figure 16.4), and determines the projective curve

$$\Gamma = \{(x{:}y{:}z) : x^2 + y^2 - z^2 = 0\}$$

in $\mathbf{RP}^2$. The affine view of this projective curve depends on the choice of the affine plane $ax + by + cz = d$. We note three of the views which can occur.

i) The affine view for $z = 1$. In this case the line at infinity is $z = 0$, and the affine view is $x^2 + y^2 = 1$, which is an ellipse. There are no points at infinity.

ii) The affine view for $x = 1$. In this case the line at infinity is $x = 0$, and the affine view is $z^2 - y^2 = 1$, which is a hyperbola. There are two points $(0{:}1{:}\pm1)$ at infinity.

iii) The affine view for $y + z = 1$. In this case the line at infinity is $y + z = 0$, and the affine view is given by

$$x^2 + y^2 - (1 - y)^2 = 0 \quad \text{and} \quad y + z = 1,$$

that is

$$x^2 = 1 - 2y = -2\left(y - \tfrac{1}{2}\right) \quad \text{and} \quad y + z = 1.$$

This is a parabola in the plane $y + z = 1$. It is the intersection of the parabolic cylinder $x^2 = -2\left(y - \frac{1}{2}\right)$ in $\mathbf{R}^3$ with the plane $y + z = 1$. To find the points at infinity, we put $y + z = 0$. This gives $x = 0, y + z = 0$; therefore there is precisely one point $(0{:}1{:}-1)$ at infinity. (Compare Theorem 16.34 below.) $\square$

Mnemonic

Ellipses, hyperbolae, and parabolae are affine views of the same projective curve.

The set of points at infinity for a projective curve depends on the view chosen. Different views will give different sets of points at infinity, as illustrated in the above examples.

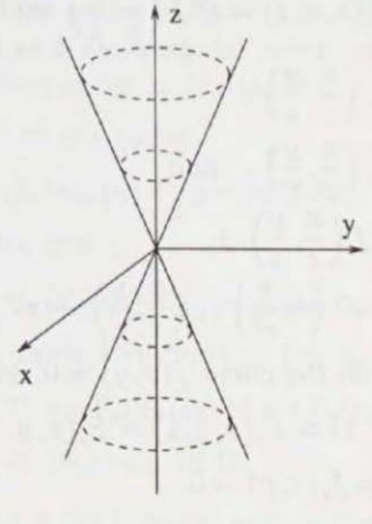

Figure 16.4 *A right circular cone in 3-space.*

16.7 Tangent lines to projective curves

The tangent lines to a plane algebraic curve $f(x, y) = 0$ are most readily defined at non-singular points, that is at points at which $\mathbf{grad}\, f \neq 0$. We consider the analogous situation for projective curves.

Definition 16.15. A *non-singular point* of the projective curve

$$F(x, y, z) = 0$$

is a point on the curve at which

$$\mathbf{grad}\, F = \left(\frac{\partial F}{\partial x}, \frac{\partial F}{\partial x}, \frac{\partial F}{\partial x}\right) \neq 0.$$

A *singular point* is a point at which

$$\mathbf{grad}\, F = \left(\frac{\partial F}{\partial x}, \frac{\partial F}{\partial x}, \frac{\partial F}{\partial x}\right) = 0.$$

The singular points of a plane curve correspond to singular points of the associated projective curve as in the following theorem.

Theorem 16.16. *(x, y) is a singular point of the plane curve $f(x, y) = 0$ if, and only if, $(x : y : 1)$ is a singular point of the associated projective curve $F(x, y, z) = 0$.*

Proof. Differentiating $F(x,y,z) = z^n f\left(\frac{x}{z}, \frac{y}{z}\right)$ we have

$$\begin{aligned} F_x(x,y,z) &= z^n \frac{1}{z} f_x\left(\frac{x}{z}, \frac{y}{z}\right), \\ F_y(x,y,z) &= z^n \frac{1}{z} f_y\left(\frac{x}{z}, \frac{y}{z}\right), \quad \text{and} \\ F_z(x,y,z) &= nz^{n-1} f\left(\frac{x}{z}, \frac{y}{z}\right) + \\ &\qquad z^n\left(-\frac{x}{z^2}\right) f_x\left(\frac{x}{z}, \frac{y}{z}\right) + z^n\left(-\frac{y}{z^2}\right) f_y\left(\frac{x}{z}, \frac{y}{z}\right). \end{aligned}$$

Thus, for a point (x,y) on the curve $f(x,y) = 0$, we have

$$F_x(x,y,1) = F_y(x,y,1) = F_z(x,y,1) = 0$$

if, and only if, $f_x(x,y) = f_y(x,y) = 0$. □

Similar results apply for the affine views given by $x = 1$ and $y = 1$, and more generally for the affine views given by $ax + by + cz = 1$.

We now determine the tangent lines at non-singular points of a projective curve. The tangent line of a projective curve is a projective line.

Theorem 16.17. *Let (x_0, y_0, z_0) be a non-singular point of the projective curve $F(x,y,z) = 0$, then the tangent line (a projective line in $\mathbf{R}P^2$) at (x_0, y_0, z_0) is*

$$\boxed{\mathbf{r}\cdot\mathbf{grad}\, F = xF_x(x_0,y_0,z_0) + yF_y(x_0,y_0,z_0) + zF_z(x_0,y_0,z_0) = 0.}$$

Proof.* We give a geometrical proof. The tangent plane to the surface $F(x,y,z) = 0$ in $\mathbf{R}^3$ at (x_0, y_0, z_0) is

$$(x - x_0)F_x + (y - y_0)F_y + (z - z_0)F_z = 0$$

where

$$F_x = \frac{\partial F}{\partial x}, \quad F_y = \frac{\partial F}{\partial y} \quad \text{and} \quad F_z = \frac{\partial F}{\partial z}$$

at (x_0, y_0, z_0). This equation is of the form

$$xF_x + yF_y + zF_z = \text{constant}.$$

Since this plane must pass through the origin (the surface is given by a pencil of lines through the origin), it has the form

$$xF_x + yF_y + zF_z = 0.$$

□

The partial derivatives F_x, F_y, and F_z must be evaluated at the fixed point (x_0, y_0, z_0).

---

* For the meaning of * see the preface.

Theorem 16.18. *The associated projective line of the tangent line to the plane curve $f(x,y)=0$ at a non-singular point (x_0,y_0) is the tangent line to the associated projective curve at $(x_0:y_0:1)$.*

Proof. The tangent line at (x_0,y_0) is

$$(x-x_0)f_x(x_0,y_0)+(y-y_0)f_y(x_0,y_0)=0.$$

The associated projective line is

$$(x-x_0z)f_x(x_0,y_0)+(y-y_0z)f_y(x_0,y_0)=0.$$

The tangent line to the projective curve at $(x_0:y_0:1)$ is

$$xF_x(x_0:y_0:1)+yF_y(x_0:y_0:1)+zF_z(x_0:y_0:1)=0,$$

that is, as in the proof of Theorem 16.16,

$$xf_x(x_0,y_0)+yf_y(x_0,y_0)+z(nf(x_0,y_0)-x_0f_x(x_0,y_0)-y_0f_y(x_0,y_0))=0.$$

The result follows since (x_0,y_0) lies on the curve $f(x,y)=0$. □

The tangent line $xF_x+yF_y+zF_z=0$ to the projective curve

$$F(x,y,z)=0$$

at $(x_0:y_0:1)$ determines the tangent line $xF_x+yF_y+F_z=0$ at $(x_0,y_0,1)$ to the affine view given by $z=1$; that is the tangent line $xF_x+yF_y+F_z=0$ at (x_0,y_0) in the case of the corresponding plane curve. We consider later the tangent lines to the projective curve at the points at infinity for the plane curve.

Worked example 16.19. Find the singular points of the projective curve

$$x^2z=y^3$$

and determine the tangent lines at the non-singular points $(x_0:y_0:z_0)$.

Solution. $F_x=2xz, F_y=-3y^2, F_z=x^2$, thus $\mathbf{grad}\,F=0$ if, and only if, $x=y=0$. There is exactly one singular point at $(0:0:1)$. The tangent at a non-singular point $(x_0:y_0:z_0)$ is

$$2x_0z_0x-3y_0^2y+x_0^2z=0.$$

□

16.8 Boundedness of the associated affine curve

One of the important applications of projective geometry to the study of plane curves is to determine boundedness.

Definition 16.20. A curve in $\mathbf{R}^2$ or $\mathbf{R}^3$ is *bounded* if there is a number K such that $|\mathbf{r}|\le K$ for each point $\mathbf{r}$ of the curve.

Theorem 16.21. *Let a given affine or plane curve have no points at infinity, then the plane curve is bounded (as a curve in $\mathbf{R}^3$ or $\mathbf{R}^2$).*

*Sketch of proof**. Our proof uses similar techniques to the proof of Theorem 15.18. Given a polynomial $f(x, y)$ of degree N, we may write it in the form $f(x, y) = g(x, y) + h(x, y)$ where $g(x, y)$ is the homogeneous polynomial consisting of all monomials of $f(x, y)$ of degree N, and $h(x, y)$ has degree $\leq N - 1$. We construct the homogeneous polynomial $F(x, y, z)$ associated with $f(x, y)$ as above. Clearly $F(x, y, 0) = g(x, y)$, and, since there are no points at infinity, the equation $F(x, y, 0) = 0$ has no non-trivial solution, that is $g(x, y)$ has no real linear factors. Therefore $g(x, y)$ is a product of irreducible quadratic homogeneous polynomials and consequently has even degree $N = 2n$. As in the proof of Theorem 15.18, there is a $K > 0$ such that

$$| g(x, y) | \geq K(x^2 + y^2)^n$$

for all real x and y. On the other hand if $\phi(x, y)$ is a homogeneous polynomial of degree r, there is an $L > 0$ such that

$$| \phi(x, y) | \leq L(x^2 + y^2)^{r/2}$$

for all real x and y (we use the inequalities

$$|x| \leq (x^2 + y^2)^{1/2} \quad \text{and} \quad |y| \leq (x^2 + y^2)^{1/2}).$$

Now $h(x, y)$ is a sum of finitely many homogeneous polynomials each of degree $\leq 2n - 1$, therefore there is an $M > 0$ such that

$$| h(x, y) | \leq M(x^2 + y^2)^{(2n-1)/2}$$

for all real x and y satisfying $(x^2 + y^2) \geq 1$. Thus we have

$$|f(x, y)| = |g(x, y) + h(x, y)| \geq (x^2 + y^2)^{(2n-1)/2}(K(x^2 + y^2)^{1/2} - M)) > 0$$

for all real x and y with

$$x^2 + y^2 > \frac{M^2}{K^2}.$$

Therefore $f(x, y) = 0$ has no solutions for

$$x^2 + y^2 > \max \left\{1, \frac{M^2}{K^2}\right\},$$

which proves that the curve $f(x, y) = 0$ is bounded. □

Worked example 16.22. Show that the affine view for $z = 1$ of the projective curve $(x^2 + y^2)^2 - (x^2 - y^2)z^2 = 0$ is bounded.

Solution. Substituting $z = 0$ into $(x^2 + y^2)^2 - (x^2 - y^2)z^2 = 0$, we obtain $x = y = z = 0$. Therefore the affine view for $z = 1$ has no points at infinity ((0:0:0) does not represent a point in $\mathbf{R}P^2$). Thus the affine curve

$$(x^2 + y^2)^2 = x^2 - y^2$$

is bounded. □

---

* For the meaning of * see the preface.

The converse of Theorem 16.21 is not true. The existence of points at infinity does not imply that the affine curve is not bounded. The points at infinity could be isolated points of the projective curve. More generally it can be shown that an affine or plane curve is bounded if, and only if, the only points at infinity are isolated.

Worked example 16.23. Find the singular points of the projective curve

$$y^2z^2 = x^2z^2 - x^4.$$

Show that the affine view for $z = 1$ has a point at infinity but is bounded.

Solution. The affine view for $z = 1$ is the figure–8 curve

$$y^2 = x^2(1 - x^2).$$

It has singular points at $(0{:}0{:}1)$ and $(0{:}1{:}0)$. Now $(1 - x^2) \geq 0$ and

$$\frac{d}{dx}(x^2(1 - x^2)) = 2x(1 - 2x^2).$$

Thus y is zero at $x = 0$ and $x = \pm 1$ and has critical points at

$$x = \pm\frac{1}{\sqrt{2}}.$$

It follows that the affine view lies in the rectangle

$$\{-1 \leq x \leq 1, -\tfrac{1}{2} \leq y \leq \tfrac{1}{2}\}.$$

However this affine view has an isolated singular point $(0{:}1{:}0)$ at infinity. Notice that for the affine view given by $y = 1$ this singular point of the projective curve becomes the origin of the (x, z)–plane, and the quadratic terms of the equation have an iterated linear factor which does not correspond to a (real) tangent at the origin. □

16.9 Summary of the analytic viewpoint

1. The projective plane $\mathbf{RP}^2$ is the set of triples $(x{:}y{:}z)$ where
   i) $(x, y, z) \neq 0$ that is x, y, z are not all zero, and
   ii) $(\lambda x{:}\lambda y{:}\lambda z) = (x{:}y{:}z)$ for each $\lambda \neq 0$.

For $(x, y, z) \neq 0$, the set $\{\lambda(x, y, z)\}$ for varying λ, including $(0, 0, 0)$ given by $\lambda = 0$, is a line in $\mathbf{R}^3$ through (x, y, z). Excluding $(0, 0, 0)$ from the line determines a point of $\mathbf{RP}^2$ in this analytic sense by ii.

2. A curve of degree n in $\mathbf{RP}^2$ is the set of points of $\mathbf{RP}^2$ satisfying $F(x, y, z) = 0$, where F is a homogeneous polynomial of degree $n \geq 1$.

3. A plane $ax+by+cz = d$ in $\mathbf{R}^3$, for which $d \neq 0$, determines (bijectively) an affine plane regarded as a subset of $\mathbf{RP}^2$; and the set of points of $\mathbf{RP}^2$, which are not on this plane, constitute the (projective) line at infinity of the affine plane. The projective line given by the equation $ax + by + cz = 0$

in $\mathbf{RP}^2$ is the line is the line at infinity of the affine plane $ax + by + cz = d$.

4. The affine plane $ax + by + cz = d$ ($d \neq 0$) intersects a projective curve of degree n in an algebraic curve of degree $\leq n$.

5. Often the affine plane considered is $z = 1$ and the projective line of points at infinity is then precisely the set $\{(x : y : 0)\}$, where x, y are not both zero. Each point in this latter set can be written $(x : 1 : 0)$ except the point $(1 : 0 : 0)$.

16.10 Asymptotes

The tangent lines to a projective curve, excluding tangent lines at points at infinity, correspond bijectively with tangent lines to the affine or plane curve. We now consider tangent lines to the projective curve at the points at infinity (see Figure 16.5).

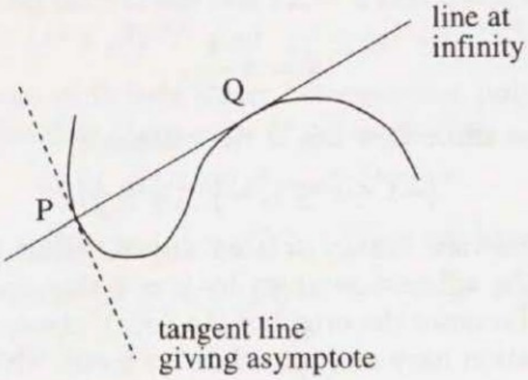

Figure 16.5 *Tangents at points at infinity.*

Definition 16.24. An *asymptote* of a plane curve Γ is a tangent to the projective curve determined by it at a point at infinity, which tangent is not the line at infinity.

Theorem 16.25. *A plane or affine curve of degree n has at most n distinct points at infinity.*

Proof. The points at infinity are the points of intersection of the associated projective curve, which has the same degree, and the line at infinity. The result follows from Theorem 16.7. ☐

Example 16.26. $\prod_{r=1}^{n}(x - ry) + 1 = 0$ has n distinct points $(r : 1 : 0)$ at infinity. For $n = 2$ this is a hyperbola.

For points at infinity on a projective curve there are two cases to consider as follows.

1. P is a point at infinity and at least one tangent at P is not the line at infinity. In this case each tangent, at P, which is not the line at infinity will determine an asymptote.

2. P is a point at infinity and the unique tangent at P is the line at infinity. In this case the point at infinity does not give rise to an asymptote.

16.10.1 Procedure for determining the asymptotes

We demonstrate the method for finding the asymptotes to a plane curve

$$f(x, y) = 0.$$

First find the points at infinity on the related projective curve

$$F(x, y, z) = z^n f\left(\frac{x}{z}, \frac{y}{z}\right) = 0.$$

Find the tangents at these points: these tangents will be projective lines. For those tangents which are not the line at infinity, determine the related affine line in the plane $z = 1$. The asymptotes to the plane curve will have the same equations as these affine lines.

Worked example 16.27. Find the points at infinity and the asymptotes of the hyperbola

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1.$$

Solution. The plane curve is the affine view for $z = 1$ of the projective curve

$$F(x, y, z) = \frac{x^2}{a^2} - \frac{y^2}{b^2} - z^2 = 0.$$

The points at infinity for the plane curve are given by $z = 0$ and

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 0:$$

the points at infinity are therefore $(a{:}b{:}0)$ and $(a{:}-b{:}0)$. The tangent line to the projective curve at (p, q, r) is

$$\frac{2p}{a^2}x - \frac{2q}{b^2}y - 2rz = 0.$$

For the two points at infinity the tangents are the projective lines

$$\frac{x}{a} = \pm\frac{y}{b}.$$

Putting $z = 1$, we now obtain the plane lines

$$\frac{x}{a} = \pm\frac{y}{b}$$

in $\mathbf{R}^2$; these are the asymptotes. □

In the above example the equations for the projective lines and plane lines corresponding to the asymptotes are the same. This will not happen in general since substituting $z = 1$ will usually give a constant term.

Example 16.28. In Example 16.14 we considered the affine views of

$$x^2 + y^2 - z^2 = 0.$$

We now investigate the asymptotes of these views.

i) The affine view for $z = 1$. In this case the line at infinity is $z = 0$. There are no points at infinity and therefore no asymptotes.

ii) The affine view for $x = 1$. In this case the line at infinity is $x = 0$. There are two points $(0\colon 1\colon \pm 1)$ at infinity. The tangents to the projective curve at these two points are $y \mp z = 0$. The asymptotes to the plane curve, given by substituting $x = 1$, are $y \mp z = 0$.

iii) The affine view for $y + z = 1$. In this case the line at infinity is $y + z = 0$. There is precisely one point $(0\colon 1\colon -1)$ at infinity. The tangent to the projective curve at this point is $y + z = 0$, which is the line at infinity. Therefore the affine curve has no asymptote.

Recall that the three homogeneous-coordinate 'axes' $x = 0$, $y = 0$ and $z = 0$ are determined by great-circles on the sphere. The diagrams in Figure 16.6 demonstrate what is happening.

16.11 Singular points and inflexions of projective curves

A singular point of a projective curve $F(x, y, z) = 0$ of degree n is a point at which

$$\mathbf{grad}\, F = (F_x, F_y, F_z) = 0.$$

By Euler's theorem (see §4.7.6),

$$nF = xF_x + yF_y + zF_z$$

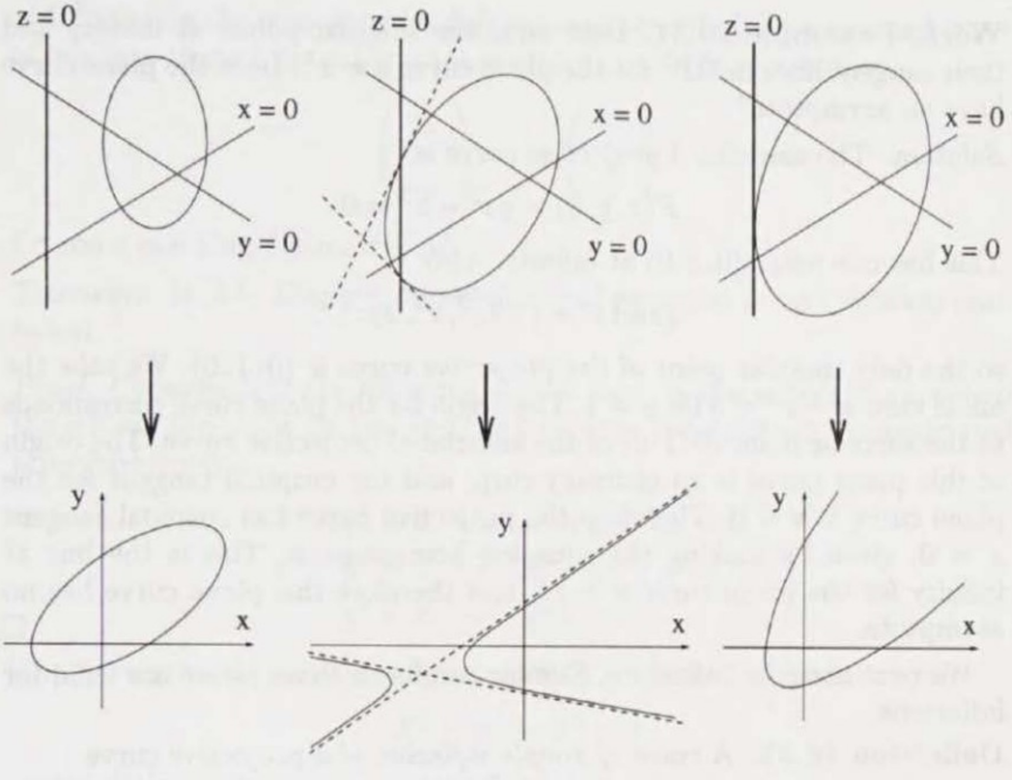
and therefore any point $(x\colon y\colon z)$, which satisfies $F_x = F_y = F_z = 0$, lies on the curve. By Theorem 16.16 above, a point in an affine view is a singular point if, and only if, the corresponding point of the projective curve is a singular point.

Definition 16.29. A singular point of a projective curve is *isolated*, *nodal*, or a *cusp* according as the associated point (not at infinity) in an affine view is isolated, nodal, or a cusp.

It can be shown that the above definition is independent of the view chosen.

Definition 16.30. A *singular point at infinity* of a plane algebraic curve $f(x, y) = 0$, is a point at infinity which is also a singular point of the associated projective curve $F(x, y, z) = 0$ defined by

$$F(x, y, z) = z^n f\left(\frac{x}{z}, \frac{y}{z}\right).$$



Ellipse Hyperbola Parabola

Figure 16.6 *Asymptotes of second order projective curves.*

In order to classify a singular point at infinity for a plane or affine curve, we can take a different affine view of the associated projective curve for which the singular point which we are considering is not at infinity, and classify it (cusp, nodal, isolated) in the usual way. It can be shown that if a singular point is a particular type in one affine view (for example ordinary cusp, 3–node, etc.), then it is of the same type in other affine views.

The tangent lines at singular points of a projective curve can be found as follows. First we take an affine view (usually given by one of $x = 1$, $y = 1$ or $z = 1$), for which the singular point is not the point at infinity, and then find the tangents to the corresponding plane curve at this singular point in one of the usual ways (see for example Chapter 15). On making homogeneous the equations of these tangent lines to the plane curve, then finding the projective lines determined by them, we obtain the equations of the required tangent lines to the projective curve. It can be shown that the tangent lines found in this way do not depend on the affine view used in determining them.

Worked example 16.31. Determine the singular points at infinity and their tangent lines in $\mathbf{RP}^2$ for the plane curve $y = x^3$. Does the plane curve have an asymptote?

Solution. The associated projective curve is

$$F(x, y, z) = yz^2 - x^3 = 0.$$

This has one point $(0:1:0)$ at infinity. Also

$$\mathbf{grad}\, F = (-3x^2, z^2, 2yz),$$

so the only singular point of the projective curve is $(0:1:0)$. We take the affine view $z^2 - x^3 = 0$ for $y = 1$. The origin for the plane curve corresponds to the singular point $(0:1:0)$ of the associated projective curve. The origin of this plane curve is an ordinary cusp, and the cuspidal tangent for the plane curve is $z = 0$. Therefore the projective curve has cuspidal tangent $z = 0$, given by making the equation homogeneous. This is the line at infinity for the plane curve $y = x^3$, and therefore this plane curve has no asymptote. □

We next consider inflexions. Similar results to those above are valid for inflexions.

Definition 16.32. A *point of simple inflexion* of a projective curve

$$F(x, y, z) = 0$$

is a point which corresponds to a point of simple inflexion in some affine view.

Again it can be shown that the above definition is independent of the view chosen. Points of higher inflexion and points of simple and higher undulation can be defined in a similar way, and again it can be shown that the definitions are independent of the view chosen.

16.12 Equivalence of curves*

Equivalence of curves is dependent on the type of transformations allowed. Two curves in the plane are congruent if there is a rigid map sending one to the other; congruence is one type of equivalence. In Chapter 2 we showed how conics can be moved to canonical position using a rigid map. We now describe another form of equivalence of plane curves, and a form of equivalence for projective curves.

16.12.1 Projective equivalence of plane curves

Definition 16.33. Two plane curves given by $f(x, y) = 0$ and $g(x, y) = 0$ are *projectively equivalent* if there is a non-singular linear transformation of $\mathbf{R}^3$ sending the homogeneous defining polynomial of the associated curve of one into that of the other, that is $G(x,y,z) = F(u,v,w)$ where

---

* For the meaning of * see the preface.

$$\begin{pmatrix} u \\ v \\ w \end{pmatrix} = M \begin{pmatrix} x \\ y \\ z \end{pmatrix}$$

for some non-singular matrix M.

Theorem 16.34. *Ellipses, hyperbolae, and parabolae are projectively equivalent.*

Proof. Consider first the following special case: in the array the curves on the left are the plane curves, and the curves on the right are the associated projective curves.

$$\begin{aligned} x^2 + y^2 = 1 &\quad\mapsto\quad x^2 + y^2 - z^2 = 0, \\ x^2 - y^2 = 1 &\quad\mapsto\quad x^2 - y^2 - z^2 = 0, \\ y^2 = x &\quad\mapsto\quad y^2 = xz. \end{aligned}$$

The homogeneous polynomial representing the last of these becomes

$$X^2 - Y^2 - Z^2 = 0$$

under the non-singular linear transformation

$$x = X + Z,\ y = Y \text{ and } z = X - Z.$$

It follows readily that these three curves are projectively equivalent: the only further transformation required is a change of coordinate axes in each case. By elementary geometrical considerations any ellipse, hyperbola, or parabola is projectively equivalent to one of these three. To prove this, first move a given (plane) conic to canonical position by a rotation and a translation of $\mathbf{R}^2$. Each of these transformations determines a non-singular linear transformation of $\mathbf{R}^3$. The rotation determines the obvious rotation which has the same effect on the xy-plane as the given rotation and which leaves the z-axis fixed. The translation of $\mathbf{R}^2$, given by

$$x \mapsto x + a \text{ and } y \mapsto y + b,$$

determines the non-singular linear transformation of $\mathbf{R}^3$ given by

$$x \mapsto x + az,\ y \mapsto y + bz \text{ and } z \mapsto z.$$

A further non-singular linear transformation (consisting of compressions along the axes) of $\mathbf{R}^2$ then reduces the (Euclidean) canonical form (see Chapter 1) of the ellipse, hyperbola, or parabola to the appropriate one of the forms given above. The three affine equations on the left of the above array are, respectively, the affine canonical forms of the ellipse, hyperbola, and parabola. □

Worked example 16.35. Prove that the acnodal cubic $x^3 - x^2 - y^2 = 0$ is projectively equivalent to the witch of Agnesi $1 - x(1 + y^2) = 0$.

Solution. The two associated projective curves are respectively

$$x^3 - x^2 z - y^2 z = 0$$

and $z^3 - xz^2 - xy^2 = 0$. The non-singular linear transformation

$$x \mapsto z, z \mapsto x, y \mapsto y$$

transforms one into the other. $\square$

16.12.2 Equivalence of projective curves

Definition 16.36. Two projective curves Φ and Γ given respectively by $F(x, y, z) = 0$ and $G(x, y, z) = 0$ are *equivalent* if $G(x, y, z) = F(u, v, w)$ where

$$\begin{pmatrix} u \\ v \\ w \end{pmatrix} = M \begin{pmatrix} x \\ y \\ z \end{pmatrix}$$

for some non-singular matrix M.

'Equivalence of projective curves' is clearly an equivalence relation. Under this equivalence, singular points are mapped to singular points, tangents to tangents etc. Two affine curves are *projectively equivalent* if they are affine views of two equivalent projective curves (see §16.12.1). Two plane curves are *affinely equivalent* if one can be obtained from the other by a translation together with a non-singular (i.e., invertible) linear map (the latter need not be a rotation). Also shearing maps, such as $x \mapsto x$, $y \mapsto x + y$, are non-singular linear maps but do not preserve angles or distance. Such affine maps do preserve 'tangents', 'two lines being parallel', 'cusps', and 'singular points', but do not preserve 'normals'.

16.13 Examples of asymptotic behaviour

We give examples of asymptotic behaviour in Figure 16.7 as follows.

i) The projective curve does not cross its tangent at a point at infinity and the tangent is not the line at infinity $\Rightarrow$ two distant parts of the affine curve typically approach the asymptote on opposite sides of the asymptote.

ii) The projective curve has, as its tangent at a point at infinity, the line at infinity $\Rightarrow$ two distant parts of the affine curve tend to infinity, though not along an asymptote.

iii) The projective curve has a simple inflexion at a point at infinity and its tangent there is not the line at infinity $\Rightarrow$ two distant parts of the affine curve approach the asymptote on the same side of the asymptote.

iv) The projective curve has a simple double point at infinity and neither

of its tangents there is the line at infinity ⇒ the resulting asymptotes of the affine curve are parallel. Note the sides of these asymptotes on which the curve in this example approaches its asymptotes. This assumes that the double point is a point of inflexion of neither branch.

v) The projective curve has a simple double point at infinity and one of its tangents there is the line at infinity ⇒ the point at infinity gives rise to only one asymptote, but two other parts of the curve tend to infinity in a non-asymptotic manner.

vi) The projective curve has a cusp at infinity and the cuspidal tangent there is not the line at infinity ⇒ two distant parts of the affine curve tend to infinity in the same direction along the asymptote, either on the same side or on opposite sides depending on the type of cusp.

vii) The projective curve has a tachnode at infinity and the cuspidal tangent there is not the line at infinity ⇒ four distant parts of the affine curve tend to infinity in the manner indicated.

Notice the two cases where a tangent to a branch of the curve at a point at infinity is not the line at infinity.

a) The branch crosses its tangent. In this case the two distant portions of the curve having the given asymptote are on the same side of the asymptote.

b) The branch does not cross its tangent. In this case the two distant portions are on different sides of their asymptote.

16.14 Worked example

We now give a longer worked example using the results of this chapter.

Worked example 16.37. Write down the associated projective curve Π for the plane curve Γ given by $x^3 + x^2 - y^2 = 0$. Prove that Γ has precisely one point at infinity, and find the tangent there. Deduce that Γ has no asymptotes. Show that Π has precisely one singular point, and that this corresponds to a nodal double point of Γ. Find the equations of the tangents to Γ at this nodal point and deduce the equations of the tangents to Π at the corresponding singular point. Let Δ be the affine view of Π for $x = 1$. Show that Δ has three asymptotes, and give a rough sketch of Δ. Let Σ be the affine view of Π for $y = 1$. Show that Σ has two asymptotes, and give a rough sketch of Σ. Give a rough sketch of the projective curve in $\mathbf{RP}^2$.

Solution. The solution is indicated in Figure 16.8. Π is given by

$$F = x^3 + x^2z - y^2z = 0.$$

We have

$$\mathbf{grad}\, F = (3x^2 + 2xz, -2yz, x^2 - y^2).$$

Now Π meets $z = 0$ where $x^3 = 0$, that is only at $(0\!:\!1\!:\!0)$. The tangent to Π at $(0\!:\!1\!:\!0)$ is $z = 0$ (given by $(x, y, z) \cdot \mathbf{grad}\, F = 0$). Thus the tangent to

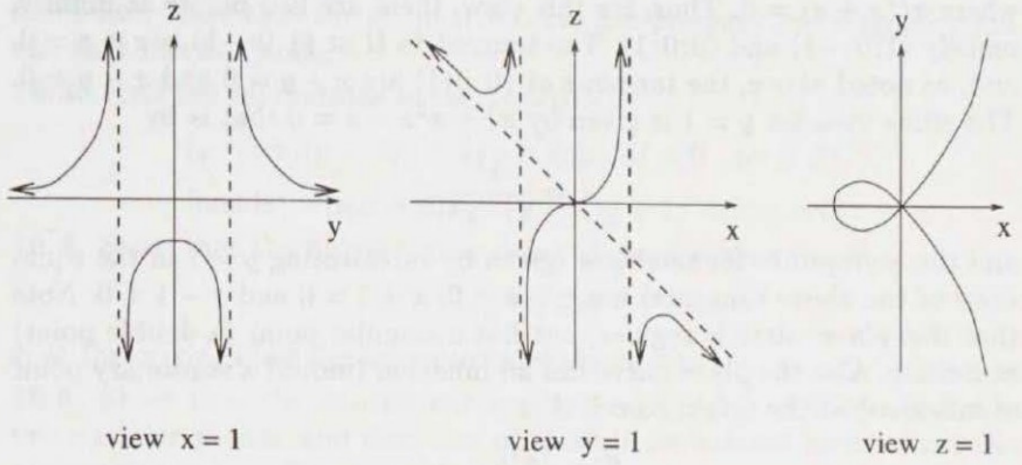

Figure 16.8 *Different affine views of a curve.*

Π at the (only) point at infinity for Γ is the line at infinity, and therefore Γ has no asymptotes.

We have **grad** $F = 0$ if, and only if,

$$3x^2 + 2xz = -2yz = x^2 - y^2 = 0.$$

The only point of $\mathbf{R}P^2$ which satisfies these equations is $(0:0:1)$, and we have easily that this point lies on Π. Thus the projective curve has precisely one singular point. The point of Γ corresponding to this singular point is the origin of $\mathbf{R}^2$. Notice that the point at infinity for Γ is not a singular point. The homogeneous polynomial of terms of lowest degree in the defining equation for Γ is $x^2 - y^2 = (x+y)(x-y)$. Since there are no repeated real linear factors, the origin is a double point and the tangent lines there are $x + y = 0$ and $x - y = 0$. The tangents to Π at the singular point (given by making these equations homogeneous) are $x + y = 0$ and $x - y = 0$.

We now consider the affine view of Π for $x = 1$. Now Π meets $x = 0$ where $y^2 z = 0$. Thus, for this view, there are two points at infinity, namely $(0:1:0)$ and $(0:0:1)$. The tangent to Π at $(0:1:0)$ is $z = 0$, and the tangents at $(0:0:1)$ are $x+y = 0$ and $x-y = 0$, as noted above. The affine view for $x = 1$ is given by $1 + z - y^2 z = 0$ that is by

$$z = \frac{1}{y^2 - 1}$$

and the asymptotes for this view (given by substituting $x = 1$ in the equations of the above tangents) are $z = 0$, $1 + y = 0$ and $1 - y = 0$. Note that this plane curve has no singular point in the plane, but has a singular point (a double point) at infinity.

We now consider the affine view of Π for $y = 1$. Now Π meets $y = 0$

where $x^2(x+z)=0$. Thus, for this view, there are two points at infinity, namely $(1{:}0{:}-1)$ and $(0{:}0{:}1)$. The tangent to Π at $(1{:}0{:}-1)$ is $x+z=0$, and, as noted above, the tangents at $(0{:}0{:}1)$ are $x+y=0$ and $x-y=0$. The affine view for $y=1$ is given by $x^3+x^2z-z=0$ that is by

$$z=\frac{x^3}{1-x^2}$$

and the asymptotes for this view (given by substituting $y=1$ in the equations of the above tangents) are $x+z=0$, $x+1=0$ and $x-1=0$. Note that this plane curve is regular, but has a singular point (a double point) at infinity. Also the plane curve has an inflexion (indeed a stationary point of inflexion) at the origin (check that

$$\frac{dz}{dx}=\frac{d^2z}{dx^2}=0).$$

Note in the sketch of the projective curve that no affine view of the projective curve is bounded, since any projective line (as a line infinity) meets the projective curve in at least one point. (Compare this with the situation for the projective curve associated with a hyperbola.) ☐

In the two views considered above the affine curves are graphs of functions, that is their equations take on the form $z=\varphi(y)$ and $z=\psi(x)$ respectively. Thus the curve is parametrised by the y or x variable respectively. The crunodal cubic is not the graph of a function even after a rotation.

The projective curve given by a quadratic homogeneous polynomial such as $x^2+y^2-z^2=0$ can be drawn in such a way that it 'resembles' a closed curve in the projective plane. This is not true for all projective curves as the above example shows. If it cannot be drawn to resemble a closed curve in the plane, we can usually note in our sketch in the projective plane that certain points must be identified in order to close the curve – recall that projective space is obtained from the sphere by identifying each point with its opposite. The projective curve Π sketched here, regarded as a curve on the sphere, will have as its 'opposite' on the sphere a similar looking curve, and when the two are joined together, they will form one continuous curve. On the other hand the quadratic cone projective curve determines on the sphere two disjoint closed curves, one of which is 'opposite' to the other.

Exercises

16.1. Find the singular points of $(x^2+y^2)^2-(x^2-y^2)z^2=0$.

$$[(1{:}1{:}\pm 2),(1{:}-1{:}\pm 2),(0{:}0{:}1)]$$

16.2. Show that the cubic

$$(x-y)(x^2+y^2)+2xyz=0$$

intersects the line $z=0$ in precisely one point and find the tangent line at this point. Show that the projective curve has precisely one singular point and that this is a node.

16.3. Find the asymptotes to the hyperbola

$$(y - \alpha x)(y - \beta x) + 2fx + 2gy + d = 0 \quad (\alpha \neq \beta).$$

$$[\text{one is} \quad -\alpha(\alpha - \beta)x + (\alpha - \beta)y + 2f + 2\alpha g = 0]$$

16.4. Show that the only singular point of the algebraic curve

$$x^4 - y^4 = 4xy^2$$

is at the origin. Find the asymptotes of the curve.

16.5. Show that the quartic curve $y^2(x^2 + z^2) - x^4 = 0$ has precisely two singular points, and that one of these is an isolated point. Find the asymptotes to the affine view given by $z = 1$.

$$[(0{:}0{:}1), (0{:}1{:}0); x^2 + z^2 - x^4 = 0; x - y = 0, x + y = 0]$$

16.6. Let $f(x, y) = g(x, y) + h(x, y) + k(x, y)$ be a polynomial, where g is non-trivial and homogeneous of degree $n \geq 2$, h is homogeneous of degree $n - 1$, and the degree of k is $\leq n - 2$. Show that the points at infinity $(x_0 : y_0 : 0)$ of $f(x, y) = 0$ are given by the real solutions of $g(x, y) = 0$. Show further that, where $g(x, y)$ has no repeated real linear factors, the asymptotes to the plane curve are the lines

$$x g_x(x_0, y_0) + y g_y(x_0, y_0) + h(x_0, y_0) = 0$$

corresponding to these solutions.

16.7. The projective curve Π given by

$$x^4 + x^2yz - y^3z + y^4 = 0$$

has as affine view for $z = 1$ the curve Σ, given by

$$x^4 + x^2y - y^3 + y^4 = 0\,.$$

Prove that the origin is a triple point of the affine curve Σ, and find the tangent lines to the curve there. Show that Π meets the axes $x = 0$, $y = 0$ and $z = 0$ altogether in precisely two points, and find the equations of the four tangents to Π at these two points. Deduce also that Σ is a bounded curve.

Show that the affine view Γ, for $x = 1$, of the projective curve Π is a graph. Write down the coordinates of the points of infinity for Γ, and determine the equations of its asymptotes. Make a rough sketch of Γ indicating the asymptotes and carefully indicating any intersection of the curve with the axes.

[$x = \pm y, y = 0 : (0{:}0{:}1), (0{:}1{:}1); x = \pm y, y = 0, y = z : (0{:}0{:}1), (0{:}1{:}1);$
$y = \pm 1, y = 0, y = z$]

16.8. The algebraic curve Σ with equation

$$y^2(1 - x) - x^2(1 + x) = 0$$

has a double point at the origin.

a) Let Π be the associated projective curve of Σ. Show that Σ has precisely one point at infinity, namely $(x{:}y{:}z) = (0{:}1{:}0)$ on Π. Let Γ be the affine view of Π for $y = 1$. Determine the tangent line to Γ at the origin, and show that it has 3–point contact with Γ at the origin. Write down the equation of the asymptote to Σ.

$[z = x, x = 1]$

b) Each line $y - m = mx$ through $V = (-1, 0)$ meets Σ in points Q and R and meets the y–axis in a point $P = (0, m)$. Show that $OP = QP = PR$, where O is the origin. The curve Σ is the right strophoid.

Draw this strophoid, in the usual way, using a drawn line and marked points V and O. For a line L through V which meets the drawn line in a point P, mark on L the points Q and R which satisfy $OP = QP = PR$. Repeat this for a suitable collection of lines through the origin, and draw the curve in the usual way.

16.9. The projective curve Π given by

$$y^4 + x^2y^2 + xy^2z - x^3z = 0$$

has as affine view for $z = 1$ the curve Σ, given by

$$y^4 + x^2y^2 + xy^2 - x^3 = 0.$$

Prove that the origin is a triple point of the affine curve Σ, and find the tangent lines to the curve there. Show that Π meets the axes $x = 0$, $y = 0$ and $z = 0$ altogether in precisely two points, and find the equations of the four tangents to Π at these two points. Deduce that Σ has no asymptotes.

Show that the affine view Γ, for $x = 1$, of the projective curve Π is a graph. Write down the coordinates of the points of infinity for Γ, and determine the equations of its asymptotes. Make a rough sketch of Γ indicating the asymptotes and carefully indicating any intersection of the curve with the axes.

$[x = \pm y, x = 0 : (0{:}0{:}1), (1{:}0{:}0); x = \pm y, x = 0, z = 0 : (0{:}0{:}1); y = \pm 1]$

16.10. The algebraic curve Σ with equation

$$(x^2 + y^2)y^2 - x^2 = 0$$

has a tachnode at the origin.

a) Let Π be the associated projective curve of Σ. Show that Σ has precisely one point at infinity, namely $(x{:}y{:}z) = (1{:}0{:}0)$ on Π. Let Γ be the affine view of Π for $x = 1$. Show that Γ has a node at the origin and find the tangent lines there. Write down the equations of the asymptotes to Σ.

$[y = \pm z, y = \pm 1]$

b) Each line $y = mx$ through the origin $O = (0, 0)$ meets Σ in points P and P', and meets the line $y = 1$ in a point Q. Prove that $OP = OP' = CQ$, where $C = (0, 1)$.

Use the following method to draw the curve Σ (Gutschoven's curve) using drawn rectangular axes and line $y = 1$. For a line L through O which meets $y = 1$ in point Q, mark on L the points P and P' which satisfy $OP = OP' = CQ$. Repeat this for a suitable collection of lines through the origin, and draw the curve in the usual way.

16.11. The algebraic curve given by

$$y^2(1-x) - x^2(m+x) = 0 \quad (m \neq 0, -1)$$

has a singular point at the origin and no other singular points. Show that the origin is an isolated point in case $m < 0$, and is a nodal double point in case $m > 0$. In the latter case write down the equations of the tangent lines.

The projective curve Π given by

$$y^2(z-x) - x^2(4z+x) = 0$$

has as affine view for $z = 1$ the curve Σ, given by

$$y^2(1-x) - x^2(4+x) = 0.$$

Show that Π meets the axes $x = 0$, $y = 0$ and $z = 0$ altogether in precisely three points, and find the equations of the four tangents to Π at these three points, including the two at the double point. Show that Σ has an asymptote and write down its equation.

Show that the affine view Γ, for $y = 1$, of the projective curve Π is a graph. Write down the coordinates of the points at infinity for Γ, and determine the equations of its asymptotes. Make a rough sketch of Γ indicating the asymptotes and carefully indicating any intersection of the curve with the axes.

$[y = \pm\sqrt{m}x; y = \pm 2x, z = x, x + 4z = 0; x = 1; 2x = \pm 1, x + 4z = 0]$

16.12. The projective curve Π given by

$$(x^2+y^2)(x-2y) + z(x^2-y^2) = 0$$

has, as affine view for $z = 1$, the affine curve Σ given by

$$(x^2+y^2)(x-2y) + x^2 - y^2 = 0.$$

Show that the origin is a singular point of Σ.

Find the other points of intersection of the projective curve with the three lines $x = 0, y = 0, z = 0$, and find the equations of the tangents at all four points.

Hence write down the equations of the asymptotes to the related affine curve Ω with equation

$$(x^2+1)(x-2) + z(x^2-1) = 0,$$

given that the tangents to the projective curve at $(0{:}0{:}1)$ have equations

$$x = \pm y.$$

Give a rough sketch of Ω, including on your sketch the asymptotes, and the tangent lines at the points where the curve crosses the axes.
(A scale of 1 unit = 2 cm is suggested.)

16.13. Show that the algebraic curve Σ with equation

$$(x-1)^2(x^2+y^2)-9x^2=0$$

has a double point at the origin.

a) Let Π be the associated projective curve of Σ. Show that Σ has precisely one point at infinity, namely $(x:y:z)=(0:1:0)$ on Π. Let Γ be the affine view of Π for $y=1$. The tangent line to Γ at the origin is $x=z$. Show that it has 4-point contact with Γ at the origin. Write down the equation of the asymptote to Σ. $[x=1]$

b) Each line $y=mx$ meets the line $x=1$ in a point P and the curve Σ in precisely 2 points Q and R. Show that Q and R lie on opposite sides of the line $x=1$, and that $QP=PR=3$. The curve Σ is a conchoid of Nicomedes.

Draw this conchoid, in the usual way, using a drawn line and origin. For a line L through the origin which meets the given line at P, mark the two points on L distant 6 cm from P (use the scale 1 unit = 2 cm). Repeat this for a suitable collection of lines through the origin, and draw the curve in the usual way.

16.14. The projective curve Π, given by

$$x\left(x^2+y^2\right)+\left(3x^2-y^2\right)z=0,$$

has as affine view for $z=1$ the trisectrix of MacLaurin Σ, given by

$$x\left(x^2+y^2\right)+\left(3x^2-y^2\right)=0.$$

Prove that the origin is a double point of the affine curve Σ and find the tangent lines to the curve there. Show that Π meets the axes $x=0$, $y=0$ and $z=0$ altogether in three points, and find the equations of the four tangents to Π at these three points, including the two at the double point. Show that Σ has an asymptote and write down its equation.

Let Γ be the affine view, for $y=1$, of the projective curve Π. Determine the equations of the asymptotes of Γ. Make a rough sketch of Γ indicating the asymptotes and carefully indicating the tangent line where Γ crosses the axis $z=0$. (You may assume that the projective curve Π has an inflexion at the point where it meets the axis $z=0$.)

16.15. The algebraic curve Σ with equation

$$x^3+xy^2-2y^2=0$$

has a cusp at the origin.

a) Let Π be the associated projective curve of Σ. Show that Σ has precisely one point at infinity, namely $(x:y:z)=(0:1:0)$ on Π. Let Γ be the affine view of Π for $y = 1$. Determine the tangent line to Γ at the origin, and show that it has 3–point contact with Γ at the origin. Write down the equation of the asymptote to Σ. [$2z = x, x = 2$]

b) Each line $y = mx$ meets Σ in a point P and meets the circle

$$(x-1)^2 + y^2 = 1$$

and the line $x = 2$ in points Q and R. By considering the x–coordinates of P, Q and R, or otherwise, show that $OP = QR$, where O is the origin. The curve Σ is the cissoid of Diocles.

Draw this cissoid, in the usual way, using a drawn line, drawn circle, and marked origin. For a line L through the origin which meets the given line at R and the given circle at Q, mark on L the point P which satisfies $OP = QR$. Repeat this for a suitable collection of lines through the origin, and draw the curve in the usual way.

$$\left[x \text{ coordinate of } P \text{ is } \frac{2m^2}{1+m^2}\right]$$

16.16. The projective curve Π, given by

$$y^2(z-x) - x^2(z+x) = 0,$$

has as affine view for $z = 1$, the strophoid of Barrow Σ, given by

$$y^2(1-x) - x^2(1+x) = 0.$$

Prove that the origin is a double point of the affine curve Σ and find the tangent lines to the curve there. Show that Π meets the axes $x = 0$, $y = 0$ and $z = 0$ altogether in three points, and find the equations of the four tangents to Π at these three points, including the two at the double point. Show that Σ has an asymptote and write down its equation.

Show that the affine view Γ, for $y = 1$, of the projective curve Π is a graph. Find its asymptotes. Make a rough sketch of Γ indicating the asymptotes and marking the tangent where it crosses the axis $z = 0$. (You may assume that the projective curve Π has an inflexion at the point where it meets the axis $z = 0$.)

16.17. The projective curve Π, given by

$$x^3 + 3xy^2 + x^2z - y^2z = 0,$$

has as affine view for $z = 1$, the folium of Descartes Σ, given by

$$x^3 + 3xy^2 + x^2 - y^2 = 0.$$

Prove that the origin is a double point of the affine curve Σ and find the tangent lines to the curve there. Show that Π meets the axes $x = 0$, $y = 0$ and $z = 0$ altogether in three points, and find the equations of the four tangents to Π at these three points, including the two at the double point. Show that Σ has an asymptote and write down its equation.

Make a rough sketch of the affine view of the projective curve Π for $y = 1$, marking the tangent where it crosses the axis $z = 0$, and the asymptotes for this view. (You may assume that the projective curve Π has an inflexion at the point where it meets the axis $z = 0$.)

$[y = \pm x; y = \pm x, 3x = z, x + z = 0; 3x = 1; x = \pm 1, x + z = 0]$

16.18. Show that the projective curve P with equation

$$x^3 - x^2y - 3x^2z + 7xz^2 - 3yz^2 - 9z^3 = 0$$

has only one singular point and find it. The cubic curve Γ is obtained from P by putting $z = 1$.

Find the equation of the tangent line to Γ at $(0, -3)$ and, by considering its intersection multiplicity with the curve, deduce that the point is a point of inflexion. Similarly show that $(3, 1)$ is a point of inflexion. Deduce that $(-3, -7)$ is the third point of inflexion and determine the slope of the tangent line at this point. Find the asymptote to the curve.
(You may assume that the singular point of P is isolated.)

In summary, to correct hyperopia, the secondary focal point of a positive correcting lens must be coincident with the eye's far point. When this is the case, an infinitely distant object is imaged at the far point. Since the far point is conjugate with the retina, an image is focused on the retina.

LENS EFFECTIVITY

Up to now, we've assumed the lens used to correct ametropia is positioned at the eye's anterior surface. This would be the case for a contact lens or corneal refractive surgery, but not for a spectacle lens, which is positioned at a significant distance in front of the eye. The distance between the cornea and the ocular (back) surface of a spectacle lens is referred to as the **vertex distance**.

Let's consider a myopic eye that can be corrected with a −6.68 D lens placed in the plane of the cornea. If we wish to correct the refractive error with a spectacle lens located 15.00 mm in front of the eye, what power spectacle lens is required?

The key to answering this question is to realize the far point of the myopic eye is at a fixed distance from the eye. This is illustrated in Figure 7-8. To correct the refractive error, the secondary focal point of the correcting lens must be coincident with this far point. In the case at hand, the far point is 14.97 cm anterior to the cornea. If the correcting lens is 15.00 mm anterior to the cornea, its secondary focal length must be −13.47 cm [(−14.97 cm) − (−1.50 cm) = −13.47 cm]. The power of a minus lens with a secondary focal length of −13.47 cm is

$$F = \frac{n'}{f'}$$

$$F = \frac{(100)\,(1.00)}{-\,13.47\ \text{cm}}$$

$$F = -\,7.42\ \text{D}$$

This myopic eye can be corrected with either a −6.68 D contact lens or a −7.42 D spectacle lens at a vertex distance of 15.00 mm. Both correct the patient's myopia and are said to have the same *effective* power. Note when we correct the patient's myopia with a spectacle lens, its absolute power is greater than that of the contact lens. Think of it this way: since the spectacle lens is closer to the far point, it must have a shorter focal length.

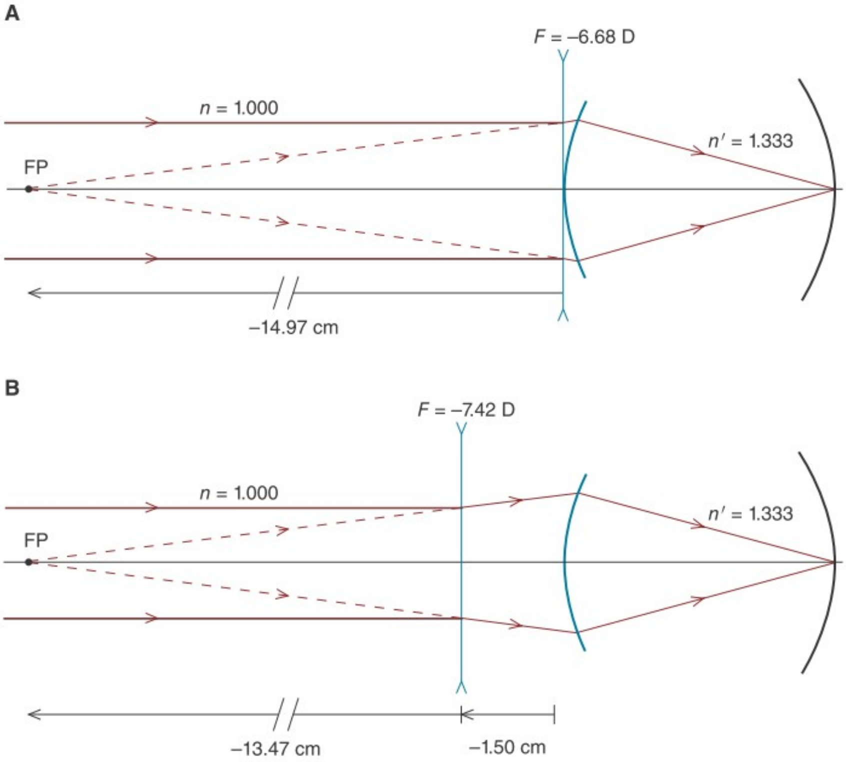

Figure 7-8. This refractive error can be corrected with (**A**) a −6.68 D contact lens or (**B**) a −7.42 D spectacle lens. In both cases, an infinitely distant object is focused at the eye's far point.

Clinical Highlight

Understanding lens effectivity is critical to understanding and solving common clinical symptoms. For instance, patients with myopia sometimes report blurred distant objects become clearer when they push their spectacles very close to their eyes. How can we explain this? Most likely, the corrective lenses are not sufficiently strong. As illustrated in Figure 7-9, by pushing the lenses closer to the eyes, the secondary focal points of the corrective lenses are made coincident with the far points, thereby increasing lens effectivity.

The principles of lens effectivity also apply to hyperopia. *Consider the 2.82 D hyperope we discussed earlier in the chapter. This hyperopic patient requires a corrective lens of +2.82 D in the plane of the cornea (i.e., a contact lens whose power is +2.82D). What power spectacle lens is required to correct this refractive error? Assume a vertex distance of 15.00 mm.*

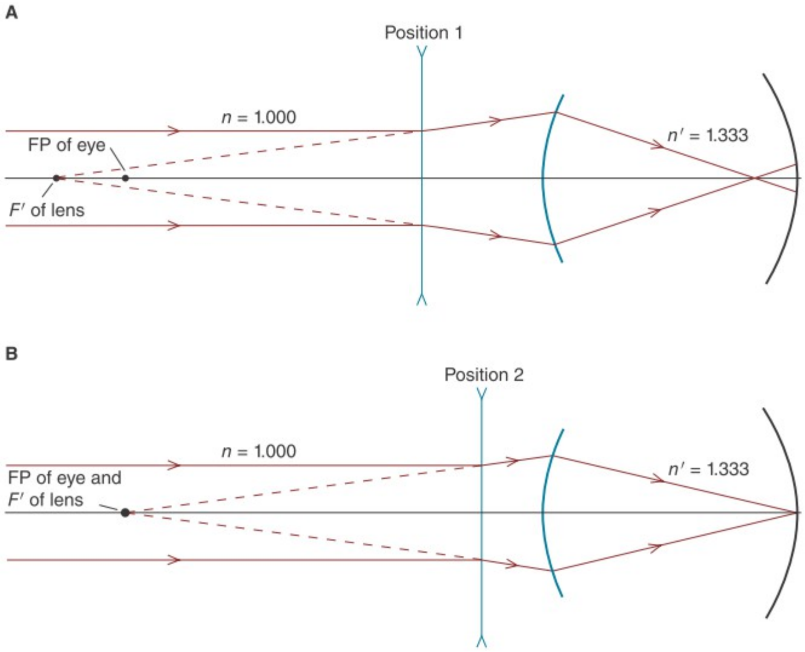

Figure 7-9. The effective power of a spectacle lens used to correct myopia is increased by moving the lens toward the eye [from position 1 in (**A**) to position 2 in (**B**)].

The secondary focal point of the corrective lens, whether it is a contact lens or a spectacle lens, must be coincident with the far point of the eye (which is 35.46 cm to the right of the cornea). From Figure 7-10, we see the secondary focal length of the spectacle lens must be 36.96 cm (35.46 + 1.50 cm = 36.96 cm). The power of this spectacle lens is

$$F = \frac{n'}{f'}$$

$$F = \frac{(100)\,(1.00)}{36.96\ \text{cm}}$$

$$F = +\,2.71\ \text{D}$$

This hyperope can be corrected with either a +2.82 D contact lens or a +2.71 D spectacle lens. The contact lens has a higher power because it must have a shorter focal length if its secondary focal point is to be coincident with the eye's far point. In this example, the difference between the power of the contact lens and the spectacle lens is small. For higher powers, however, lens effectivity is an important clinical factor. For instance, a patient who is corrected with a +10.00 D contact lens requires a spectacle lens whose power is +8.70 D.

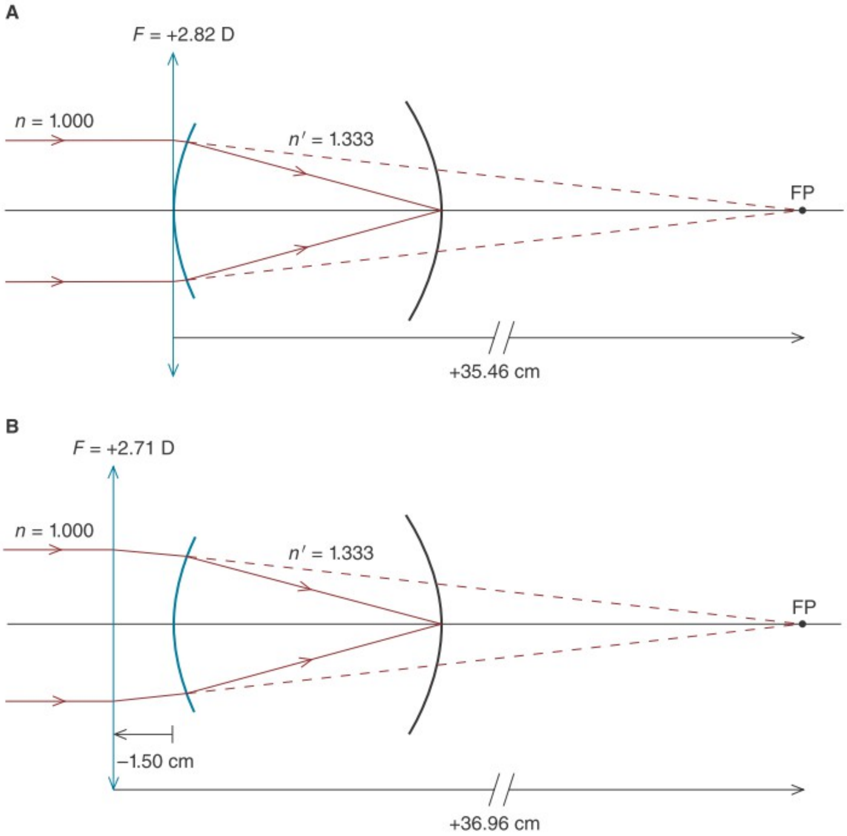

Figure 7-10. This refractive error can be corrected with (**A**) a +2.82 D contact lens or (**B**) a +2.71 D spectacle lens. In both cases, an infinitely distant object is focused at the eye's far point. Although lens effectivity is relatively small with this low power prescription, it can be significant with higher power lenses.

Clinical Highlight

Hyperopic patients sometimes notice their distance visual acuity improves when they slide their spectacles down their nose so they are farther from their eyes. What is happening here? Most likely, the lenses—when worn at the normal distance—are not sufficiently strong. By moving the lenses away from his eyes, the hyperopic patient is moving the secondary focal points of the spectacle lenses closer to his far points (Fig. 7-11). Rather than using a stronger lens, the same effect can be obtained by moving a lens away from the cornea, thereby increasing its effectivity.

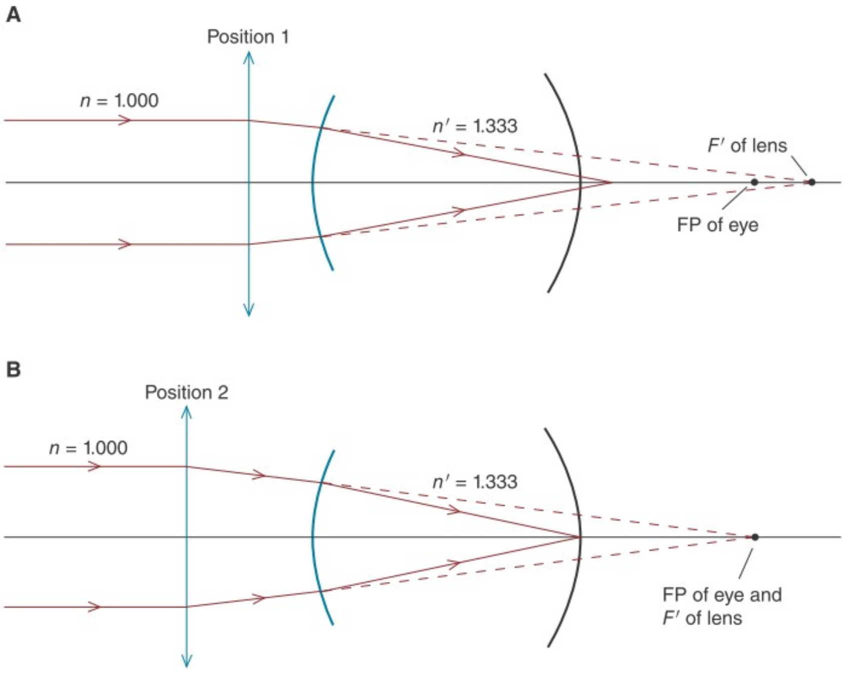

Figure 7-11. The effective power of a plus spectacle lens that is used to correct hyperopia is increased by moving the lens away from the eye [from position 1 in (**A**) to position 2 in (**B**)].

Up to now, we've discussed examples that involve replacing a contact lens with a spectacle lens. The same principles apply to replacing a spectacle lens with a contact lens. As a practical matter, refractions are almost always performed at the spectacle plane, about 15.00 mm in front of the cornea. Therefore, it is more common to calculate the contact lens power from the spectacle power than vice versa.

Let's look at an example. *Your refraction at a vertex distance of 15.00 mm results in a spectacle prescription of −9.00 D in each eye. If the patient wishes to be fit with contact lenses, what power should they be?*

First, without doing any calculations, you should know that the power of the contact lenses will be less than the spectacle lenses. Since the contact lenses are closer to the eyes, they are farther from the far point and consequently have a longer focal length and lower power.[8] To be specific, whereas the secondary focal length for the spectacles is −11.11 cm (e.g., 100/−9.00 D = −11.11 cm), the secondary focal length for the contact lenses is −12.61 cm [e.g., (−11.11 cm) + (−1.5 cm) = −12.61 cm]. A −7.93 D contact lens has this focal length (e.g., 100/−12.61 cm = −7.93 D).

Just to be sure we have these important concepts down, let's do one more example. *If we perform a trial-lens refraction at a distance of 12 mm and find +12.00 D, what power contact lens should be prescribed?*

Before we do any calculations, we know that the contact lens must have a shorter focal length than the spectacle lens, which means it has more power. Rather than a focal length of 8.33 cm (for the spectacle lens), the contact lens focal length is 1.2 cm shorter, or 7.13 cm. Such a contact lens has a dioptric power of +14.02 D.

Lens effectivity can also be calculated using equations. Although some people prefer to use equations, I think it's better to solve these problems without them. It's all too easy to forget equations, but once you understand the basic concepts of lens effectivity, they should stay with you over the course of your professional career.

CORRECTION OF AMETROPIA WITH LASER AND SURGICAL PROCEDURES

Ametropia is most often corrected with an ophthalmic lens positioned in the spectacle plane or a contact lens in the corneal plane. In recent years, it has become commonplace to compensate (or partially compensate) for refractive errors with surgical and laser procedures.

The first widely utilized surgical procedure was *radial keratotomy* (RK). This procedure was used primarily to compensate for myopia. Radial incisions are made in the cornea, leading to the flattening of this tissue and a resultant decrease in the eye's refractive power (Fig. 7-12).

Photorefractive procedures that utilize excimer laser technology have supplanted radial keratotomy. In *photorefractive keratectomy* (PRK), the corneal epithelium is removed prior to using an excimer laser to sculpt the underlying stroma. With *laser-assisted in situ keratomileusis* (LASIK), a microtome or laser is used to create a corneal flap (Fig. 7-13). The exposed stroma is sculpted with the goal of adjusting the refractive power of the eye and reducing the amount of

---

[8] When we say that one corrective lens is stronger (or more powerful) than another, we are typically referring to the absolute power of the lenses. That is, a −10.00 D lens is said to be stronger than a −5.00 D lens.

Av Cambucha

Remark: One frequently encounters the expression for $\tilde{E}_v$ with the first term missing. This is appropriate if the energy taken with respect to the ground state $n_j = 0$, in which case the numerator in the expression for q_v is absent.

(d) Last, we consider electronic degrees of freedom. Here no closed formulation is available; one simply begins with the listing of the energies of the molecular electronic states. The electronic ground state is set at energy zero; relative to this, the electronic energy levels are specified as

$$\varepsilon_e = g_{e0} + g_{e1}\varepsilon_{e1} + g_{e2}\varepsilon_{e2} + \ldots. \tag{1.12.48}$$

Normally, the excited electronic energy levels are very large compared to k_BT, whence it is usually sufficient to set the electronic molecular partition function as

$$q_e = g_{e0} + g_{e1}e^{-\varepsilon_1/k_BT} + g_{e2}e^{-\varepsilon_2/k_BT}, \tag{1.12.49}$$

and then use Eq. (1.12.49), as is, to determine how these electronic degrees of freedom contribute to the various thermodynamic functions of state as specified in Chapter 10.

Intervening Remark

A note of caution: The above exposition on the application of statistical mechanics is very rudimentary. While conveying the essence of the approach, the derivations apply only to highly idealized cases. We have not considered interactions among gaseous systems, rotation–vibration effects, anharmonicities in vibrations, electron interactions, and the like, which are needed for a realistic description of physical properties of actual systems. Such topics are handled in more advanced and specialized treatments in numerous textbooks on statistical mechanics, and fall outside the limited scope of the present discussion. Just be aware of the limitations inherent in the above treatment.

Statistical Treatment of Nonmetallic Solids

Nonmetallic solids will be considered as consisting of a great number of monatomic constituents held rigidly together as a lattice, and executing harmonic vibrations within their confined spaces. We neglect any internal degrees of freedom and ignore the six translational and rotational degrees of freedom of the entire rigid body, leaving us with $3N - 6 \approx 3N$ vibrational coordinates that are inserted in the partition function for the solid.

As an introduction, rewrite the expression for the molar energy of harmonic oscillators, cited above, to specify the average molar energy of a set of oscillators vibrating at a single frequency ν:

$$\tilde{E} = \tilde{E}_0 + 3R\frac{\Theta_v}{e^{\Theta_v/T} - 1}; \quad \tilde{E}_0 = \frac{3}{2}N_A h\nu, \quad \Theta_v \equiv h\nu/k_B, \tag{1.12.50}$$

where N_A is the Avogadro's number. Then the heat capacity is given by

$$\tilde{C}_V = 3R\frac{(\Theta_v/T)^2 e^{\Theta_v/T}}{\left(e^{\Theta_v/T} - 1\right)^2}. \tag{1.12.51}$$

This relation, commonly known as Einstein's (1905) law of heat capacities, correctly corresponds to the limiting cases $\tilde{C}_V = 0$ at $T = 0$ and to $\tilde{C}_V = 3R$ at infinite temperature—the law of Dulong and Petit. It immediately rationalizes the deviations of the observed $\tilde{C}_V$ values from this law at lower temperatures that had mystified scientists before the advent of quantum mechanics. However, the above equation generally deviates to some extent from experiment; in particular, at low T, the above relation shows that $\tilde{C}_V \sim T^{-2}e^{-\Theta_v/T}$, while experiments conform to a $\tilde{C}_V \sim T^3$ variation.

To accommodate these findings, Debye (1912) eliminated the unrealistic assumption that all atoms vibrate at the same fixed frequency. Since the N atoms on the crystal form a coupled system, one anticipates a spread of oscillator frequencies that needs to be introduced. For this purpose, Debye adopted the theory of a homogeneous elastic continuum, in which c_l and c_t are the velocities of one longitudinal and two transverse waves propagating in a volume V. As is well established (a euphemism for: "Everyone knows that…"), the number of frequencies in the range ν to $\nu + d\nu$ as given by the theory of elasticity is specified by

$$dZ = 4\pi V\left(\frac{1}{c_l^3} + \frac{2}{c_t^3}\right)\nu^2 d\nu. \tag{1.12.52}$$

The total number of available frequencies is $3N$, corresponding to a range of frequencies $0 \le \nu \le \nu_0$. Then

$$Z = 3N = \frac{4}{3}\pi V\left(\frac{1}{c_l^3} + \frac{2}{c_t^3}\right)\nu_0^3. \tag{1.12.53}$$

On combining Eqs. (1.12.52) and (1.12.53), we find that

$$dZ = \frac{9N}{\nu_0^3}\nu^2 d\nu, \tag{1.12.54}$$

which will now be used as the applicable distribution function for available frequencies. Then the energy of 1 mol of solid is specified by

$$\tilde{E} - \tilde{E}_0 = \frac{9R}{\nu_0^3 k_B}\int_0^{\nu_0} \frac{h\nu^3 d\nu}{e^{h\nu/k_BT} - 1} = \frac{9RT^4}{\Theta_v^3}\int_0^{\Theta_v/T} \frac{y^3 dy}{e^y - 1} = \frac{9RT}{x_D^3}\int_0^{x_D} \frac{y^3 dy}{e^y - 1}, \tag{1.12.55}$$

where $y \equiv h\nu/k_BT, x_D \equiv h\nu_0/k_BT$. Hence, the heat capacity is found to be

$$\frac{\tilde{C}_V}{3R} = \frac{12}{x_D^3}\int_0^{x_D} \frac{y^3 dy}{e^y - 1} - \frac{3x_D}{e^{x_D} - 1}. \tag{1.12.56}$$

The fraction in the integral can be expanded in an infinite series before the integration is attempted. The detailed execution, which involves some mathematical acrobatics, leads to the approximate result

$$\frac{\tilde{C}_V}{3R} = \frac{4}{5}\frac{\pi^4}{x_D^3} - \frac{3x_D}{e^{x_D} - 1} + \text{Correction Terms}. \tag{1.12.57}$$

At low temperatures, hence, large x_D, only the first term is of importance, which shows that the heat capacity varies as $\tilde{C}_V \sim T^3$, in good agreement with experiment.

Despite the cobbling together of elements of classical and quantum statistics, the above theory is consistently used in the analysis of data, as manifested by the empirical determination of Θ_D values for a large variety of materials. One of the saving graces is the fact that the distribution function appears under the integral sign. Hence, even considerable deviations of the real from the posited distribution function can be tolerated, without greatly changing the value of the integral in Eq. (1.12.56).

Electronic Heat Capacity of Metals

We consider the heat capacity attributed to N electrons circulating freely among N atoms that constitute a regular array of a solid. They are distributed among the N energy states of a partially filled energy band in accord with the Fermi–Dirac theory (Section 10.1) which is characterized by the Fermi energy ε_F. For a brief review of essentials, see the appendix below. Thus, at low temperatures, $k_BT \ll \varepsilon_F$, the energy required to heat N electrons from absolute zero to temperature T is given by (almost all the action involves electrons with energy at or close to ε_F)

$$E_{el}(T) = \int_{\varepsilon_F}^{\infty} d\varepsilon(\varepsilon - \varepsilon_F)f(\varepsilon;T)\rho(\varepsilon) + \int_{0}^{\varepsilon_F} d\varepsilon(\varepsilon_F - \varepsilon)[1 - f(\varepsilon;T)]\rho(\varepsilon). \tag{1.12.58}$$

Here $\rho(\varepsilon)$ is the density of states (DOS) in the range $d\varepsilon$ about ε; f is the Fermi function derived in Section 10.1. The first integral represents the energy required to elevate electrons at the Fermi level to the $f(\varepsilon;T)\rho(\varepsilon)$ available energy states per unit volume at an energy $\varepsilon > \varepsilon_F$; the upper band edge energy at $W/2$ has been replaced by infinity because $\rho(\varepsilon)$ vanishes over that range. The second integral similarly shows the energy required to remove $[1 - f(\varepsilon;T)]\rho(\varepsilon)$ electrons per unit volume from energy $\varepsilon < \varepsilon_F$; to the Fermi level; the lower band edge energy at $-W/2$ has been replaced by zero, because $\rho(\varepsilon)$ vanishes in that range.

From the above, we obtain the electronic heat capacity as

$$C_{el} = (\partial E_{el}/\partial T) = \int_{0}^{\infty} d\varepsilon(\varepsilon - \varepsilon_F)(\partial f/\partial T)(\rho(\varepsilon)). \tag{1.12.59}$$

At low temperatures, $(\partial f/\partial T)$ differs from zero only for energies very close to ε_F; we may thus introduce the approximation

$$C_{el} = \rho(\varepsilon_F)\int_{0}^{\infty} d\varepsilon(\varepsilon - \varepsilon_F)(\partial f/\partial T), \tag{1.12.60}$$

where

$$\frac{\partial f}{\partial T} = \frac{\varepsilon - \varepsilon_F}{k_BT^2}\,\frac{e^{(\varepsilon-\varepsilon_F)/k_BT}}{\left[e^{(\varepsilon-\varepsilon_F)/k_BT} + 1\right]^2}. \tag{1.12.61}$$

Notation

All manifolds are assumed to be smooth and connected. The notation we use is generally standard. $C^{k+\alpha}$, $0 < \alpha < 1$, is the space of function whose kth derivatives satisfy a Hölder condition with exponent α, C^{ω} is the space of real analytic functions, and the Sobolev space $H_0^1(\Omega)$ is the completion of smooth functions with compact support in Ω in the norm $(\int_{\Omega}|\nabla u|^2)^{1/2}$. Our Laplacian, Δ, on real-valued functions has the sign so that $\Delta u = +u''$ on $\mathbf{R}^1$. The Ricci curvature of the standard unit sphere S^n with metric g in $\mathbf{R}^{n+1}$ is $(n-1)g$, and its scalar curvature is $n(n-1)$. If α is a one-form on a Riemannian manifold, then $\alpha^{\#}$ is the dual vector field. In classical tensor notation we use a semicolon to denote covariant differentiation. ω_n is the volume of the unit sphere S^n in $\mathbf{R}^{n+1}$.

I. Gaussian Curvature

1. Surfaces in $\mathbf{R}^3$. As sometimes occurs, one of the most interesting unresolved problems involving Gaussian curvature is also one of the easiest to understand. Let $z = u(x, y)$ be a surface in $\mathbf{R}^3$. Its Gaussian curvature $K(x, y)$ is given by the formula

$$\frac{u_{xx}u_{yy} - u_{xy}^2}{\left(1 + |\nabla u|^2\right)^2} = K(x, y). \tag{1.1}$$

Turn this around and let K be a given C^∞ function of x and y. Is there a surface $z = u(x, y)$ with curvature K? Thus one wants to solve (1.1) for u. The most modest question is to at least find this surface locally, say in some neighborhood of the origin. If K is a real analytic function, then a local solution exists by the Cauchy–Kovalevsky theorem. If $K(0,0) > 0$, then (1.1) is elliptic at the origin, while if $K(0,0) < 0$, then it is hyperbolic there. In either case standard machinery allows one to conclude that there is a solution in some neighborhood of the origin. The case $K(0,0) = 0$ is not yet fully understood. If $K(x, y) \geqslant 0$ or $\nabla K(0,0) \neq 0$, then Lin **[Li]** has recently shown that (1.1) is locally solvable, using the Nash–Moser implicit function theorem. Nothing more is known. It is even quite possible that there are some functions $K \in C^\infty$ for which (1.1) has no solution in any neighborhood of the origin—just as for the classical Lewy example. Equations such as (1.1) that involve the determinant of the hessian of a function are usually called *Monge–Ampère* equations.

The problem of solving (1.1) is closely related to the problem of realizing an abstract Riemannian metric $ds^2 = E\,d\xi^2 + 2F\,d\xi\,d\eta + G\,d\eta^2$ on $\mathbf{R}^2$ locally as the graph of a smooth surface $z = z(x, y)$ in $\mathbf{R}^3$, so then

$$ds^2 = dx^2 + dy^2 + dz^2. \tag{1.2}$$

Rewrite this as $ds^2 - dz^2 = dx^2 + dy^2$. Since $dx^2 + dy^2$ is the standard flat metric on $\mathbf{R}^2$, one seeks $z(\xi, \eta)$ with $z(0,0) = 0$, $\nabla z(0,0) = 0$ so that the metric $g = ds^2 - dz^2$ is flat, i.e., has zero Gaussian curvature in some neighborhood of the origin. This leads to a Monge–Ampère equation similar to (1.1), with similar difficulty if the Gaussian curvature of ds^2 is zero. If one can find $z(\xi, \eta)$, then since g is flat an easy geometric argument shows that in geodesic coordinates we can write $g = dx^2 + dy^2$. In these new coordinates $z(x, y)$ satisfies (1.2). It is likely that a good understanding of (1.1) will at the same time resolve the question of whether one can always locally isometrically embed a 2-manifold in $\mathbf{R}^3$.

Once one understands the local solvability of (1.1), it is natural to seek a global solution in a bounded open set in $\mathbf{R}^2$, possibly with boundary conditions. We will discuss this later in Chapter 4 under the special assumption that $K > 0$, so one can use techniques for elliptic equations. There seems to be little information if $K \leqslant 0$ (see [**Az**]).

In the early years of this century, Minkowski and Weyl posed the following problems:

Minkowski problem. Prove the existence of a compact convex surface in $\mathbf{R}^3$ whose Gaussian curvature is prescribed as a given positive function of the unit normal.

Weyl problem. Let g be a given metric on the sphere S^2 with positive Gaussian curvature K. Prove the existence of a compact convex surface in $\mathbf{R}^3$ with g as its metric, i.e., isometrically embed (S^2, g) in $\mathbf{R}^3$ assuming $K > 0$.

Both of these problems lead to nonlinear elliptic partial differential equations. They were eventually solved by Nirenberg [**N**] and Pogorelov [**P1**]. More recently, a higher-dimensional version of the Minkowski problem has also been solved (see [**P2**]), but there is no information on any such version of the Weyl problem; for instance, if (S^n, g) has positive sectional curvature, can it be embedded in $\mathbf{R}^N$ for some "good" N depending on n?

A related question was asked by Oliker [**O**]. Let $\Sigma^n \hookrightarrow \mathbf{R}^{n+1}$ be a smooth compact graph over the standard unit sphere $S^n \hookrightarrow \mathbf{R}^{n+1}$, so if $x \in S^n$ then the points y on Σ^n can be written as a radial graph $y = u(x)x$, where u is some positive function defined on S^n (and can be extended to $\mathbf{R}^{n+1} - \{0\}$ to be constant along radii). The Gauss–Kronecker curvature K of Σ^n is given by a Monge–Ampère equation involving the determinant of the hessian of u on S^n. Conversely, given a positive function $K(|x|)$ on $\mathbf{R}^{n+1} - \{0\}$, Oliker asked if there is a closed convex surface $\Sigma^n \hookrightarrow \mathbf{R}^{n+1}$ over S^n whose Gauss–Kronecker curvature is K. Combining Oliker's [**O**] work with a significant improvement by Delanoe [**Del**], the result is that there is at least one such hypersurface if K satisfies the additional assumption that there are numbers $0 < R_1 \leqslant R_2$ such that for all x on S^n

$$\inf K(R_1 x) \geqslant R_1^{-n} \quad \text{and} \quad \sup K(R_2 x) \leqslant R_2^{-n}. \tag{1.3}$$

Moreover, the proof gives a hypersurface Σ^n in the shell between the spheres of radii R_1 and R_2. If assumption (1.3) is satisfied for some other numbers $R_2 < R_1' \leqslant R_2'$, then of course one finds another solution, so the solution is not unique. Oliker gives some additional assumption guaranteeing the uniqueness—up to homothety—of the hypersurface. Oliker's existence proof of a solution of the Monge–Ampère equation uses the continuity method, while Delanoe's uses the Schauder fixed point theorem.

Treibergs and Wei **[TW, T]** discuss similar problems for the mean curvature, so they are led to a quasi-linear elliptic equation.

2. Prescribing the curvature form on a surface. If (M^2, g) is a compact two-dimensional Riemannian manifold without boundary, then the Gauss–Bonnet theorem asserts that

$$\int_M K_g \, dA_g = 2\pi\chi(M). \tag{1.4}$$

If one thinks of $\Omega = K\,dA$ as the curvature two-form, then one type of converse to Gauss–Bonnet is, given any two-form Ω satisfying $\int_M \Omega = 2\pi\chi(M)$, find a metric g so that $\Omega = K\,dA$. This was solved by Wallach and Warner **[WW]**, who gave the following simple proof. Fix a metric g_0 on M and seek g *pointwise conformal* to g_0, that is,

$$g = e^{2u} g_0 \tag{1.5}$$

for some function u to be determined. Using classical formulas one finds that

$$\Omega = K\,dA = (K_0 - \Delta_0 u)\,dA_0 = \Omega_0 - (\Delta_0 u)\,dA_0.$$

Thus one wants to solve the linear equation $(\Delta_0 u)\,dA_0 = \Omega_0 - \Omega$, which we can rewrite as

$$\Delta_0 u = *(\Omega_0 - \Omega), \tag{1.6}$$

where $*$ is the Hodge operator in the g_0 metric. Since

$$\int_M (\Omega_0 - \Omega) = 0, \tag{1.7}$$

by linear elliptic theory, equation (1.6) has a solution u which is unique up to an additive constant. This solves the problem.

We do not believe anyone has solved the analogous problem on compact surfaces with boundary, or the more difficult question in higher dimensions (except in the case of Kähler manifolds, in which case this is the Calabi problem to be discussed in Chapter 3).

3. Prescribing the Gaussian curvature on a surface. For a surface M^2 there are two types of questions:

1. Find a metric g with constant Gaussian curvature. Here—and in similar higher-dimensional problems—the point is to obtain metrics with special properties which often help clarify the geometry of M.

2 (Inverse problem). Given a function K, find a metric g whose Gaussian curvature is K.

If the manifold M is not compact, one may wish to require that the metric be complete, while if M is compact with boundary, then we may impose some boundary conditions.

In practice, one often seeks the unknown metric g by picking some metric g_0 and then somehow deforming it to the desired metric g. The simplest type of deformation is the pointwise conformal deformation (1.5). From a geometric viewpoint, this does not give much flexibility since there is only one unknown function u while on an n-dimensional manifold the metric is locally an $n \times n$ symmetric matrix and hence has $n(n+1)/2$ components. Nonetheless, these deformations are surprisingly useful—and their geometric interpretation is often significant for geometric and physical problems.

Throughout these lectures we shall see several other effective ways to deform a metric, but much work remains to be done on this issue.

(a) *Compact surfaces.* One aspect of the two above problems, which may be viewed as proving the existence of a solution of a certain partial differential equation such as (1.1) or (1.6), is first finding the obstructions there may be to the existence of a solution. For instance, the Gauss–Bonnet theorem (1.4) gives some topological obstructions to the existence of certain metrics. We used this in (1.7). For the "inverse problem" on the torus T^2, since $\chi(T^2) = 0$ there is no metric with $K > 0$ (or $K < 0$) everywhere, since (1.4) implies that either $K \equiv 0$ or else K changes sign. There is a similar obvious sign condition on K for other Euler characteristics.

THEOREM 1.8 (KAZDAN–WARNER). *On a compact M^2, a function $K \in C^\infty(M^2)$ is the Gaussian curvature of some metric g if and only if K satisfies the obvious Gauss–Bonnet sign condition.*

There are two proofs of this. To begin with, for any metric g there is a complicated formula for the Gaussian curvature K in terms of the first two derivatives of g. We write this briefly as

$$F(g) = K. \tag{1.9}$$

Thus, given K, (1.9) is a quasilinear partial differential equation for g. The shortest proof **[KW5]** begins with a known metric g_0 with constant curvature K_0, so $F(g_0) = K_0$, and then appeals to the inverse function theorem to solve (1.9) for K near K_0 in an appropriate topology. Next one observes that if "K near K_0" means in the L_p norm, then given any function K with $K(x_0) = K_0$ for some x_0, there is a diffeomorphism ϕ of M so that $|K \circ \phi - K_0| < \varepsilon$ in L_p (the diffeomorphism just spreads a neighborhood of x_0 over most of M). Thus one can solve

$$F(g_1) = K \circ \phi. \tag{1.10}$$

But now the metric $g = \phi^{*-1}(g_1)$ satisfies (1.9) (i.e. from the viewpoint of M, both K and $K \circ \phi$ are the same functions). The only difficulty in carrying out this program is that the inverse function theorem does not immediately apply in some standard cases, namely on S^2 and T^2; but this can be circumvented by additional technical devices.

The second proof is geometrically richer. To solve (1.9) one picks some metric g_0 on M and seeks the desired metric g pointwise conformal to g_0, so $g = e^{2u}g_0$ for some function u to be found in order to satisfy (1.9), that is, $F(e^{2u}g_0) = K$.

This last equation is exactly

$$\Delta_0 u = K_0 - Ke^{2u}, \tag{1.11}$$

where Δ_0 and K_0 are the Laplacian and Gaussian curvature of g_0. If one wishes, one can ignore the geometric origins of this equation and ask for which functions K_0 and K can one solve it on any compact manifold M^n of any dimension. It turns out that the theory of this equation is surprisingly intricate—with many cases still not understood. We shall only summarize briefly (see **[KW1]** for details).

The simplest case is if both $K_0 < 0$ and $K < 0$; then (1.11) has a unique solution on M^n for any n. This is easily proved using sub and super solutions.

If $K_0 = 0$, then there are two necessary conditions on K ($\not\equiv 0$) for the solvability:

(i) K changes sign,

(ii) $\int K \, dA_0 < 0$.

If $\dim M \leqslant 2$, these conditions are also sufficient. The existence proof uses the calculus of variations and breaks down if $\dim M \geqslant 3$, where no sufficient conditions are known, despite the fact that the equation $\Delta_0 u = -Ke^{2u}$ looks so simple.

Finally, if $K_0 > 0$, even less is known. Only the case where $\dim M = 1$ is clearly understood (then one can solve (1.11) if and only if K is positive somewhere). If $\dim M = 2$, then one can solve (1.10) if K_0 is sufficiently small—by the calculus of variations. Only for the special case of $M = S^2$ or P^2 with their canonical metrics is a little more known. Say $K_0 = c > 0$ is a constant. Then Moser **[M]** used the calculus of variations to prove that on S^2 (resp. P^2) if $0 < c < 1$ (resp. $0 < c < 2$), then there is a solution if and only if K is positive somewhere. Since $K_0 = c = 1$ on S^2 and P^2 with their standard metrics, this proves Theorem 1.8 on P^2, but just misses on S^2. Indeed, if $c \geqslant 1$, there is a *nonexistence* result on S^2 which is implied by the following identity that every solution of $\Delta_0 u = c - Ke^{2u}$ must satisfy:

$$\int_{S^2} X(K) e^{2u} \, dA_0 = (c-1) \int_{S^2} (\operatorname{div} X) K e^{2u} \, dA_0, \tag{1.12}$$

where X is in the six-dimensional space of conformal vector fields (i.e. the Lie algebra of the group of conformal maps) on S^2. The special case where X is in the three-dimensional space of gradients of first-order spherical harmonics was proved by Kazdan and Warner **[KW1]**. Later, Bourguignon and Ezin **[BE]** observed that one should add the other conformal vector fields, i.e., the three-dimensional orthogonal group $O(3)$. In particular, if $c = 1$ and $K = \psi$ is a first-order spherical harmonic (plus a constant if one wishes), then (1.12) is not satisfied with $X = \nabla\psi$ because then $X(K) = |\nabla\psi|^2$ so the left side is positive while the right side is zero.

It is not known if the existence of a function u satisfying (1.12) is sufficient for the solvability of (1.11) on S^2. In fact, this is not even known in the special case where K is rotationally symmetric and one seeks a rotationally symmetric solution (in this special case (1.11) reduces to an ordinary differential equation). As we shall see later, similar issues arise in other problems.

Berger [**B**] has suggested using (1.11) to give a proof of the uniformization theorem for Riemann surfaces: one is given g_0 on M and seeks g with $K \equiv$ constant. If $\chi(M) \leqslant 0$, then the existence of g is a consequence of the above discussion, while if $M = S^2$ there is still no direct proof using (1.11). In the S^2 case, the obstruction (1.12) causes difficulty. One would also like to know that if g_0 (and K) are invariant under some group action, then there is an invariant solution u; this is true for (1.11) if both $K_0 < 0$ and $K < 0$ since the solution is unique in this case.

Despite these difficulties in solving (1.11), one can still use it to prove Theorem 1.8, the idea being to solve

$$\Delta_0 u = K_0 - (K \circ \phi) e^{2u} \tag{1.13}$$

for some function u *and* some diffeomorphism ϕ. The procedure here [**KW3**] is similar to the first proof of Theorem 1.8 outlined above.

(b) *Noncompact surfaces.* If M is not compact, but has a boundary, one can impose boundary conditions and ask the same questions—and run into similar difficulties (see Cherrier [**Ch**]).

Little is known if (M, g_0) is complete but not compact and one seeks a complete metric g with curvature K. The appropriate Gauss–Bonnet result is an inequality found by Cohn–Vossen (see [**Bl**]):

$$\int_M K \, dA \leqslant 2\pi\chi(M). \tag{1.14}$$

Except for [**KW2**], where all possible complete metrics on $\mathbf{R}^2$ are determined, essentially all work has centered on the case of pointwise conformal deformations on $\mathbf{R}^2$ with its standard flat metric g_0, so one wants to solve (1.11) in the very special case

$$\Delta_0 u = -K e^{2u}. \tag{1.15}$$

The results depend on the sign of $K(x)$ as $|x| \to \infty$. We give some of these results. Again, the case $K \leqslant 0$ is simpler to understand.

If $K \leqslant 0$ and $K(x) \leqslant -c/|x|^2 < 0$ as $|x| \to \infty$, then Sattinger [**Sa**] (sharpening earlier results by Ahlfors, Osserman, and others) showed that there is *no* solution. On the other hand, the work of Ni [**Ni1**] (see also [**KN**]) and McOwen [**Mc1**] proves that if $-c/|x|^l \leqslant K(x) \leqslant 0$ for some $l > 2$, then for every b satisfying $-(l-2)/2 < b < 0$ there is a solution u with the asymptotic behavior

$$u(x) = -b \log|x| + u_\infty + O(|x|^\gamma) \tag{1.16}$$

as $|x| \to \infty$; here u_∞ is a constant and this holds for any

$$\gamma > max(-1, 2 - l - 2b).$$

Note $\gamma < 0$ since $2 - l - 2b < 0$. Thus the metric $g = e^{2u}g_0$ is also complete. Moreover, the total curvature satisfies

$$\int_{\mathbf{R}^2} K\, dA_g = \int_{\mathbf{R}^2} Ke^{2u}\, dA_0 = 2\pi b. \tag{1.17}$$

Thus, the choice of b determines the total curvature.

If K is positive somewhere, it is useful to recall a classical result of Bonnet which asserts that if a complete Riemannian manifold has $K > \text{const} > 0$, then the manifold is compact. Thus, on a complete noncompact M one needs some decay of $K(x)$ as $|x| \to \infty$. Aviles **[Av]** and McOwen **[Mc2]** show that if K is positive somewhere and $K(x) = O(|x|^{-l})$ as $|x| \to \infty$, where $l > 0$, then for every b satisfying $\max(0, 2 - l) < b < 2$ there is a solution with the asymptotic behavior (1.16) and with total curvature (1.17). From (1.16) the resulting metric $g = e^{2u}g_0$ is complete as long as $c \leqslant 1$, which is consistent with the Cohn–Vossen's Gauss–Bonnet inequality (1.14).

In addition, Aviles shows that under certain growth restrictions on $K(x)$ the inequality (1.14) is both necessary and sufficient for the metric $g = e^{2u}g_0$ to be complete.

Even in this case of $\mathbf{R}^2$ with the standard flat metric, our understanding of (1.15) requires more work. Little is known for other 2-manifolds. The next-simplest case is probably the hyperbolic disc H^2 with its metric g_0 having curvature $K_0 = -1$. Then (1.11) is

$$\Delta_0 u = -1 - Ke^{2u}. \tag{1.18}$$

Now the Laplacian is *not* uniformly elliptic, and there are many bounded harmonic functions. There should be interesting new phenomena waiting to be found (see **[AvM]**).

Obs: surface in $\mathbb{R}^3$

As sometimes occurs, one of the most intriguing unresolved problems involving Gaussian curvature is also one of the easiest to understand.

Let $z = u(x,y)$ be a surface in $\mathbb{R}^3$.
Its Gaussian curvature
$K(x,y)$ is given by the formula

$$\frac{u_{xx}\,u_{yy} - u_{xy}^2}{(1 + |\nabla u|^2)^2} = K(x,y).$$

Medindo o Mundo

Bernhard Rieman

David Hilbert – queria lançar o plano de reconstruir os fundamentos da matemática, para torná-los consistentes e livres de paradoxos.

Gödel, com sua tese de doutorado, pôs um ponto final a essa pretensão, demonstrando que havia problemas na matemática que eram impossíveis de serem resolvidos.

A deslumbrante clareza e exatidão da matemática era, na realidade, um labirinto repleto de paradoxos.

Gödel provou: 1) Em um sistema formal axiomático consistente que possa expressar fatos sobre aritmética básica, há enunciados verdadeiros que não podem ser provados; 2) Que a consistência do sistema não pode ser provada dentro do mesmo sistema.
São os teoremas da incompletude.

Chapter 8

The Curvature of Space

Curvature and Intrinsic Geometry of a Surface in the Works of Euler

By the *curvature* of a curve at a point we mean the limit of the ratio of the angle $\Delta\alpha$ between the tangents at the endpoints of an arc to the length Δs of that arc as the latter contracts to the point; that is, the limit

$$k = \frac{d\alpha}{ds} = \lim_{\Delta s \to 0} \frac{\Delta\alpha}{\Delta s}. \tag{8.1}$$

k is also the reciprocal of the *radius of curvature* at the point in question, that is, the radius of the osculating circle at that point. (The osculating circle at a point P of a curve is defined as the limit of circles determined by three points on the curve as they tend to P.) The concepts of the curvature of a curve and of the osculating (literally "kissing," from the Latin *osculans*) circle were already known to Leibniz.[1] Leibniz also suggested the possibility of characterizing the curvature of a surface by means of an osculating sphere.[2]

Euler characterized the curvature of a surface in his *Investigations of the curvature of surfaces* (Recherches sur la courbure des surfaces. Berlin, 1767) *[176, vol. 28, pp. 1–22]*. Euler called a normal section of a surface $z = f(x, y)$ perpendicular to the xOy plane a *principal section*. By varying the angle φ between a normal section and the principal section Euler found that at each point of the surface there is a maximal radius of curvature f and a minimal radius of curvature g, that their planes are perpendicular to one another, and

---

[1] Leibniz first considered osculation of curves—in particular, osculation of curves and circles—in his *New reflections on the nature of the angles of tangency and osculation and their use in mathematical practice to replace complex figures with simpler ones* (Meditatio nova de natura Anguli contactus et osculi, horumque usu in practica Mathesi ad figuras faciliores succedaneas difficilioribus substituendas. Leipzig 1686) *[312, v. 7, pp. 326–329]*.

[2] In a letter to Johann Bernoulli, dated July 29, 1698.

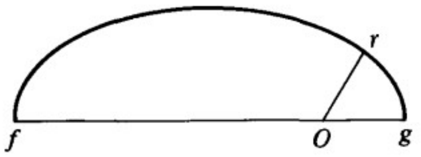

Figure 101

that the connection between an arbitrary radius of curvature $r = r(\varphi)$ and the radii of curvature f and g is given by

$$r = \frac{2fg}{f + g - (f - g)\cos 2\varphi}.$$

Euler writes:

> For a simple derivation of this formula we join the maximal and minimal osculating radii by putting $Of = f$ and $Og = g$ and describe on fg a semi-ellipse with one focus at O (Figure 101). Then for the section MN one must take the angle fOr, doubled with respect to the angle EZM, and the line Oz will be equal to the osculating radius for the section MN. Thus drawing conclusions about the curvature of surfaces, at first glance a matter of great complexity, reduces for each element to the determination of two osculating radii one of which is maximal and the other minimal for that element; these two things entirely determine the nature of the curvature, and we obtain the curvature of all possible sections perpendicular to the given element *[176, vol. 28, p. 21]*.

In 1837 Charles Dupin (1784 1873) *[157, p. 109]* modified Euler's formula to read

$$\frac{1}{r} = \frac{1}{f}\cos^2 \varphi + \frac{1}{g}\sin^2 \varphi.$$

In this paper *On solids whose surfaces can be developed onto a plane* (De solidis quarum superficiem in planum explicare licet. Petersburg, 1772) *[176, vol. 28, pp. 161–186]* Euler introduced the concept of a *developable surface*, that is, a surface that can be applied to a plane without folding or tearing, and proved the fundamental theorem that such a surface is a cylinder, or a cone, or a surface formed by the tangents to a space curve. His point of departure was that on such a surface an infinitesimal triangle must be congruent to the corresponding triangle in the plane to which the surface is applied. Further, he introduced on the surface curvilinear coordinates t, u equal to the rectangular coordinates of the corresponding points of the plane and, denoting the partial derivatives $\partial x/\partial t$, $\partial y/\partial t$, $\partial z/\partial t$ by l, m, n, and $\partial x/\partial u$, $\partial y/\partial u$, $\partial z/\partial u$ by λ, μ, ν, set down the developability conditions in the form $l^2 + m^2 + n^2 = 1, \lambda^2 + \mu^2 + \nu^2 = 1, l\lambda + m\mu + n\nu = 0$, that is, as the requirements of unicity and perpendicularity of the partial derivatives with respect to t and u of the radius vector of a point of the surface. An equivalent form of this condition is that the square of an arc element of a curve on a developable surface equals the sum of the squares of the differentials of the coordinates,

$$ds^2 = dt^2 + du^2,$$

that is, the arc element of a developable surface coincides with the arc element of a plane.

In a note published only in 1862 *[176, vol. 29, pp. 437–440]* Euler also established the general conditions of applicability of a surface to other surfaces. These results of Euler pertain to the so-called *intrinsic geometry of a surface*, that is, the study of properties of a surface that are unchanged when the surface is bent.

Euler's work on *geodesics* also pertains to the intrinsic geometry of surfaces. A *geodesic* is the shortest of all curves on a surface joining two of its points (in the plane the geodesics are straight lines and on a sphere they are great circles).[3]

The problem of finding geodesics on a surface was first posed in 1697 by Johann Bernoulli (1667–1748). Shortly after that, Johann Bernoulli wrote a letter to l'Hospital to the effect that he had found the general differential equation of geodesics. This result was published only in 1742 *[50, p. 364]*. Jacob Bernoulli (1654–1705) showed in 1698 that when cylindrical and conical surfaces are applied to planes, their geodesics go over into straight lines.

Euler was the first to publish the differential equation of geodesics. He did this in the paper *On the shortest curve on an arbitrary surface joining two arbitrary points* (De linea brevissima in superficie quacumque duo quaelibet puncta jungente. Petersburg, 1732) *[176, v. 25, pp. 1–12]*. Euler's equation was

$$\frac{Qddx + Pddy}{Qdx + Pdx} = \frac{dxddx + dyddy}{dt^2 + dx^2 + dy^2},$$

where t, x, y are rectangular coordinates in three-dimensional space, and the functions P and Q are determined from the differential equation of the surface $Pdx = Qdy + Rdt$. Euler returned to the problem of geodesics many times. In the second volume of his *Mechanics* (Mechanica. Petersburg) *[177, v. 2, p. 426]* he showed that, "in the absence of forces," the path of a point on a surface is a geodesic (an assumption used earlier by Bernoulli). In this connection, Euler showed that the *principal normal of a geodesic* (a straight line in the osculating plane of that curve passing through the point of contact and perpendicular to the tangent) always coincides with the normal to the surface.

---

[3] Many of Euler's papers deal with the determination of geodesics. The first was published in 1728 *[176, vol. 25, pp. 1–12]*, and the last was published posthumously *[176, vol. 25, pp. 269–279]*. Euler called geodesics *shortest curves*. The term *geodesic* first appeared in Laplace's *Celestial Mechanics* (Paris, 1799). Later it was applied to all quadrics. After the appearance of Liouville's paper (1814) it was applied to all surfaces.

We note that in the cartography paper *On the representation of the surface of a sphere in the plane* Euler compared the arc length elements of the plane and the sphere and proved the impossibility of an isometric mapping of a sphere to a plane. Also, he posed the question about the three mappings of the sphere to the plane that are of greatest importance in cartography, namely, the mapping in which the meridians and parallels are mapped onto an orthogonal system of lines, the mapping that preserves angles between curves (conformal mapping), and the mapping that preserves areas (equiareal mapping).

Independently of Euler, Monge considered developable surfaces in his *Memoir on evolutes, radii of curvature and various kinds of inflection of curves with twofold curvature* (Mémoire sur les développées, des rayons de courbure et les differents genres d'inflexion des courbes à double courbure. Paris, 1785) *[374]*. We note that Monge's book *Applications of analysis to geometry* (Applications de l'analyse à la géométrie. Paris, 1807) *[373]* contained the first systematic exposition of the theory of surfaces.

Intrinsic Geometry of Surfaces in the Work of Gauss

The general theory of the intrinsic geometry of a surface was formulated by Carl Friedrich Gauss in his *General investigations of curved surfaces* (Disquisitiones generales circa superficies curvas. Göttingen, 1828) *[196, vol. 4, pp. 217–258]*. Gauss's paper was the result of the assignment, given to him in 1820, to produce a cartographic survey of the kingdom of Hanover. This assignment made him reflect on problems of geodesy. In turn, this brought him to the theory of surfaces.

Gauss's theory unified the surface theories of Euler and Monge and the theory of quadratic forms developed by him in his *Arithmetical investigations* (Disquisitiones arithmeticae. Göttingen, 1801) *[196, vol. 1]*. In *Investigations of curved surfaces* Gauss introduced curvilinear coordinates p, q of points of the surface and defined the functions

$$a = \frac{dx}{dp}, \qquad b = \frac{dy}{dp}, \qquad c = \frac{dz}{dp}, \qquad a' = \frac{dx}{dq}, \qquad b' = \frac{dy}{dq},$$

$$c' = \frac{dz}{dq}; \qquad bc' - cb' = A, \qquad ca' - ac' = B', \qquad ab' - ba' = C;$$

$$\frac{ddx}{dp^2} = \alpha, \qquad \frac{ddx}{dpdq} = \beta, \qquad \frac{ddx}{dq^2} = \gamma, \qquad \frac{ddy}{dp^2} = \alpha',$$

$$\frac{ddy}{dpdq} = \beta', \qquad \frac{ddy}{dq^2} = \gamma', \qquad \frac{ddz}{dp^2} = \alpha'', \qquad \frac{ddz}{dpdq} = \beta'', \qquad \frac{ddz}{dq^2} = \gamma''.$$

In modern terms, the vectors $\{a, b, c\}$ and $\{a', b', c'\}$ are the partial derivatives of the radius vector of a point on the surface with respect to p and q

(Gauss denoted ordinary and partial derivatives the same way); the vector $\{A, B, C\}$ is the cross product of $\{a, b, c\}$ and $\{a', b', c'\}$ and its direction is that of the normal to the surface; and $\{\alpha, \beta, \gamma\}$, $\{\alpha', \beta', \gamma'\}$, and $\{\alpha'', \beta'', \gamma''\}$ are the second partial derivatives of the radius vector of a point on the surface with respect to p and q.

Further, Gauss introduced the quadratic forms

$$ds^2 = Edp^2 + 2Fdpdq + Gdq^2$$

and

$$Ddp^2 + D'dpdq + D''dq^2,$$

where

$$aa + bb + cc = E, \quad aa' + bb' + cc' = F, \quad a'a' + b'b' + c'c' = G,$$

$$A\alpha + B\beta + C\gamma = D, \quad A\alpha' + B\beta' + C\gamma' = D', \quad A\alpha'' + B\beta'' + C\gamma'' = D''.$$

The first of these forms, the so-called first fundamental form, gives the square of an arc length element of the surface, that is, of an element of length of an arc of a curve on the surface, and the second differs from the modern second fundamental form only by the multiplier $AA + BB + CC = EG - FF$.

Gauss introduced the all-important concept of "measure of curvature" now known as the *Gaussian curvature* of a surface. Making use of the spherical image of the surface, that is, the mapping that associates to a point P on the surface, a point P' on the unit sphere, such that the radius OP' is parallel to the normal to the surface at P (in modern terms, the end of the unit normal to the surface with beginning at a fixed point), Gauss defined the concepts of total curvature and "measure of curvature" as follows:

> We shall say that a part of a curved surface bounded by a given contour has *total curvature* given by the area of the corresponding figure on the surface of the sphere. One must draw a clear distinction between the total curvature and a kind of specific curvature that we shall call the *measure of curvature*. The latter pertains to a point on the surface and is the fraction obtained by dividing the total curvature of an element of the surface adjacent to the point by the area of that element, and thus gives the ratio of corresponding infinitesimal areas on the sphere and on the curved surface. We hope that our subsequent exposition will fully explain the utility of these new concepts" *[196, vol. 4, p. 226]*.

Gauss goes on to show that

> the "measure of curvature" at a point of the surface is equal to a fraction whose numerator is 1 and whose denominator is the product of the two principal curvatures of the normal sections.
>
> It is clear that the measure of curvature is positive for convex-convex or concave-concave surfaces (this is a trivial distinction) and negative for convex-concave ones. If the surface is made up of parts of both

kinds, then on their boundary the measure of curvature must vanish *[196, vol. 4, pp. 231]*.

Then Gauss obtains further expressions for the "measure of curvature" of which the most important are the expression of the "measure of curvature" k in terms of the coefficients of his two forms,

$$k = \frac{DD'' - D'D'}{EG - FF},$$

and the expression in terms of the coefficients of the first form alone and their derivatives with respect to p and q:

$$\begin{aligned} 4(EG - FF)^2 k = {} & E\left(\frac{dE}{dq}\frac{dG}{dq} - 2\frac{dF}{dp}\frac{dG}{dq} + \left(\frac{dG}{dp}\right)^2\right) + \\ & + F\left(\frac{dE}{dp}\frac{dG}{dq} - \frac{dE}{dq}\frac{dG}{dp} - 2\frac{dE}{dq}\frac{dF}{dq} + \frac{dF}{dp}\frac{dF}{dq} - \right. \\ & \left. - 2\frac{dF}{dp}\frac{dG}{dp}\right) + G\left(\frac{dE}{dp}\frac{dG}{dp} - \frac{dE}{dp}\frac{dF}{dq} + \left(\frac{dE}{dq}\right)^2\right) - \\ & - 2(EG - FF)\left(\frac{ddE}{dq^2} - 2\frac{ddF}{dpdq} + \frac{ddG}{dp^2}\right). \end{aligned}$$

In connection with the last formula Gauss makes the following comment:

> The formula in the last section leads, of itself, to the following remarkable
>
> *Theorem.* If a curved surface is applied to any other surface then the measure of curvature at each of its points remains unchanged.
>
> Also, it is clear that every finite part of a curved surface will, after application to another surface, retain its total curvature.
>
> The special case to which geometers have until now limited their investigations is the case of surfaces applicable to a plane. Our theory readily shows that the measure of curvature of such surfaces at any point is zero. . . .
>
> What we have set forth in the previous section involves a special approach to the investigation of surfaces worthy of the close attention of geometers. Namely, when a surface is regarded not as the boundary of a solid but as a solid with one vanishing dimension, flexible but not stretchable, then the properties of the surface are partly dependent on the form to which it has been reduced and in which it is being studied, and partly independent [of it in the sense that] they remain invariant regardless of its form under bending. The latter properties, whose investigation opens a new and fruitful area of geometry, include the measure of curvature and total curvature as defined by us. They also include the study of geodesic curves, as well as many other matters to be discussed in the sequel. When this approach is adopted, then the plane, and surfaces applicable to a plane, such as cylindrical and conical surfaces,

> are regarded as essentially the same, and the general method of characterizing a surface studied in this manner is based on the formula $\sqrt{Edp^2 + 2Fdpdq + Gdq^2}$ that expresses the connection of the line element of the surface with two variables p and q *[196, vol. 4, pp. 237–238]*.

Gauss is defining the *intrinsic geometry* of a surface invariant under bending and application to another surface. Some of the properties studied in intrinsic geometry are the lengths of curves on the surface, the angles between curves, and what Gauss calls *geodesic curves*, that is, geodesics. Gauss's theorem, called by him a *remarkable theorem* (Theorema Egregium), asserts that the *measure of curvature* is a property that belongs to intrinsic geometry.

Further, Gauss considers the total curvature of a geodesic triangle (that is, a triangle whose sides are arcs of geodesics). The total curvature of such a triangle is given by $\int k d\sigma$, where $d\sigma$ is an element of the surface of the triangle. He finds that

> the total curvature of a triangle is equal to the part of the spherical surface that corresponds to the triangle taken with a plus or minus sign according as the surface on which the triangle lies is concave-concave or concave-convex; as the unit of area we take a square with side one (the radius of the sphere); then the area of the sphere is 4π. It follows that the [surface of the] part of the sphere corresponding to the triangle is to the surface of the sphere as $\pm(A + B + C - \pi)$ to 4π. This theorem, that undoubtedly belongs with the most beautiful theorems of the theory of surfaces, can be stated as follows:
>
> *The excess above* 180° *of the sum of the angles of a triangle formed by geodesic curves on a curved concave-concave surface and the defect below* 180° *of the sum of the angles of a triangle formed by geodesic curves on a concave-convex surface are each measured by the area of the part of the spherical surface that corresponds to the given triangle via normal directions, provided that the whole surface* (*of the sphere*) *is taken as* 720 *degrees [196, vol. 4, pp. 245–246]*.

This theorem of Gauss implies that the Gaussian curvature at a point is equal to the limit of the ratio of the angular excess $A + B + C - \pi$ of a geodesic triangle ABC on the surface to its area as the triangle shrinks to the given point.

Minding's Theory of Surfaces of Constant Curvature

Gauss's work on the intrinsic geometry of surfaces was continued by Ferdinand Minding (1806–1885), who worked in Dorpat (now Tartu). In his *Remark on the development of curved lines on surfaces* (Bemerkung über die Abwickelung krummer Linien auf Flächen. Berlin, 1830) *[366]*, Minding introduced the fundamental concept of *geodesic curvature* of a curve on a surface, defined as the limit of the ratio of the angle between tangent geodesics at the endpoints of an arc of the curve to the arc length as the arc shrinks to a point, and showed that this limit is invariant under bending. In the paper *How to decide whether two surfaces are mutually applicable; including remarks on surfaces of constant measure of curvature* (Wie sich entscheiden lässt ob zwei gegebene krumme Flächen auf einander abwickelbar sind, nebst Bemerkungen über die Flächen von unveränderlicher Krümmungsweise. Berlin, 1839) *[367]* Minding expressed the line element of a surface with constant "measure of curvature" as

$$ds^2 = dp^2 + \left(\frac{1}{\sqrt{k}}\sin p\sqrt{k}\right)^2 dq^2$$

and concluded that

> two surfaces of equal constant measure of curvature can be applied to each other in infinitely many ways, since any two points of one can be associated to two arbitrary points of the other provided that the lengths of the shortest curves between the points of each pair are equal. This implies the following consequences:
>
> Every surface whose measure of curvature is zero [results from] the bending of a plane—this much is well known.
>
> Every surface whose measure of curvature (k) is constant and positive can be applied to a sphere of radius $1/\sqrt{k}$ *[367, pp. 375–376]*.

Further, Minding discovered helical surfaces and, in particular, surfaces of constant negative curvature. One such surface is given by the parametric equations

$$r = \sqrt{x^2 + y^2} = \frac{1}{\cosh\varphi}, \qquad z = \varphi - \tanh\varphi.$$

Minding comments that

> This surface is the result of rotating a curve like ... *CBE* ... (Figure 102) about the zz-axis which it approaches asymptotically *[367, p. 380]*.

The curve *CBE*, which is characterized by the constancy of the length of the segment of the tangent between the point of tangency and the zz-axis, is called a *tractrix*, and the surface of revolution referred to by Minding is called a *pseudosphere*.

In *Contributions to the theory of shortest curves on curved surfaces* (Beiträge zur Theorie der kürzesten Linien auf krummen Flächen. Berlin, 1840) *[368]* Minding established the trigonometric relations in geodesic triangles on such surfaces and noted that these formulas could be obtained from the corresponding formulas of spherical geometry on a sphere of radius r by multiplying r by the complex number i.

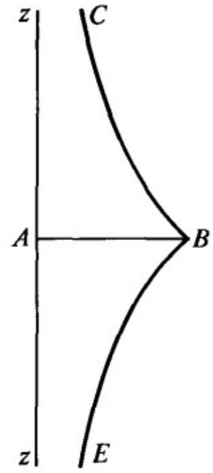

Figure 102

Interpretation of the Lobačevskian Plane on a Pseudosphere

In spite of the fact that Minding's paper appeared in the same journal (*Crelle's*) as Lobačevskiĭ's *Imaginary geometry*, neither of them noticed that the trigonometric formulas of the hyperbolic plane coincide with the trigonometric formulas of a surface of constant negative curvature.[4]

The person who *did* notice the sameness of these formulas was E. Beltrami, who considered the matter in *An attempt at an interpretation of non-Euclidean geometry [42, pp. 374 405]*. Beltrami constructed a model of the hyperbolic plane in a circle and associated to the points of the hyperbolic plane of curvature $-1/R^2$ the coordinates u, v of the corresponding points of the circle. He found that in this coordinate system the line element is given by

$$ds^2 = R^2\frac{(a^2 - u^2)du^2 + 2uvdudv + (a^2 - v^2)dv^2}{a^2 - u^2 - v^2}.$$

Beltrami computed the total curvature of a surface with this line element and noticed that the Gaussian curvature of the hyperbolic plane is everywhere equal to the same number $-1/R^2$; that is, the hyperbolic plane can be viewed as a surface of constant negative curvature.

Thus, speaking of surfaces of constant negative curvature, Beltrami concluded that

---

[4] Lobačevskiĭ's paper appeared in vol. 17 (1837) of *Crelle's Journal* and Minding's paper in vol. 20 (1840) of that journal. B. L. Laptev *[265, p. 20]* explains that Lobačevskiĭ did not borrow the latter volume from the library of Kazan University.

> the theorems of non-Euclidean planimetry apply to them. Further, most of these theorems can be thought of concretely only if we refer them to such surfaces and not to the plane *[42, p. 381]*.

That is why Beltrami suggested that all surfaces of constant negative curvature be called *pseudospherical* surfaces.

Beltrami also showed that each of the sheets of Minding's pseudosphere is isometric to the part of the hyperbolic plane enclosed between two parallel lines and a horocycle perpendicular to them. He also found parts of the hyperbolic plane isometric to other surfaces of revolution of constant negative curvature determined by Minding.

Riemannian Geometry

In the paper *On the hypotheses which lie at the foundations of geometry [122, pp. 55–71]* Riemann introduced a notion of an n-*ply extended manifold* broader than either of the similar notions introduced by Grassmann and Schläfli. After defining this manifold Riemann posed the question of the "measure-relations of which such a manifold is capable" and of the possibility "to express geometrically the calculated results." After noting that the foundations of these two parts of the question are established in Gauss's celebrated memoir *Disquisitiones generales circa superficies curvas [122, pp. 59–60]*, Riemann writes:

> Position-fixing being reduced to quantity-fixings, and the position of a point in the *n*-ply extended manifold being consequently expressed by means of *n* variables $x_1, x_2, x_3, \ldots x_n$, the determination of a line comes to the giving of these quantities as functions of one variable. The problem consists then in establishing a mathematical expression for the length of a line, and to this end we must consider the quantities x as expressible in terms of certain units. I shall treat this problem only under certain restrictions, and I shall confine myself in the first place to lines in which the ratios of the increments dx of the respective variables vary continuously. We may then conceive these lines broken up into elements, within which the ratios of the quantities dx may be regarded as constant; and the problem is then reduced to establishing for each point a general expression for the linear element ds starting from that point, an expression which will thus contain the quantities x and the quantities dx. I shall suppose, secondly, that the length of the linear element, to the first order, is unaltered when all the points of this element undergo the same infinitesimal displacement, which implies at the same time that if all the quantities dx are increased in the same ratio, the linear element will vary also in the same ratio. On these suppositions, the linear element may be any homogeneous function of the first degree of the quantities

> dx, which is unchanged when we change the signs of all the dx, and in which the arbitrary constants are continuous functions of the quantities x. To find the simplest cases, I shall seek first an expression for manifoldness of $n - 1$ dimensions which are everywhere equidistant from the origin of the linear element; that is, I shall seek a continuous function of position whose values distinguish them from one another. In going outwords from the origin, this must either increase in all directions or decrease in all directions; I assume that it increases in all directions, and therefore has a minimum at that point. If, then, the first and second differential coefficients of this function are finite, its first differential must vanish, and the second differential cannot become negative; I assume that it is always positive. This differential expression, then, of the second order remains constant when ds remains constant, and increases in the duplicate ratio when the dx, and therefore also ds, increase in the same ratio; it must therefore be ds^2 multiplied by a constant, and consequently ds is the square root of an always positive integral homogeneous function of the second order of the quantities dx, in which the coefficients are continuous functions of the quantities x. For Space, when the position of points is expressed by rectilinear co-ordinates, $ds = \sqrt{\sum (dx)^2}$ *[122, pp. 60–61]*.

(In Clifford's translation we changed his term n-*dimensional manifoldedness* to Riemann's n-ply extended manifold). By *Space* Riemann means three-dimensional Euclidean space. After considering various possible cases of the dependence of ds on the differentials dx, Riemann restricts himself to "manifolds for which the line element is given by the square root of a differential expression of the second degree," that is,

$$ds^2 = \sum_i \sum_j g_{ij} dx_i dx_j, \tag{8.2}$$

where $g_{ij} = g_{ji}$ are functions of the variables x_i.

Riemann's requirement guarantees that his n-dimensional space is locally Euclidean. The quadratic form (8.2) is assumed to be positive definite, that is, for all dx_i not simultaneously zero $ds^2 > 0$. Hence each pair of points with infinitesimally different coordinates x_i and $x_i + dx_i$ are a definite distance ds apart. By integrating this distance along different lines we determine their length. Among the different lines we can find the shortest (geodesic) lines $x_i = x_i(t)$ that are solutions of the differential equations

$$\frac{d^2 x_i}{ds^2} + \sum_j \sum_k \Gamma^i_{jk} \frac{dx_j}{ds} \frac{dx_k}{ds} = 0, \tag{8.3}$$

where the Γ^i_{jk} are point functions expressed in terms of the coefficients g_{ij} by means of the relations

$$\sum_i g_{il} \Gamma^l_{jk} = \frac{1}{2}\left(\frac{\partial g_{lk}}{\partial x_j} + \frac{\partial g_{il}}{\partial x_k} - \frac{\partial g_{jk}}{\partial x_l}\right). \tag{8.4}$$

The spaces defined in this way are called *Riemannian spaces*. Surfaces in ordinary space are particular Riemannian spaces for $n = 2$; in this case, an instance of a geometry of the kind defined by Riemann is the so-called intrinsic geometry of a surface, elaborated by Gauss in the work *General investigations of curved surfaces* alluded to by Riemann. Clearly, Euclidean space is a special case of a Riemannian space whose geodesics are Euclidean straight lines.

A more general example of a Riemannian space is a hypersurface in $(n + 1)$-dimensional Euclidean space and, in particular, a hypersphere in this space. The geodesics of a hypersphere are its great circles—sections by two-dimensional planes passing through its center. Elliptic space, obtained from a sphere by identifying antipodal points, and Lobačevskian space are also examples of Riemannian spaces.

One of the most important concepts of Riemannian geometry is the *curvature of a space*. The curvature is defined at every point in every two-dimensional direction passing through this point. To determine the curvature of a Riemannian space at a point one considers a geodesic triangle, that is, a curvilinear triangle bounded by arcs of three geodesics, one of whose vertices is at the given point and two of whose sides issuing from this vertex are tangent to the given two-dimensional direction. For this triangle ABC one computes the angular excess $A + B + C - \pi$ (as defined, the angular excess can be positive, zero, or negative), as well as the area, and forms the ratio of the angular excess over the area of the triangle. Now one lets the triangle shrink to the given vertex but insists that the sides issuing from it continue to be tangent to the given two-dimensional direction. It is obvious that in this limiting process the area of the geodesic triangle tends to zero. Since the geometry of the two-dimensional surface in which the passage to the limit is taking place is locally Euclidean and the angular excess of a Euclidean plane is zero, it follows that the angular excess of the geodesic triangle also tends to zero. But the ratio of the angular excess over the area of the triangle tends to a definite limit called the *curvature of the Riemannian space* at the given point in the given two-dimensional direction.

The curvature of n-dimensional Euclidean space, regarded as a special case of a Riemannian space, is equal to zero at all of its points; that is why a Euclidean space is called Riemannian space of *zero curvature* and Riemannian spaces different from Euclidean space are called *curved spaces*.

Riemann defined the curvature of his space in the following manner; in a neighborhood of the point at which he wanted to define curvature he introduced coordinates x_i equal to zero at the point and such that distance s of points in the neighborhood of this point was given in terms of the coordinates by the relation $s^2 = \sum_i x_i^2$. Riemann writes:

> When we introduce these quantities, the square of the line-element is Σdx^2 for infinitesimal values of the x, but the term of next order in it is equal to a homogeneous function of the second order of the $\frac{1}{2}n(n - 1)$ quantities $(x_1 dx_2 - x_2 dx_1)$, $(x_1 dx_3 - x_3 dx_1)$ ... an infinitesimal, there-

> fore, of the fourth order; so that we obtain a finite quantity on dividing this by the square of the infinitesimal triangle, whose vertices are $(0,0,0,\dots)$, $(x_1, x_2, x_3, \dots)$, $(dx_1, dx_2, dx_3, \dots)$. This quantity retains the same value so long as the x and the dx are included in the same binary linear form, or so long as the two geodesics from 0 to x and from 0 to dx remain in the same surface-element; it depends therefore only on place and direction. It is obviously zero when the manifold represented is flat, i.e., when the squared line-element is reducible to $\Sigma\, dr^2$, and may therefore be regarded as the measure of the deviation of the manifold from flatness at the given point in the given surface-direction. Multiplied by $-\frac{3}{4}$ it becomes equal to the quantity which Privy Councillor Gauss has called the total curvature of a surface *[122, pp. 62–63]*.

In view of Riemann's choice of coordinates, the expansion of the square of the line element ds^2 in the neighborhood of the point he considered is given by

$$ds^2 = \sum_i dx_i^2 + \sum_i \sum_j \sum_k c_{ij,k} x_k dx_i dx_j + \sum_i \sum_j \sum_k \sum_l c_{ij,kl} x_k x_l dx_i dx_j + \dots,$$

where $c_{ij,k}$ and $2c_{ij,kl}$ are the values of the derivatives $\dfrac{\partial g_{ij}}{\partial x_k}$ and $\dfrac{\partial^2 g_{ij}}{\partial x_k \partial x_l}$ at the point under consideration. In the first place, Riemann notes that there is no linear term in this expansion, that is, that $c_{ij,k} = 0$. The reason for this is that his coordinate lines are geodesics satisfying equation (8.3), where the coefficients Γ^i_{jk} are expressed in terms of g_{ij} by formulas (8.4). Then Riemann claims that the second-order terms in the expansion of ds^2 form a quadratic form in the $x_i dx_j - x_j dx_i$. If for the sake of uniformity we denote the infinitesimals x_i by δx_i then the latter magnitudes can be written as $\Delta x_{ij} = \delta x_i dx_j - \delta x_j dx_i$. These quantities determine a parallelogram on the vectors $\{dx_i\}$ and $\{\delta x_i\}$, so that the quadratic terms in the expansion can be written as

$$\Delta\sigma^2 = \sum_i \sum_j \sum_k \sum_l R_{ij,kl} \Delta x_{ij} \Delta x_{kl}.$$

The quantity obtained by Riemann, which he calls the fraction from the division of $\Delta\sigma^2$ by the area of the triangle on the vectors $\{dx_i\}$ and $\{\delta x_i\}$, is actually the limit of this fraction as the triangle in question shrinks to the point. Nowadays, a quantity proportional to that defined by Riemann (with a proportionality factor such that in the case of a surface it coincides with the Gaussian curvature) is called the *Riemannian curvature* of the space at a given point in a given two-dimensional direction. Riemann goes on to give our earlier geometric interpretation of the curvature he defined. He notes that on surfaces in ordinary space "the difference between the angle sum of an infinitesimal triangle and two right angles is proportional to the area of the triangle" and writes:

> To give an intelligible meaning to the curvature of an n-fold manifold at a given point and in a given surface-direction through it, we must start from the fact that a geodesic proceeding from a point is entirely determined when its initial direction is given. According to this we obtain a determinate surface if we prolong all the geodesics proceeding from the given point and lying initially in the given surface-direction; this surface has at the given point a definite curvature, which is also the curvature of the n-fold continuum at the given point in the given surface-direction *[122, p. 64]*.

Riemannian geometry was applied by Riemann to the theory of differential equations in *A mathematical work containing an attempt to answer the question proposed by the most illustrious Paris Academy: To determine the heat state of a homogeneous solid so that a system of isothermal curves given at a certain moment in time remains a system of isothermal curves at an arbitrary moment in time and so that the temperature at a point is expressed as a function of time and two more independent variables* (Commentatio mathematica qua respondere tentatur questioni ab Ill$^{\text{ma}}$ Academia Parisensi proposita: Trouver quel doit être l'état calorifique d'un corps solide homogène pour qu'une système de courbes isothermes, à un instant donné, restent isothermes après un temps quelconque, de telle sorte que la température d'un point puisse s'exprimer en fonction du temps et de deux autres variables indépendentes), written in 1861 and published in his collected works (Leipzig, 1876) *[454, pp. 391–404]*. In this paper Riemann solved the problem of reducing the differential equation of heat conduction

$$\sum_i \frac{\partial}{\partial s_i}\left(\sum_j b_{ij}\frac{\partial u}{\partial s_j}\right) = h\frac{\partial u}{\partial t}$$

to simplest form— a problem equivalent to that of transforming the quadratic form $\sum_i \sum_j b_{ij} ds_i ds_j$ to a sum of squares. Riemann found that this can be done if and only if the expression

$$K = \frac{1}{2}\frac{\sum\limits_i \sum\limits_j \sum\limits_k \sum\limits_l (ij,kl)(ds_i\delta s_j - ds_j\delta s_i)(ds_k\delta s_l - ds_l\delta s_k)}{\left(\sum\limits_i \sum\limits_j b_{ij} ds_i ds_j\right)\left(\sum\limits_i \sum\limits_j b_{ij}\delta s_i \delta s_j\right) - \left(\sum\limits_i \sum\limits_j b_{ij} ds_i \delta s_j\right)^2},$$

that is invariant under a change of variables, vanishes. Of this expression, he denotes by (111), Riemann says:

> The expression $\sqrt{\sum_i \sum_j b_{ij} ds_i ds_j}$ can be regarded as a line element of an n-tuply extended space that is outside the bounds of our intuition. If we lead from point $(s_1, s_2, \ldots, s_n)$ in this space all possible geodesics whose initial directions are characterized by the ratios $\alpha ds_1 + \beta\delta s_1 : \alpha ds_2 + \beta\delta s_2 : \ldots : \alpha ds_n + \beta\delta s_n$ (where α and β are arbitrary quantities) then these lines form a certain surface which we can think of as located in the

> ordinary space of our intuition. Then expression (111) is the curvature of this surface at the point $(s_1, s_2, \ldots, s_n)$ *[454, p. 403]*.

The quantities (ij, kl), the so-called four-index Riemann symbols, are the same quantities that we denoted earlier by $R_{ij,kl}$. We note that the quantities $R_{ij,kl}$ can be expressed in terms of the coefficients g_{ij} and their derivatives, using the quantities Γ^i_{jk} (expressed in terms of the g_{ij} and their derivatives by formulas (8.4)), by means of the formula

$$R_{ij,kl} = \left(\frac{\partial \Gamma^h_{jk}}{\partial x_i} - \frac{\partial \Gamma^h_{ik}}{\partial x_j} + \Gamma^h_{ir}\Gamma^r_{jk} - \Gamma^h_{jr}\Gamma^r_{ik}\right) g_{hl}.$$

In the paper mentioned previously Riemann also used the quantities Γ^i_{jk} but denoted them as p_{ijk}.

Riemann's investigations were continued by Elwin Bruno Christoffel (1829–1900) in the paper *On the transformation of homogeneous differential expression of second degree* (Über die Transformation der homogenen Differentialausdrücke zweiten Grades. Berlin, 1869) *[114, vol. 1, pp. 368–377]*, in which he posed the question of the conditions under which the geometry determined by a form $\sum_i \sum_j g_{ij} dx_i dx_j$ coincides with the geometry determined by a form $\sum_i \sum_j h_{ij} dy_i dy_j$. Just as Riemann's intention was to develop Gauss's theory of surfaces, so Christoffel's intention was to generalize the problem of superposition of surfaces. Christoffel's necessary condition for the coincidence of geometries turned out to be the coincidence of the differential forms $\sum_i \sum_j \sum_k \sum_l R_{ij,kl} dx_i dx_k \delta x_j \delta x_l$, computed for the two given forms. Christoffel denoted the quantities Γ^i_{jk} by $\left\{{jk \atop i}\right\}$ and the quantities $\sum_l g_{il} \Gamma^l_{jk}$ by $\left[{jk \atop i}\right]$. That is why these quantities are often called *Christoffel symbols of the first and second kind*, respectively.

Riemannian Spaces of Constant Curvature

After defining Riemannian spaces of variable curvature and noting that Euclidean spaces are spaces of zero curvature Riemann dwelled at length on spaces of constant nonzero curvature:

> Manifolds whose curvature is constantly zero may be treated as a special case of those whose curvature is constant. The common character of these continua whose curvature is constant may be also expressed thus, that figures may be moved in them without stretching. For clearly figures could not be arbitrarily shifted and turned round in them if the curvature at each point were not the same in all directions. On the other hand, however, the measure-relations of the manifold are entirely determined by the curvature; they are therefore exactly the same in all directions at one point as at another, and consequently the same constructions can be made from it: whence it follows that in aggregates with

constant curvature figures may have any arbitrary position given them. The measure-relations of these manifolds depend only on the value of the curvature, and in relation to the analytic expression it may be remarked that if this value is denoted by α, the expression for the line-element may be written

$$\frac{1}{1 + \frac{1}{4}\alpha \sum x^2}\sqrt{\sum dx^2}$$

[122, p. 65].

The latter expression generalizes the previously mentioned expression, obtained by Minding, of the line element of a surface of constant curvature in terms of its Gaussian curvature.

The simplest example of a Riemannian space of constant positive curvature is a sphere in $(n + 1)$-dimensional Euclidean space; the Riemannian curvature of a sphere of radius r, of any dimension, in all two-dimensional directions is equal to $1/r^2$, for the area of any spherical triangle is the product of r^2 and the angular excess of the triangle.

An example of an n-dimensional Riemannian space of constant negative curvature is n-dimensional Lobačevskian space, first defined by Beltrami in the paper *Fundamental theory of spaces of constant curvature* (Teoria fondamentale degli spazî di curvatura costante. Milan, 1869) *[42, pp. 406–429]* published in the same year as his previously discussed paper. This space can also be viewed as one of the sheets of a sphere of radius qi in $(n + 1)$-dimensional pseudo-Euclidean space. The Riemannian curvature of such a sphere in all two-dimensional directions is $-1/q^2$ since the area of an arbitrary spherical triangle on this sphere is the product of its angular defect by $-q^2$.

We wish to mention here a remarkable theorem of F. Schur established in the paper *On the connection between spaces of constant curvature and projective spaces* (Über dem Zusammenhang der Räume constanten Krümmungmasses mit den projectiven Räumen. Leipzig, 1886) *[517]* which asserts that, on a Riemannian manifold, the constancy of the Riemannian curvature in all two-dimensional directions at each point implies the constancy of the Riemannian curvature at all points. Schur's proof is purely geometric and is based on a projective mapping of the bundle of linear elements at one point onto a similar bundle at another point. An analytic proof of this result was given by Luigi Bianchi (1856–1928) in the paper *On four-index symbols and on Riemannian curvature* (Sui simboli a quatro indici e sulla curvatura di Riemann. Rome, 1902) *[56]*.

Elliptic Geometry

Another form of n-dimensional Riemannian space of constant positive curvature is a sphere in $(n + 1)$-dimensional Euclidean space with identified antipodal points called n-dimensional *elliptic space* or *non-Euclidean space of Riemann*. When $(n + 1)$-dimensional Euclidean space is completed to $(n + 1)$-dimensional projective space, pairs of antipodal points of a sphere in $(n + 1)$-dimensional Euclidean space are projected from its center onto the points of its plane at infinity. Since this plane is an n-dimensional projective space, elliptic space can be viewed as a metrized projective space. The details are as follows.

An arbitrary sphere of $(n + 1)$-dimensional Euclidean space is given by an equation of the form

$$A \sum_i x_i^2 + 2 \sum_i b_i x_i + c = 0,$$

which can be written in homogeneous coordinates as

$$A \sum_i x_i^2 + 2 \sum_i b_i x_i x_0 + c(x_0)^2 = 0.$$

The latter equation shows that our sphere intersects the plane at infinity, $x_0 = 0$, in the imaginary quadric $\sum_i x_i^2 = 0$. Hence an elliptic space can be described as a projective space with a given imaginary conic. The distance ω between two points X and Y of an elliptic space of curvature $1/r^2$ is connected with the angle φ between the corresponding diameters of the sphere by the relation $\omega = \varphi r$. On the other hand, Edmond Laguerre (1834–1886) showed in the paper *On the theory of foci* (Sur la theorie des foyers. Paris, 1853) *[298, vol. 2, pp. 6–15]* that the angle φ between two straight lines in Euclidean space can be expressed in terms of the cross ratio (ij, xy) of the straight lines x, y and two *isotropic straight lines* i, j, that is, imaginary lines of zero length that lie in the plane of x and y and pass through the point of intersection of x and y, by means of the relation

$$\varphi = \frac{1}{2i} \ln(ij, xy). \tag{8.5}$$

Since the imaginary lines i, j that join the center of the sphere to the points I, J of the imaginary quadric $\sum_i x_i^2 = 0$ in the plane at infinity are, in view of the equation of the quadric, isotropic, Laguerre's formula (8.5) yields an expression for the distance ω between points X, Y of elliptic space in terms of the cross ratio (IJ, XY) of these points and the two points of intersection of the straight line XY and the imaginary quadric:

$$\omega = \frac{r}{2i} \ln(IJ, XY). \tag{8.6}$$

An elliptic metric in the projective plane was defined in 1859 by Cayley in the *Sixth memoir upon quantics [103, vol. 2, pp. 561–592]*. An elliptic metric in space, and the term *elliptic geometry*, were introduced by Klein in 1871 in the paper *On the so-called non-Euclidean geometry [282, vol. 1, pp. 254–305]*, in which he wrote that

> The basis of a general projective metric in space is provided by an arbitrary *fundamental surface of the second order.*
>
> To define the distance between two points one joins them by a straight line. It intersects the fundamental surface in two new points that are in a definite cross ratio with the two given points. *The logarithm of this cross ratio multiplied by an arbitrary constant c yields what one should call the distance between the two given points [282, vol. 1, p. 300].*

Klein gave a similar definition of the angle between two planes (see p. 238). Further Klein wrote:

> By a *motion* is meant the totality of linear transformations that leave the fundamental surface invariant.
>
> By *spheres* one means quadric surfaces that meet the fundamental surface along a plane curve. The center of the sphere is the pole of the plane that contains the osculating curve....
>
> If the fundamental surface is *imaginary* then all straight lines have finite length and each pencil of planes has finite angle sum. *Elliptic* geometry comes under this case (provided that the constant c' in the definition of angles is taken as $\sqrt{-1}/2$, so that the sum of the angles in a pencil of planes is π).
>
> We do not investigate the case when the fundamental surface is *real* and *ruled* (like a hyperboloid of one sheet) for this case is no way connected with the three geometries (elliptic, hyperbolic, parabolic) considered here.
>
> Finally, if the fundamental surface is *real* and *nonruled* then for the interior points of the surface we obtain a metric that includes the metric of hyperbolic geometry provided that we again take the constant c' to be $\sqrt{-1}/2$.
>
> *Parabolic* geometry is included as a special case of the general metric; this case arises if the fundamental surface specializes (degenerates) into an imaginary conic section. The fundamental conic section of parabolic geometry is the so-called imaginary circle at infinity *[282, vol. 1, p. 301].*

Klein's *fundamental surface* is now called by Cayley's term *the absolute.* We note that Klein's *linear transformations* are collineations, his *hyperbolic geometry* is Lobačevskian geometry, and his *parabolic geometry* is Euclidean geometry; the *imaginary circle at infinity* is the imaginary circle $\sum_i x_i^2 = 0$ in the plane at infinity of Euclidean space that plays the role of the absolute of this space. Klein did not investigate the geometry of the exterior of an oval (nonruled) quadric and the geometry of a ruled quadric. The reason for this is that, unlike elliptic geometry and Lobačevskian geometry, the geometry of these spaces is locally not Euclidean but pseudo-Euclidean.

We also note that the only difference between formula (8.6) and formula (6.27) for Lobačevskian space is that in one case we have the pure imaginary constant r/i and in the other the real constant q.

Clifford Parallels and Surfaces

The geometry of elliptic space was significantly developed by William Kingdon Clifford (1845–1879) in his *Preliminary sketch of biquaternions* (London, 1879) *[122, pp. 181–200]*.

After defining elliptic, hyperbolic, and parabolic geometries whose absolutes are, respectively, an imaginary quadric, a real (oval) quadric, and an imaginary conic in a real plane, Clifford investigates *elliptic geometry*. After defining poles and polar planes and mutually polar straight lines with respect to an absolute and pointing out that two points that are polar conjugates with respect to the absolute "are a *quadrant* apart," that is, are $(\pi/2)r$ apart, or, if $r = 1$, are $\pi/2$ apart, Clifford notes that

> Through an arbitrary point can in general be drawn *one* line perpendicular to a given plane; namely, the line joining the point to the pole of the plane. If, however, the point *is* the pole of the plane, every line through it is perpendicular to the plane. Similarly, from a point not on the polar of a given line can be drawn one and only one perpendicular to the line; namely, the line through the point which meets the given line and its polar *[122, p. 192]*.

and further:

> *In general, two lines can be drawn so that each meets two given lines at right angles, and these are polars of one another*. One line may therefore be converted into another by rotation about two polar axes. These axes are determined as the lines which meet the two given lines and their polars. If we travel continuously along one of these lines and draw perpendiculars on the other, one of these axes determines the shortest distance between the lines, and the other the longest. If then these two are equal, the lines are equidistant along their whole length. Thus *there is a case of exception in which two lines and their polars belong to the same set of generators of a hyperboloid; the lines are then equidistant along their whole length, and meet the same two generators of one system of the absolute*. I shall use the word *parallel* to denote two lines so situated; and they shall be called *right* parallel or *left* parallel according as one is converted into the other by a right-handed or left-handed twist. Through an arbitrary point can be drawn one right parallel and one left parallel to a given line; the angle between them is twice the distance of the point from the line. There are many points of analogy between the *parallels* here defined and those of parabolic geometry. Thus, if a line meets two parallel lines, it makes equal angles with them; and a series of parallel lines meeting a given line constitute a ruled surface of zero curvature. The geometry of this surface is the same as that of a finite parallelogram whose opposite sides are regarded as identical *[122, pp. 192–193]*.

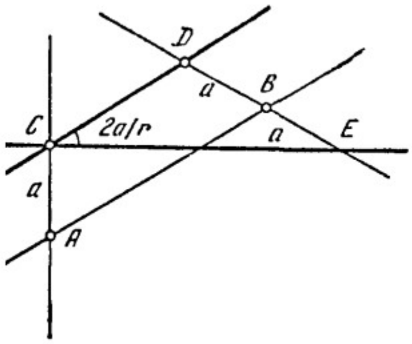

Figure 103

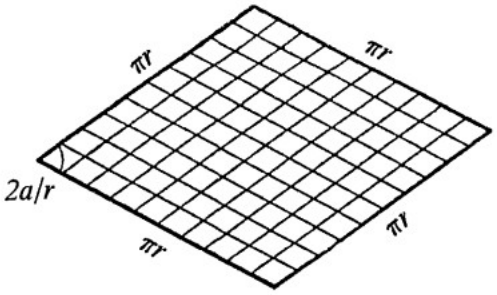

Figure 104

The parallels defined by Clifford are now called *paratactic straight lines*;[5] one must bear in mind that, unlike parallels in Euclidean (*parabolic*) geometry, Clifford parallels are skew straight lines. Figure 103 illustrates the construction of a right, CD, and left, CE, Clifford parallel through a point C to a straight line AB. From the point C one drops the perpendicular CA to the straight line AB and constructs its polar DBE. On the latter one lays off on either side of the point B segments BD and BE equal to the segment $CA = a$. The required parallels are the straight lines CD and CE; the angle DCE is measured in terms of the segment $DE = 2a$ and is equal to $2a/r$. The surface constructed by Clifford is now known as a *Clifford surface*. It is a ruled quadric obtained by rotating one of two paratactic straight lines about the other; its rectilinear generators in both families are paratactic to the axes; at the same time it is also a surface of revolution about the polar of the first axis. The geometry of a Clifford surface is Euclidean. Its area is finite and equal to $\pi^2 r^2 \sin 2a/r$, for it is isometric to a rhombus with sides πr and acute angle $2a/r$ (Figure 104) with sides in each pair of opposite sides glued together. To prove that the geometry of this surface is Euclidean it suffices to write down its parametric equations in homogeneous coordinates whose basis points are located on the axes of the surface,

$$x_0 = \cos\frac{a}{r}\cos u, \qquad x_1 = \cos\frac{a}{r}\sin u,$$

$$x_2 = \sin\frac{a}{r}\cos v, \qquad x_3 = \sin\frac{a}{r}\sin v,$$

and to compute the line element

$$ds^2 = \sum_i dx_i^2 = r^2\left(\cos^2\frac{a}{r}\,du^2 + \sin^2\frac{a}{r}\,dv^2\right).$$

---

[5] This term was introduced by E. Study in the paper *[568]*.

.8 5 7! ! # # 83 # ! ! 7! ! ! !

If in the latter we put

$$U = r\cos\frac{a}{r}\cdot u, \qquad V = r\sin\frac{a}{r}\cdot v,$$

then we have $ds^2 = dU^2 + dV^2$.

If one eliminates from the parametric equations of the Clifford surface the parameters u and v then one obtains its equation in the form

$$\sin^2\frac{a}{r}(x_0^2 + x_1^2) - \cos^2\frac{a}{r}(x_2^2 + x_3^2) = 0.$$

A Clifford surface is the simplest solution of the Clifford-Klein problem of finding spaces with a Euclidean metric that are not isometric to Euclidean space in the large.

Clifford's Idea of the Geometrization of Physics

W. K. Clifford was also interested in questions of the philosophy of space. In his philosophical work *Philosophy of pure science* (London, 1873) there are his famous words on Lobačevskian geometry!

> What Vesalius was to Galen, what Copernicus was to Ptolemy, that was Lobatchewsky to Euclid. There is, indeed, a somewhat instructive parallel between the last two cases. Copernicus and Lobatchewsky were both of Slavic origin. Each of them has brought about a revolution in scientific ideas so great that it can only be compared with that wrought by the other. And the reason of the transcendent importance of these two changes is that they are changes in the conception of the Cosmos *[123, vol. 1, p. 356]*.

What Clifford is saying here is that Lobačevskiĭ's discovery that Euclidean geometry is not the only conceivable geometry is just as revolutionary as Vesalius' shattering of the myth of the exclusive position of man in the animal kingdom and Copernicus' discovery that the Earth is just one of the planets.

Clifford expressed his interesting thoughts on space in his posthumously published *The Common sense of the exact sciences* (London, 1885) *[121]*. Clifford begins the chapter on space with the words

> Geometry is a physical science *[121, p. 43]*,

and at the end of the chapter on position he writes:

> We may conceive our space to have everywhere a nearly uniform curvature, but that slight variations of the curvature may occur from point to point, and themselves vary with the time. These variations of the curvature with the time may produce effects which we not unnaturally attribute to physical causes independent of the geometry of our space.

> We might even go so far as to assign to this variation of the curvature of space "what really happens" in that phenomenon which we term the motion of matter *[121, pp. 202–203]*.

Clifford developed these ideas in greater detail in his report *On the space theory of matter* (Cambridge, 1876). First he paraphrases Riemann:

> Riemann has shewn that as there are different kinds of lines and surfaces, so there are different kinds of space of three dimensions; and that we can only find out by experience to which of these kinds the space in which we live belongs. In particular, the axioms of plane geometry are true within the limits of experiment on the surface of a sheet of paper, and yet we know that the sheet is really covered with a number of small ridges and furrows, upon which (the total curvature not being zero) these axioms are not true. Similarly, he says although the axioms of solid geometry are true within the limits of experiment for finite portions of our space, yet we have no reason to conclude that they are true for very small portions; and if any help can be got thereby for the explanation of physical phenomena, we may have reason to conclude that they are not true for very small portions of space *[122, p. 21]*.

Then he states the following four principles:

> (1) That small portions of space *are* in fact of a nature analogous to little hills on a surface which is on the average flat; namely, that the ordinary laws of geometry are not valid in them.
> (2) That this property of being curved or distorted is continually being passed on from one portion of space to another after the manner of a wave.
> (3) That this variation of the curvature of space is what really happens in that phenomenon which we call the *motion of matter*, whether ponderable or etherial.
> (4) That in the physical world nothing else takes place but this variation, subject (possibly) to the law of continuity *[122, pp. 21–22]*

These principles form a program of geometrization of physics.

Riemann's Topology

In addition to the theory of Riemannian spaces Riemann also founded topology—one of the most important disciplines that significantly broadened our notions of space.

We have already pointed out that Euler interpreted Leibniz's term *geometry of position* in a topological sense, whereas Carnot and Grassmann gave it narrower interpretations. Euler's interpretation of the term was developed by the German physicist Johann Benedict Listing (1808–1862), who suggested the now generally accepted term *topology* in his *Preliminary studies on topology* (Vorstudien zur Topologie. Göttingen, 1847) *[329]*. Listing's term comes from replacing Leibniz's Latin *situs* (place) with its Greek counterpart *topos*. Listing studied

> *linear complections, that is, lines or curves or sets of such, located on a surface, such as a plane or a sphere, or arbitrarily disposed in space [329, p. 867].*

He investigated knots, chains, plaits, and other forms of mutual disposition of linear complections—later he called them *linear complexes*—with numerous examples drawn from biology and technology. Listing's work *The census of spatial complexes or a generalization of Euler's therorem on polyhedra* Der Census räumlicher Komplexe oder Verallgemeinerung des Euler'schen Satzes von den Polyedern. Göttingen, 1862) *[330]* dealt with more general *spatial complexes*.

Gauss interpreted Leibniz's ideas in the same topological sense. Gauss devoted to topological investigations, as to non-Euclidean geometry, a number of rough notes and letters (see *[196, vol. 8, pp. 407–410]* and the study of Jean Claude Pont *[435a, pp. 31–38]*). When he founded the topology of two-dimensional manifolds and laid the foundations of multidimensional manifolds Riemann also interpreted Leibniz's ideas in the same way. Riemann laid the foundations of two-dimensional topology in his *Theory of Abelian functions* (1857) *[454, pp. 82–142]*, mentioned earlier. In this work he wrote, with reference to Leibniz, that

> For the study of functions which arise as integrals of exact differentials, some theorems belonging to *analysis situs* are nearly indispensable *[454, p. 91]*.

Riemann associates to algebraic functions $f(x, y)$ in the complex variables x and y multisheeted surfaces now called *Riemann surfaces*. He divides these surfaces into

> simply connected ones, in which every closed curve bounds a region of the surface—as, for example, a disk—and multiply connected ones, for which this does not happen—as, for example, an annulus bounded by two concentric circles *[454, p. 22]*.

and points out that by means of a system of cuts it is possible to make a multiply connected surface into a simply connected one. Riemann introduces the characteristic p of a plane algebraic curve (later called by Clebsch *[119]* the genus of the curve) which he defines as half the number of cuts needed to make the corresponding multiply connected Riemann surface into a simply connected one. The number p is now called the *genus of the surface*. We note that, as S. L'Huillier showed *[323]*, for polyhedra the genus p is connected with the Euler characteristic $\chi = N_0 - N_1 + N_2$ of a polyhedron by means of the relation $\chi = 2 - 2p$. For a sphere $p = 0$, for a torus $p = 1$, and for a sphere with p handles it is equal to p. Riemann showed that for a Riemann surface the genus p, the number n of its sheets, and the number w of its branch points are connected by the relation $w - 2n = 2p - 2$.

In a survey that is a supplement to the article *On the hypotheses that lie at the foundations of geometry* Riemann adds a remark in connection with the first chapter of the article *Notion of an n-ply extended magnitude*:

> Chapter 1 is at once an introduction to investigations on *analysis situs* *[454, p. 286]*.

Fragments dealing with *analysis situs* were published in 1876 in an edition of Riemann's collected works *[454, pp. 479–482]*. In these fragments Riemann generalized the topological properties of a two-dimensional surface to an n-dimensional manifold, here called an *n-stretch* (*n-Streck*). Here Riemann defines what are now called *homologous* n-stretches:

> an n-stretch A is said to be transformable into an n-stretch B if A and parts of B together form the complete boundary of an interior $(n + 1)$-stretch *[454, p. 479]*.

Then he gives the extremely important definition:

> If in the interior of a continuously extended manifold it is possible to make every unbounded n-stretch bounding by means of m definite parts of nonbounding n-stretches then this manifold has $(m + 1)$-tuple connection of the n-th dimension.
>
> A continuously extended manifold is called *simply connected* if the connection of every dimension is simple *[454, p. 479]*.

It is easy to verify that for a two-dimensional manifold of genus p Riemann's *connection* is $(2p + 1)$-ple. Then Riemann explains the dependence of the connection of the boundary of a manifold on the connection of the manifold itself.

These ideas of Riemann were set forth by his friend Enrico Betti in the previously mentioned paper *On spaces of an arbitrary number of dimensions* *[55, vol. 2, pp. 273–290]*. By "spaces" Betti meant manifolds in multidimensional Euclidean spaces. He wrote:

> If in an n-dimensional space R, bounded by one or more $(n - 1)$-dimensional spaces, every closed m-dimensional space, $m < n$, is the boundary of a part of a linear connected $(m + 1)$-dimensional space, entirely contained in R, then we shall have a connection in $m + 1$ dimensions and we shall say that R has a *simple* connection of the m-th species. If a space R has only simple connections, then we shall say that it is simply connected. If, however, one can imagine in R a number p_m of closed m-dimensional spaces which cannot form the boundary of a linear connected part of an $(m + 1)$-dimensional space, entirely contained in R, and such that every other closed m-dimensional space forms

> by itself or with some or all of these spaces the boundary of a linear connected part of an $(m + 1)$-dimensional space, entirely contained in R, then we shall say that R has a connection of $(p_m + 1)$-th order of the m-th species *[55, vol. 2, p. 278]*.

These ideas were further developed by Poincaré. Already in the memoir *On curves defined by differential equations* (Sur les courbes definies par les équations differentielles. Paris, 1881–1885) *[431, vol. 1, pp. 90–161]* he made extensive use of topological properties of curves to give qualitative descriptions of solutions of differential equations. Poincaré devoted to the topology of multidimensional manifolds the large memoir *Analysis situs* (the title is taken over from Riemann) (Paris, 1895) *[431, vol. 6, pp. 193–288]* and five supplements to it (Palermo-London-Paris, 1899 1904).

Poincaré determined $(n - p)$-dimensional manifold in n-dimensional space by means of p equations and q inequalities between the n coordinates. Then he defined the boundary of a manifold, homomorphism between manifolds, and homology—the fundamental concept of combinatorial topology. Using this concept he defined the *Betti numbers* of a manifold, that is, Betti's *orders of connection* (in the twenties of this century Solomon Lefschetz (1884–1972) and James Alexander (1888–1971) proposed to call *Betti numbers* numbers b_i one less than Poincaré's *Betti numbers*; cf. *[308]*). Poincaré extended Euler's theorem to polyhedra with arbitrary Betti numbers by showing that

$$N_0 - N_1 + N_2 - \cdots + (-1)^n N_{n-1} = b_0 - b_1 + b_2 - \cdots - (-1)^n b_{n-1}.$$

The polynomial $\sum b_i t^i$ is called the *Poincaré polynomial*. In the same paper Poincaré also laid the foundation for the homotopic theory of manifolds in which a leading role is played by the noncommutative *Poincaré group* introduced by him.

Topological Spaces

At the beginning of the 20th century, in connection with the spread of the group-theoretic viewpoint, mathematicians began to study *abstract spaces* together with the study of topological invariants of manifolds that are submanifolds of Euclidean spaces or are obtained from such manifolds by identification of points (as in the case of obtaining the projective plane from a sphere) or by splitting them into points of various sheets (as in the case of constructing the Riemann surface of an algebraic function out of its domain of definition in the complex plane). One of the first works in this direction was the paper *On certain points of the functional calculus* (Sur quelques points du calcul fonctionelles. Palermo, 1906) *[184]* of the French mathematician Maurice Fréchet (1878–1973). In this paper Fréchet defines for the first time an *abstract metric space* exemplified by a space of functions or curves. To construct an abstract space Fréchet found it necessary

> to generalize, first of all, the theory of linear sets that has brought about so much progress in the theory of functions of a single variable,

by which theory he meant the, by that time, extensively developed theory of sets of points of the real line. Fréchet goes on to say:

> If we assume this preliminary investigation of sets then there arises a difficulty. The first generalization that seems natural is that of the notion of a continuous function. But if one wishes to consider operations where the variable is an element of arbitrary nature, then we must first know what is to be meant by neighboring elements or by the limit of a sequence of elements. This seems impossible: usually one gives a special definition of limit for each category of elements under study— points, curves, and so on. I circumvented this difficulty by a method similar to that which allows one to reason in the theory of abstract groups about a composition of explicitly indeterminate form.
>
> Now I note that almost all (but not all) classical definitions of limit can be formulated as follows: in the given category of elements one can associate to each pair of elements a number $\rho(A, B)$ whose properties are very close to the properties of distance of two points, namely that A coincides with B if $\rho(A, B) = 0$ and A tends to B if $\rho(A, B)$ tends to zero. If we accept this hypothesis, less general but nevertheless very broad, then we obtain numerous more specific results.
>
> The approach just outlined leads to the generalizing of almost all theorems about linear sets and about continuous functions (at least those that can be formulated independently of the nature of the investigated sets) *[184, pp. 1–2]*.

When mentioning abstract groups Fréchet emphasizes that he is applying the same methods of creating abstract mathematical concepts that have hitherto been used only in algebra, where, together with the abstract theory of groups, founded in the seventies of the 19th century, there also appeared Dedekind's abstract ring theory.

Developing his program, Fréchet defines a general metric space, which he calls *class* (V), as

> a set of elements of arbitrary nature such that we know how to determine whether two given elements are identical or not and, in addition, such that to any two of them, A, B, we can associate a number $(A, B) = (B, A)$ with the following two properties:
>
> 1′ The necessary and sufficient condition that (A, B) is zero is the identity of A and B.
>
> 2′ There exists a completely determined positive function $f(\varepsilon)$ such that the inequalities $(A, B) \le \varepsilon$ and $(B, C) \le \varepsilon$ imply $(A, C) \le f(\varepsilon)$ for all elements A, B, C. In other words, for (A, C) to be small it suffices that (A, B) and (B, C) are small *[184, p. 18]*.

At present, metric spaces are defined by means of three axioms: the *identity axiom* that coincides with Frechet's axiom 1′; the *symmetry axiom* $(A, B) = (B, A)$ that Frechet regards as part of the definition of distance; and the *triangle inequality axiom* $(A, B) + (B, C) \geq (A, C)$ that replaces Fréchet's axiom 2′.

Fréchet goes on to consider sets in metric spaces, limits of sequences, and limit points of sets. All limit points of a set form its *derived set*. Sets that contain all their limit points are called *closed*, and complements of closed sets with respect to the whole space are called *open* sets. The intersection of all closed sets containing a given set M is called the *closure* $\bar{\bar{M}}$ of the set M. Then, after defining the Cauchy criterion for a sequence of elements $A_1, A_2, \ldots$ of the metric space as the possibility of associating to every $\varepsilon > 0$ an integer n with the property that the inequality $(A_n, A_{n+p}) > \varepsilon$ is satisfied for every p, Fréchet defines a *complete* metric space as a metric space in which every sequence satisfying the Cauchy criterion has a, necessarily unique, limit.

Fréchet restricts himself to spaces that can be regarded in at least one way as the derived sets of countable sets of their elements. He considers metric spaces of functions with different definitions of distance.

The definition of limit points and closed sets made it possible to introduce continuous mappings and homeomorphisms of the metric spaces considered by Fréchet. Fréchet's paper became the starting point for the development of a general theory of abstract spaces and for the development of the basic concepts of functional analysis.

Since distance is not needed for the study of topological properties of abstract spaces, just as it is not needed for the study of topological properties of lines and surfaces, soon after the appearance of abstract spaces Felix Hausdorff (1868–1942) in his *Foundations of set theory* (Grundzüge der Mengenlehre. Leipzig, 1914) *[217; 218]* defined an *abstract topological space*. Hausdorff defined a topological space as any collection of elements, called *points*, with a distinguished collection of subsets $\{U\}$, such that to each point x there are associated some, and, at the very least, one of the sets of the system $\{U\}$, called *neighborhoods* $U(x)$ of x; the intersection of any two neighborhoods $U_1(x)$ and $U_2(x)$ contains a neighborhood $U_3(x)$ of this point, and if y is a point of a neighborhood $U(x)$ then there exists a neighborhood $U(y)$ of y contained in $U(x)$. Prescribing neighborhoods makes it possible to define limit points of any set M as points x such that every neighborhood of x contains at least one point of M other than x. Just as in Fréchet spaces so too in a topological (Hausdorff) space one defines derived, closed, and open sets. It is easy to see that all neighborhoods are open sets.

Every Fréchet metric space is a topological space. In fact, one can take as neighborhoods the sets of points whose distances from the points of a (fixed) countable set, whose derived set is the whole space, are less than some rational numbers. It is easy to see that the number of such neighborhoods is countable, or, as one says, the space has a *countable basis*.

A further development of the Hausdorff definition is the definition of a topological space proposed by the Polish mathematician Kazimierz Kuratowski (1896–1980) in the paper *The operation $\bar{A}$ of analysis situs* (L'operation $\bar{A}$ de l'analysis situs. Warsaw, 1922) *[296]*. By *operation $\bar{A}$* Kuratowski means the transition from a set A to its closure $\bar{A}$. According to Kuratowski, a topological space is a collection of elements of arbitrary nature, called *points*, on whose subsets A there is defined an operation of *closure* satisfying the following axioms:

1′ for the union $A + B$ of two sets A and B we have $\overline{A + B} = \bar{A} + \bar{B}$;
2′ a set A is contained in its closure, $A \subset \bar{A}$;
3′ the closure of the empty set $\varnothing$ coincides with it, $\overline{\varnothing} = \varnothing$;
4′ the closure of the closure coincides with the closure, $\bar{\bar{A}} = \bar{A}$.

If for every set there is defined its closure $\bar{A}$ then the points of $\bar{A}$ not in A are called the *limit points of* A; the sets A that coincide with their closures A are called the *closed sets*, and their complements relative to the whole space are called the *open sets*.

The Soviet mathematician Pavel Sergeevič Aleksandrov [Alexandroff] (1896–1983) proposed in the paper *On the foundation of* n*-dimensional topology* (Zur Begründung der *n*-dimensionalen Topologie. Leipzig, 1925) *[14]* a more symmetric form of Kuratowski's definition:

1. A topological space is a set of elements of arbitrary nature, called *points*, in which certain subsets, called *open sets*, have been singled out such that:
   1′ the whole space is an open set;
   2′ the null set is an open set;
   3′ the intersection of finitely many open sets is an open set;
   4′ every union of open sets is an open set.
2. A topological space is a set of elements of arbitrary nature, called points, in which certain subsets, called *closed sets*, have been singled out such that:
   1′ the whole space is a closed set;
   2′ the null set is a closed set;
   3′ every union of closed sets is a closed set;
   4′ the intersection of finitely many closed sets is a closed set.

In the first case a closed set is defined as the complement of an open set and in the second case an open set is defined as the complement of a closed set. Neighborhoods can be defined as subsystems of open sets such that an arbitrary open set can be represented as the union of sets of this subsystem (see *[218, p. 258]*).

To different systems of closed or open subsets in the same set of points there correspond different topologies on this set. For example, our axiom systems are satisfied if

(A) the only closed (and open) sets are the whole space and the null set;
(B) the closed (and open) sets are all sets of points of the space.

In case (A) the closures of all nonempty sets, including single points, coincide with the whole space. In case (B) the closure of each set coincides with this set, and a minimal system of neighborhoods is a system in which the neighborhood of each point is that point alone. Then the space has no limit points and is called *discrete*; the space of case (A) is called *trivial*.

Hausdorff ruled out case (A) by means of the following axiom: for any two points of the space there are disjoint neighborhoods *[218, p. 260]*. Sometimes Hausdorff's axiom is replaced with a weaker one due to Frigyes Riesz, that the closures of all single points of the space are the points themselves *[456, vol. 1, pp. 155 169]*—or by an even weaker axiom introduced by the Soviet mathematician Andreĭ Nikolaevič Kolmogorov (1903 1987), that any two points of the space have different closures *[15, p. 58]*.

A very important class of topological spaces is the class of *compact spaces* such that every covering of the space by means of open sets contains a finite subcovering. The Soviet mathematicians P. S. Aleksandrov and Pavel Samuilovič Uryson [Urysohn] (1898–1924) studied such spaces in the case when the minimal cardinality of a system of neighborhoods is greater than the cardinality of a countable set and called them *bicompact [16]*. For these spaces P. S. Aleksandrov developed a homology theory analogous to the homology theory of manifolds in Euclidean spaces. By now mathematicians have found a great many topological invariants of the most varied topological spaces.

One of the most obvious topological invariants is the dimension of a topological space. Whereas it is possible to have a one-to-one correspondence between manifolds of different dimensions, a one-to-one bicontinuous correspondence can only be established between manifolds of the same dimension. If the points of a topological space have neighborhoods homeomorphic to n-dimensional Euclidean space then it is natural to say that the dimension of the space is n. In more complicated cases dimension was defined by the Dutch mathematician Luitzen Egbertus Jan Brouwer (1882–1966) in the paper *Proof of the invariance of the dimension number* (Beweis der Invarianz der Dimensionzahl. Leipzig, 1911) *[80]*. The ideas of Brouwer were developed by Urysohn in *A memoir on Cantor manifolds* (Memuar o kantorovyh mnogoobraziyah. 1928) *[599]* and by the German mathematician Karl Menger (b. 1902) in *Dimension theory* (Dimensionstheorie. Leipzig, 1932) *[362]*. They defined dimension by induction on the dimension number, beginning with the dimension -1 which they assigned to the empty set.

Urysohn and Menger also proposed another definition of dimension, equivalent to the preceding for the most important topological spaces: a nonempty space is n-dimensional if every finite covering of the space has a finite subdivision of order $\leq n$ and there exists a finite covering of the space without finite subdivisions of order $< n$. A nonempty space is infinite-dimensional if it is not n-dimensional for any nonnegative n. The dimension of the null set is again taken to be -1.

In the previously mentioned paper Brouwer proved his famous *fixed-point* *theorem*: every continuous mapping of an n-dimensional simplex into itself has at least one fixed point. This theorem was first proved by the Latvian mathematician Piers Bohl (1865–1921), who worked in Riga, in the paper *On the motion of a mechanical system near an equilibrium position* (Über die Bewegung eines mechanischen Systems in der Nähe einer Gleichgewichtlage. Berlin, 1904) *[64, pp. 79–125]*. The Bohl-Brouwer theorem was extended to infinite-dimensional analogues of an n-dimensional simplex by the Soviet mathematician Andrei Nikolaevič Tihonov [Tychonoff] (b. 1906) *[597]*. Bohl came to the fixed-point theorem in connection with the problem of proving the existence of a solution of a system of differential equations connected with the notion of certain mechanical systems he investigated. The Bohl-Brouwer theorem was later used to prove the existence of solutions of finite systems of ordinary differential equations, and the Tihonov theorem was used to prove the existence of solutions of infinite systems of differential equations.

The Influence of the General Theory of Relativity

We have already pointed out the importance of Einstein's discovery of the special theory of relativity for the elaboration of the concept of pseudo-Euclidean geometry. For example, the appearance of Weyl's book *Space, time, matter [626]* in which, among other matters, he set forth his axiomatization of n-dimensional Euclidean space, was connected with the general theory of relativity. But the importance of the general theory of relativity for the development of geometry is far broader and deeper. Whereas in the special theory of relativity spacetime was viewed as a pseudo-Euclidean space, in the general theory it is viewed as an analogue of a Riemannian space that stands in the same relation to such a space as pseudo-Euclidean space to Euclidean space. Such a space is now called a *pseudo-Riemannian* or *general Riemannian space*. Just as in a Riemannian space, so too at each point of this space there is given the square of a line element

$$ds^2 = \sum_i \sum_j g_{ij} dx^i dx^j,$$

where the g_{ij} are point functions and, although the quadratic form is no longer positive definite, it can be reduced at each point to the form

$$ds^2 = -(dx^0)^2 + (dx^1)^2 + (dx^2)^2 + (dx^3)^2.$$

The first sketch of the general theory of relativity was set forth by Einstein together with the German mathematician Marcel Grossmann (1878–1936) in *Outline of a generalized theory of relativity and theory of gravitation* (Entwurf einer verallgemeinerten Relativitätstheorie und Theorie der Gravitation. Leipzig, 1913), and the final theory was presented in *Foundations of the general theory of relativity* (Grundlagen der allgemeinen Relativitätstheorie. Leipzig, 1916) *[340, pp. 109–164]*.

Already in the 1913 paper Einstein and Grossmann used the *tensor calculus* created by the Italian geometer Gregorio Ricci-Curbastro (1853–1925) in *Principles of a theory of differential quadratic forms* (Principii di una theoria delle forme differenziale quadratiche. Milan, 1884) *[453, vol. 1, pp. 138–171]* and subsequently developed together with Tullio Levi-Civita (1873–1941) in *Methods of the absolute differential calculus and their applications* (Méthodes du calcul différentiel absolu et leurs applications. Leipzig, 1901) *[453, vol. 2, pp. 185–271]*. Ricci gave the name *covariant system of the first order* to the functions a_i of the coordinates x^i that change as a result of a coordinate transformation $x^{i'} = x^{i'}(x^1, \ldots, x^n)$ in accordance with the rule

$$a_{i'} = \sum_i a_i \frac{\partial x^i}{\partial x^{i'}}, \tag{8.7}$$

exemplified by the law of transformation of partial derivatives $\frac{\partial \varphi}{\partial x^i}$, and the name *contravariant system of the first order* to functions a^i of the coordinates x^i that transform in accordance with the opposite rule

$$a^{i'} = \sum_i a^i \frac{\partial x^{i'}}{\partial x^i}, \tag{8.8}$$

exemplified by the law of transformation of the differentials dx^i of the coordinates. Ricci considered scalars as systems of zero order.

Ricci called the functions a_{ij}, a^{ij}, and a^i_j that transform in accordance with the respective rules

$$a_{i'j'} = \sum_i \sum_j a_{ij} \frac{\partial x^i}{\partial x^{i'}} \frac{\partial x^j}{\partial x^{j'}}, \quad a^{i'j'} = \sum_i \sum_j a^{ij} \frac{\partial x^{i'}}{\partial x^i} \frac{\partial x^{j'}}{\partial x^j}, \quad a^{i'}_{j'} = \sum_i \sum_j a^i_j \frac{\partial x^{i'}}{\partial x^i} \frac{\partial x^j}{\partial x^{j'}}, \tag{8.9}$$

twice covariant, *twice contravariant*, and *mixed* systems of the second order.

Ricci defined in a similar way systems of higher order. Contravariant systems of the first order at a point can be regarded as coordinates of vectors; covariant systems of the first order at the same point can be regarded as coefficients of linear forms defined on these vectors; twice covariant systems of the second order can be regarded as coefficients of bilinear forms defined on these vectors, and mixed systems of the second order can be regarded as matrices of linear transformations defined on these vectors. Einstein and Grossmann proposed that Ricci's "systems" be called *tensors* (and thus extended to them the term *elastic tensor* and that the "orders" of the systems be called *ranks*. The Dutch geometer Jan Arnoldus Schouten (1883–1971) in his *Ricci calculus* (Der Ricci-Kalkül. Berlin, 1924) *[510]* called Ricci's systems *affinors* and thereby extended to them a term used by F. Jung for linear operators; he called "orders" of the systems *valences*, borrowing this term from chemistry.

Most mathematicians now use the term *tensor* in the sense of Einstein and *valence* in the sense of Schouten. Following Einstein's suggestion, in the tensor calculus one omits the summation sign when summing with respect to covariant and contravariant indices. We will follow this rule in the following.

The coefficients of the quadratic form that defines the metric of a Riemannian space form a twice covariant tensor g_{ij}; the quadratic form is written in tensor notation as

$$ds^2 = g_{ij}dx^i dx^j, \tag{8.10}$$

and the equation of the geodesics is written as

$$\frac{d^2x^i}{dt^2} + \Gamma^i_{jk}\frac{dx^j}{dt}\frac{dx^k}{dt} = 0. \tag{8.11}$$

The Christoffel symbols Γ^i_{jk} do not form a tensor and transform under coordinate transformations in accordance with a more involved law. But the four-index Riemann symbols, now written as $R_{ij,k}^{\cdot\cdot\cdot l}$, do form a tensor of valence four called the *curvature tensor*.

Covariant differentiation as defined by Ricci associates to every tensor field in a Riemannian space—that is, to every function that defines a tensor at every point of a region in a Riemannian space—the field of a new tensor that has one additional covariant valence. The covariant derivative $\nabla_i\varphi$ of a scalar is its partial derivative $\dfrac{\partial\varphi}{\partial x^i}$ with respect to the coordinate x^i. The covariant derivatives $\nabla_j a^i$ and $\nabla_j a_i$ of vectors a^i and a_i are given by

$$\nabla_j a^i = \frac{\partial a^i}{\partial x^j} + \Gamma^i_{jk}a^k, \qquad \nabla_j a_i = \frac{\partial a_i}{\partial x^j} - \Gamma^k_{ji}a_k. \tag{8.12}$$

The covariant derivatives $\nabla_k a_{ij}$ and $\nabla_k a^i_j$ of the tensors a_{ij} and a^i_j have the form

$$\nabla_k a_{ij} = \frac{\partial a_{ij}}{\partial x^k} - \Gamma^l_{ki}a_{lj} - \Gamma^l_{kj}a_{il}, \qquad \nabla_k a^i_j = \frac{\partial a^i_j}{\partial x^k} + \Gamma^i_{kl}a^l_j - \Gamma^l_{kj}a^i_l. \tag{8.13}$$

The Geometry of the General Theory of Relativity

Einstein formulated the principle of general relativity in *The foundations of the general theory of relativity* as follows:

> The general laws of nature are to be expressed by equations which hold good for all systems of co-ordinates, that is, are covariant with respect to any substitutions whatever (generally covariant) *[340, p. 117]*.

The most important element of the general relativity theory is the geometric interpretation of gravity. In this theory gravitation is linked to the curvature of space, whose definition in a pseudo-Riemannian space is the same as that in a Riemannian space; the greater the density of matter in a certain region, and thus the intensity of the gravitational field, the greater the curvature of pseudo-Riemannian spacetime. A mass point subject to gravitational forces alone moves along a geodesic which satisfies the same equations as in Riemannian space.

Light rays, too, propagate along geodesics of pseudo-Riemannian spacetime. The deflection of the trajectories of material particles and of light rays from straight lines represents the attraction of particles of matter and of light by the heavy masses that gives rise to the gravitational field. In this connection we quote from Einstein's paper *On the ether* (Über den Aether. Zürich, 1924) *[166]*:

> General relativity theory sets aside one other shortcoming of classical dynamics: in the latter, inertia and weight appear as phenomena that are completely independent from one another in spite of the fact that both are conditioned by the same material constant -- mass. Relativity theory surmounts this shortcoming by establishing for the dynamical behavior of an electrically neutral particle the law of geodesics in which the interaction of inertia and gravitation is already inseparable. This interaction imparts to the ether a metric that varies from point to point and properties that determine the dynamical behavior of material points. In turn, these are determined by physical factors, namely the distribution of mass or energy. Thus the ether of general relativity differs from the ether of classical mechanics in that it is no longer "absolute" but is determined in the sense of its properties, that vary in space, by the distribution of weighted matter. This definition is complete provided that the world is spatially finite and closed *[166, p. 89]*.

Here the word *ether* is used in the sense of curved space whose geometric properties are determined by matter; in other papers Einstein replaces this term by the term *space-time continuum*. Einstein's reference to the finite and closed character of the universe reflects his original view that the curvature of space implies that space is finite and closed. (Cf. the paper *[649]* of Yakov Borisovič Zel'dovič (1914–1988).)

General relativity theory has given a physical interpretation to the curvature of pseudo-Riemannian spacetime. Light rays propagate along the isotropic geodesics of this spacetime. The deviation of the trajectories of material points and light rays from geodesics represents the attraction of material points and light by the heavy masses that give rise to the gravitational field.

The primary connection between non-Euclidean geometry and general relativity is that the discovery of non-Euclidean geometry extended the range of conceivable spaces and thus prepared the ground for the discovery of spaces of variable curvature, both Riemannian and pseudo-Riemannian; the latter represents the mathematical apparatus of general relativity. However, there is also a direct link between general relativity and non-Euclidean

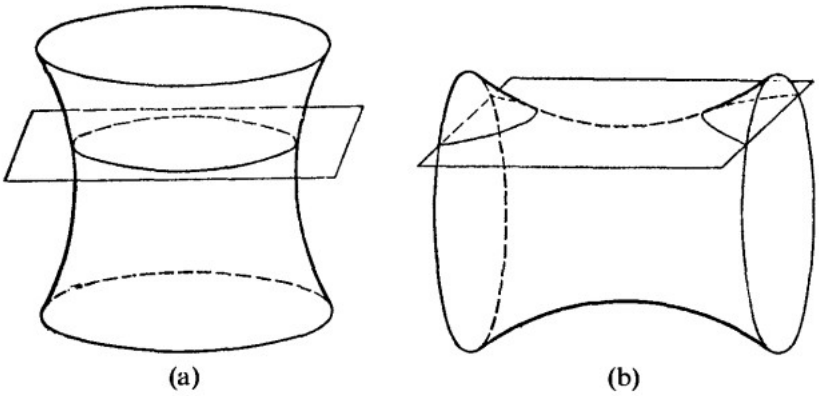

Figure 105

geometry, but what is involved is a four-dimensional rather than a three-dimensional space as in the case of special relativity. The geometry in question describes the spacetime of general relativity "in the mean," under the assumption of the uniform distribution of matter. This view was presented by Einstein already in the paper *Cosmological considerations linked to the general relativity theory* (Kosmologische Betrachtungen zur allgemeinen Relativitätstheorie. Berlin, 1917) *[340, pp. 175–189]*. Here Einstein considered a uniform distribution of matter in space alone, regarding space itself as a sphere in four-dimensional Euclidean space and spacetime as a cylinder in five-dimensional space. However, if we proceed from the assumption that we are dealing with a uniform distribution of matter throughout the spacetime continuum then spacetime is a sphere of real or imaginary radius in five-dimensional pseudo-Euclidean spaces of indices 4 and 3, respectively. If we assume, for simplicity, that the hypersurfaces $t =$ const. are parallel hyperplanes, then, in time, the "space section" of the world decreases or increases, depending on the position of the cutting hyperplane. In the first case the curvature of the "space section" is constant and positive, whereas in the second case it is constant and negative (Figures 105a and 105b), in full agreement with astronomical observations. This confirmation shows that real spacetime, that is, a pseudo-Riemannian space of variable curvature, corresponds in the mean to the picture just outlined; the theory of an expanding universe of constant negative curvature was proposed by A. A. Friedmann in the paper *On the possibility of a world of constant negative curvature* (Über die Möglichkeit einer Welt mit konstanter negativer Krümmung des Raumes. Leipzig, 1924) *[188]*.

The view of spacetime as a four-dimensional pseudo-Riemannian space of index 3 with positive curvature was proposed by the Belgian astronomer Willem de Sitter (1872 1934) in the paper *On Einstein's theory of gravitation and its astronomical consequences* (Brussels, 1917) *[541]*. In the paper *Geometrical note on de Sitter's world* (London, 1924) *[158]* Patrick du Val showed that "de Sitter's world" is a Lobačevskian space of positive curvature, that is, a sphere of real radius in five-dimensional pseudo-Euclidean space of index 4 with identified antipodal points (see also *[129a]*).

Einstein's Philosophy of Space

The discovery of the general theory of relativity was a brilliant concretization of the connection between matter and space and time, which are an existence form of matter— an issue often addressed by the classics of Marxism.

Einstein dealt with the philosophical questions of space in many of his papers. One relevant passage is the preceding quotation from his paper *On the ether*. The following quotation is from the paper *Geometry and experience* (Geometrie und Erfahrung. Berlin, 1921) *[165]*:

> Of all sciences mathematics is held in especially high esteem, for its theorems are absolutely true and indisputable while the areas of other sciences are to some extent debatable and there is always the danger of their results being overturned by new discoveries. But it is not fitting for a researcher working in some other area of science to envy mathematics, for the propositions of mathematics rest not on real objects but exclusively on objects of our imagination. In fact, it is little wonder that one attains logical agreement of deductions if one earlier reached agreement concerning the principal propositions (axioms) as well as the methods to be employed for deriving from the principal propositions other propositions. At the same time, the deep esteem for mathematics has another basis, which is that mathematics is that which gives to the exact sciences a measure of confidence which they could not otherwise attain.
>
> In this connection there arises a riddle that has worried researchers of all times. Whence the remarkable correspondence between mathematics and real things if mathematics is just a product of human thought unrelated to any experience? Can the human mind understand the properties of real things without any experience, just by way of reflection?
>
> To my mind, a concise answer to this question is this: to the extent to which the theorems of mathematics can be applied to reflect the real world they are not exact; they are exact to the extent to which they do not refer to reality. It seems to me that complete clarity in this matter can be achieved only by following the kind of mathematics known as axiomatics. The progress achieved through axiomatics consists in the fact that it sharply separated its formal-logical content from its objective and intuitive content. By point, straight line, and so on, in axiomatic geometry one should mean only contentless ideas. That which gives them content lies outside mathematics.
>
> On the other hand, however, it is true that mathematics in general and geometry in particular owe to their origins the necessity of learning

> a little about the behavior of objects existing in reality. This is shown by the very word "geometry" which means "measurement of the earth" *[165, pp. 3–5]*.

In this paper Einstein arrives

> at the viewpoint held by as original and deep a thinker as Henri Poincaré: Euclidean geometry differs from all conceivably possible axiomatic geometries by its simplicity. And since axiomatic geometry contains no statements about actual reality and can make such statements only in conjunction with physical laws, it seems possible and reasonable to adhere to Euclidean geometry regardless of the properties of reality. On the other hand, in case of an observed disagreement between theory and experience, it is easier to agree to change physical laws than axiomatic Euclidean geometry. If one forgets all about the connection between a practically rigid body and geometry, then it is not easy to refuse to admit that Euclidean geometry must be viewed as simplest.
>
> Why did Poincaré and other researchers reject the equivalence that thrusts itself upon one between a practically rigid body of real experience and a geometric body? Simply because, when one considers them more closely, real rigid bodies in nature turn out not to be rigid at all, since their geometric behavior, that is, their possible mutual disposition, depends on temperature, external forces, and so on. Thus the initial direct connection between geometry and physical reality is destroyed and we are forced to shift to the following more general position characteristic of Poincaré's viewpoint. Geometry (G) tells us nothing about the behavior of real objects; this behavior is described only by geometry together with the totality of physical laws (Ph). In symbolic terms we can say that only the sum (G) + (Ph) lends itself to experimental verification. Thus one can choose arbitrarily (G) as well as different parts of (Ph); all of these laws represent agreements. To avoid contradictions it is necessary to choose the rest of (Ph) so that (G) and all (Ph) are experimentally verifiable *[165, pp. 7–8]*.

We see that Einstein refers here to the philosophical works of Poincaré mentioned earlier but, unlike Poincaré, who treated "objective reality" and "laws of nature" in the spirit of Mach, Einstein proceeds from "physical reality" and the possibility of "choosing arbitrarily" (G), that is, geometric axioms which, together with (Ph), that is, physical laws, must confront experience. Thus Einstein interprets Poincaré's position in materialistic terms and, like Lobačevskiĭ, believes that the question of which of the conceivable geometric systems corresponds to the geometry of the real world must be decided experimentally.

It should be pointed out that Einstein frequently refers to Mach, whom he regards as one of his predecessors. In the obituary *Ernst Mach* (Ernst Mach. Leipzig, 1916) Einstein considered Mach's critique of Newton's mechanics and wrote:

> The quoted lines show that Mach clearly understood the weak points of classical mechanics and came close to discovering the general relativity theory. And that half a century before its creation! *[167]*.

Einstein regarded Mach's idea that the inertia of a body is explainable by its interaction with other bodies—what Einstein called *Mach's principle*—as one of the factors in the preparation of the general relativity theory. Mach's idea that "space and time cannot be completely separated from one another" *[347, p. 350]* is very close to the ideas of special relativity theory.

Undoubtedly, Einstein's famous *thought experiments* were influenced by Mach. At the same time Einstein did not agree with Mach's doctrine of sensations as elements of the world. He not only interpreted the terms *sensations* and *experience* in a materialist spirit but also ascribed his viewpoint to Mach when he said (apropos Mach's use of the term *sensations*) that

> frequently, as a result of insufficient familiarity with his, that is, Mach's, works, some persons tend to confuse them with the terminology of philosophical idealism and solipsism *[167]*.

Here Einstein's opinion was based on the fact that he took Mach's materialist terminology literally and throught it inconceivable that a serious physicist could be a subjective idealist. Later Einstein changed his opinion about Mach's philosophy and during a meeting of the French philosophical society, while answering a question from Emile Meyerson, he referred to Mach as a "deplorable philosopher" (*un déplorable philosophe*) and accused him of a "myopic view of science that led him to reject the existence of atoms" *[364, p. 62]*.

Parallel Displacement

The heightened interest in Riemannian geometry brought about by general relativity theory resulted in an extremely important discovery in this geometry, a concept known as *parallel displacement of vectors*. The discovery was made by Levi-Civita in the paper *The notion of parallelism in an arbitrary manifold and the geometric characterization of Riemannian curvature implied by it* (Nozione di parallelismo in una varieta qualunque e consequente specificazione geometrica della curvatura Riemannina. Palermo, 1917) *[320]*.

If a vector a^i is defined at a point A of a Riemannian space then the result of its displacement to a point B of the line $x^i(t)$ is a solution of the differential equation

$$\frac{da^i}{dt} + \Gamma^i_{jk} a^j \frac{dx^k}{dt} = 0, \tag{8.14}$$

that can be written with the help of the covariant derivative as

$$\nabla_k a^i \frac{dx^k}{dt} = 0. \tag{8.15}$$

It follows that if one defines along a coordinate line a vector field of vectors obtained by parallel displacement of a given vector then at all points of this line the covariant derivative with respect to the corresponding coordinate is equal to zero. Parallel displacement of vectors admits of a visual geometric definition. Parallel displacement of vectors from a point A of the space to an infinitely near point B is generated by mapping a neighborhood of the point A onto a neighborhood of the point B that is the result of applying first a reflection (along geodesics) in the point A in the neighborhood of A, and then a reflection in C, the midpoint of the geodesic arc from A to B, in a neighborhood of C that contains the neighborhood of A. Under this neighborhood mapping the increments of the coordinates of the point A map to the increments of the coordinates of the point B and, consequently, the differentials of the coordinates of A, that is, the vectors at A, map to the differentials of the coordinates of B, that is, the vectors at B. The name *parallel displacement* is due to the fact that the product of two reflections in two points in ordinary space is a translation of this space. Levi-Civita showed that the curvature of a Riemannian space, at a given point, in a two-dimensional direction is the limit of the ratio of the angle by which a vector is rotated as a result of parallel displacement along a closed contour passing through the given point to the area of the surface bounded by this contour when the contour shrinks to the given point (this is Levi-Civita's *geometric characterization of Riemannian curvature*).

The Problem of a Unified Field Theory

In general relativity theory the geometric properties of space are determined by the gravitational field alone, without any effect of the electromagnetic field on the geometry of space. After creating the general theory of relativity Einstein posed the problem of constructing a geometry of four-dimensional spacetime determined by the electromagnetic as well as the gravitational field. The first attempt of construction of a unified field theory was made by Hermann Weyl in his paper *Gravitation and electricity* (Gravitation und Elektrizität. Leipzig, 1918) *[340, pp. 200–216]*. Besides the metric quadratic form

$$ds^2 = \sum_{\mu,\nu} g_{\mu\nu} dx^\mu dx_\nu \tag{2}$$

Weyl considers also the linear form

$$d\phi = \sum_{\mu} \phi_\mu dx_\mu \tag{7}$$

and writes that

> *The internal metrical connexion of space thus depends on a linear form* (7) *besides the quadratic form* (2)—which is determined except as to an arbitrary factor of proportionality *[340, p. 206]*.

The vector ϕ_μ is the *vector-potential* of the electromagnetic field $F_{\mu\nu}$ given by

$$F_{\mu\nu} = \partial\phi_\mu/\partial x_\nu - \partial\phi_\nu/\partial x_\mu.$$

The geometry constructed by Weyl is called the *Weyl connection*. Weyl expounded this theory also in his *Space, Time and Matter* (1918) *[626]*.

Einstein himself devoted the last 35 years of his life to the search for a unified field theory. Of other attempts at constructing a unified field theory we note, first of all, the paper of Theodor Kaluza (1885–1954) *On the unicity problem of physics* (Zum Unitätsproblem der Physik. Berlin, 1921) *[259]*. To increase the number of relevant parameters Kaluza went in the direction of increasing the number of dimensions of his space and assumed that in addition to the four dimensions of physical spacetime there is a fifth dimension without a direct physical sense. Proceeding from Kaluza's idea the mathematician Veblen and the physicist Pauli proposed in 1930–1933 a unified field theory in which five coordinates are viewed as the projective coordinates of particles in a four-dimensional space.

A detailed history of unified field theories in the first third of the 20th century is given by Vladimir Pavlovič Vizgin in the book *Unified field theories in the first third of the 20th century* (Edinye teorii polya v pervoĭ treti XX veka. Moscow, 1985) *[615]*.

We note that when Einstein posed the question of a unified field theory he assumed that the theories of interactions of the gravitational and electromagnetic fields exhaust all forms of physical interactions. The discovery, in the last few decades, of "strong" and "weak" interactions that do not coincide with these interactions deprived the problem posed by Einstein of the importance he attached to it. In his "Remarks to the Einsteinian sketch of a unified field theory" the famous German physicist Werner Heisenberg (1901–1976) wrote:

> This attempt, grandiose in its conception, failed from the very beginning. At the time when Einstein concerned himself with the unified field theory new elementary particles were continuously discovered and with them their associated new fields. This meant that there existed no hard, solid, empirical basis for the implementation of the Einsteinian program and Einstein's attempts produced no conclusive results whatever. However, the failure that dogged the Einsteinian program also had deeper foundations than the uncertainty of empirical facts; these foundations have to do with the relations of Einstein's field-theoretic view of quantum theory. Einstein proceeded from the classical nonlinear field theory of matter for the metric tensor of the field that defined his geometry.

> Einstein hoped that in the end it will be possible to think of atoms and elementary particles in such a theory as singular solutions of the nonlinear equations of the field. In reality, however, the element of discreteness that expresses the existence of elementary particles has a far wider character. It becomes dominant as soon as we go over to the domain of atoms and elementary particles; which is why their description by means of a field theory of the classical type is out of the question. Conversely, we now know that there operate here quantum-mechanical laws whose structure was understood in the twenties. Since Einstein could not come to terms with such a structure, he did not make an attempt to approach the unified field theory using quantum laws.
>
> Nevertheless, experiments with elementary particles carried out in connection with quantum theory contain very many arguments in favor of Einstein's program.
>
> In the last ten years many elementary particles have been discovered and thus also many new fields. Also, it became clear that elementary particles can change into one another. If two elementary particles with very high kinetic energy collide in some way then there can arise new particles, and the laws that govern the coming into existence and the disappearance of elementary particles can, apparently, be formulated by means of relatively simple selection rules and the corresponding quantum numbers. It follows that all elementary particles "consist," so to say, of one and the same substance that can be simply called "energy" or "matter"; their structure and their ability to go over into one another should follow from a simple law for matter.
>
> Thus, by the nature of things, a satisfactory theory of elementary particles must, at the same time, be a unified field theory of matter *[221a, pp. 120 - 125]*.

An attempt to create such a unified theory of elementary particles was made by Heisenberg himself.

Spaces with Affine Connection

Although the problem of a unified field theory has not yielded any substantial results for physics, it has been remarkably fruitful for geometry. Weyl's theory was further developed by Schouten, who introduced the general notion of a space with an affine connection in the paper *On different forms of connection that can be laid at the foundation of a differential geometry* (Über die verschiedenen Arten der Übertragung die einer Differentialgeometrie zugrunde gelegt werden können. Berlin, 1922) *[511]*. A detailed exposition of Schouten's theory is found in his *Ricci calculus*. A space with an affine connection is defined as a manifold of points with coordinates x^i at each of whose points there is given a point function $\Gamma^i_{jk} = \Gamma^i_{kj}$ that is not expressible in the general case in terms of the point functions g_{ij}. Because of this last condition it is not possible, in the general case, to define in a space with an affine connection the length of lines, but it *is* possible to define parallel displacement of vectors by formula (8.14). In a space with an affine connection geodesics are defined. They are solutions of the equations (8.11). For each arc of a geodesic there is defined its midpoint. In such a space one can define reflections in points along geodesics. Just as in a Riemannian space, the geometric sense of parallel displacement of vectors is that it is determined by a mapping of a neighborhood of a point of the space onto a neighborhood of an infinitely near point that is the result of two reflections in two points along geodesics. The name *affine connection* is due to the fact that the mapping of vectors at a point of space onto vectors at an infinitely near point of this space is an affine transformation of vector spaces.

It is clear that Riemannian and pseudo-Riemannian spaces are special cases of spaces with an affine connection. In such spaces the mapping of vectors at one point onto vectors at an infinitely close point under parallel displacement is an isometry of Euclidean and pseudo-Euclidean spaces, respectively.

The space introduced by Weyl in his unified field theory is also a space with an affine connection. In this space the mapping of vectors at one point onto vectors at an infinitely close point under parallel displacement is a similarity transformation.

Even more general spaces were introduced by the French mathematician Élie Cartan (1869–1951). In the papers *On manifolds with an affine connection and the generalized relativity theory* (Sur les variétés à connexion affine et la théorie de la relativité généralisée. Paris, 1923) *[96, part 3, pp. 659–746, 798–825, 921–992]*, *Spaces with a conformal connection* (Les espaces à connexion conforme. Paris, 1923) *[96, part 3, pp. 747–797]* and *On manifolds with a projective connection* (Sur les variétés à connexion projective. Paris, 1924) *[96, part 3, pp. 825–861]* Cartan introduced the notion of a *space with a homogeneous connection*. Whereas in the case of a space with an affine connection there is associated to every point a vector space that can be regarded as an affine space, and under parallel displacement of vectors the space at one point is mapped by an affine transformation onto the space at an infinitely near point, in the case of a space with a homogeneous connection there corresponds to every point of the space a homogeneous space with a definite group of transformations. Also, for every pair of infinitely near points there is specified a transformation of the spaces associated with these points that preserves their geometry. In addition to spaces with an affine connection and special cases of such spaces noted above, the most important spaces with a homogeneous connection are *spaces with a projective* and *conformal connection*, respectively. To each point of these spaces there is associated, respectively, a projective or conformal space, and for each pair of infinitely near points of a space with a connection there is specified, respectively, a projective or conformal mapping of one of the spaces associated with these points onto the other.

Differentiable Manifolds

The spaces introduced by Riemann and the groups introduced by Lie, bearing the names of their respective inventors, as well as pseudo-Riemannian spaces, Weyl spaces, and the more general spaces with an affine or other homogeneous connection were defined only locally—in the domain of a certain coordinate system. The introduction of topological manifolds made possible the study of differential-geometric spaces in the large. In every n-dimensional topological manifold one can define a homeomorphic mapping of a neighborhood U of every point onto some domain of n-dimensional Euclidean space, and the coordinate system in the Euclidean space provides coordinates for the neighborhood U. This system of coordinates in the neighborhood U is now called a *system of local coordinates* or a *local map* of the manifold, and the totality of local maps is called the *atlas* of the manifold. A manifold is called *differentiable of class* v if (1) the domains of the maps of the atlas cover the whole manifold; and (2) if U and U' are two domains of maps of the atlas with nonempty intersection and a point x in the intersection has coordinates x^i and $x^{i'}$ in the two maps then the functions $x^{i'} = f(x^1, \dots, x^n)$ have continuous partial derivatives up to and including order v, and the jacobian $\det\left(\frac{\partial x^{i'}}{\partial x^j}\right)$ is different from zero throughout the intersection of the domains. The manifold is called *analytic* if the functions in (2) are analytic.

The definitions of a differentiable manifold and of an analytic manifold were formulated by Oswald Veblen (1880–1960) and by John Henry Constantine Whitehead (1904–1960) in *The foundations of differential geometry* (Cambridge, 1932) *[612]*.

With every point of a differentiable manifold there is associated a vector space with vectors $\{dx^i\}$ whose coordinates are the differentials of the coordinates x^i; these spaces are called the *tangent spaces* of the differentiable manifold. Under coordinate transformations $x^i \to x^{i'}$ the coordinates of the vectors and tensors of the tangent spaces transform according to the rules (8.7)–(8.9), and so on. If in every tangent space of a differentiable manifold there is given a metric tensor g_{ij} that determines an inner product in the Euclidean or pseudo-Euclidean space then the differentiable manifold is called, respectively, a *Riemannian* or *pseudo-Riemannian space in the large*. If in each of the tangent spaces of a differentiable manifold there is given an object Γ^i_{jk} that transforms under coordinate transformations according to the same rule as the coefficients Γ^i_{jk} of Riemannian spaces then the differentiable space is called a *space with an affine connection in the large*.

Fibrations

Spaces with connections are special cases of fiber spaces. Unlike spaces with Schouten-Cartan connections, fiber spaces are considered in the large. The initial form of the theory of fiber spaces in the large was the theory of "sphere-spaces," that is, fiber spaces whose "fibers" are spheres. This theory arose in connection with the solution of the problem of continuous mapping of an n-dimensional sphere onto an m-dimensional one for, if $n > m$, then to every point of the m-dimensional sphere there corresponds an $(n - m)$-dimensional manifold of the n-dimensional sphere, so that the latter "stratifies" or "fibrates" into these manifolds; the resulting fibres are also called *spheres*. The theory of such spaces was constructed by the American mathematician Hassler Whitney (b. 1907) in the paper *Sphere-spaces* (Boston, 1935) *[632]*. In the paper *On the theory of sphere bundles* (Boston, 1940) *[633]* Whitney calls these spaces *sphere-bundles*. The most complete account of Whitney's theory is contained in his lectures *On the topology of differentiable manifolds* (Ann Arbor, 1941) *[634]*. Together with *sphere-bundles* Whitney also considered *plane-bundles*. Whitney associated to every differentiable manifold a *tangent plane-bundle* consisting of the tangent spaces of the manifold and *tangent sphere-bundle* consisting of spheres in these tangent spaces with centers at the points of tangency, with one sphere in each tangent space. In the first case, the points of the *fibers* characterize the vectors of the differentiable manifold; in the second, they characterize the directions issuing from a point of the manifold.

Soon Whitney's *sphere-bundles* were replaced by arbitrary manifolds. Then there arose the more general concept of a *fiber bundle* or a *fiber space*. The general theory of such spaces was set forth by the American mathematician Norman Steenrod (1910–1971) in the monograph *The topology of fiber bundles* (Princeton, 1951) *[560]*, which completed the development of this theory.

The simplest fiber space is the *direct product* of two topological spaces S and T, that is, the totality of pairs (s, t) of elements s in S and t in T where the closed sets of the topological product are sets of pairs (s, t) in which both elements s and t vary over closed sets in the spaces S and T, respectively. In this case one may view the set of pairs (s, t_0) with fixed t_0 as a *fiber* and the space T of all possible elements t_0 as a basis of the fiber space. One can also view the set of pairs (s_0, t) with fixed s_0 as a *fiber* and the space S as a basis of the same fiber space. In this case the fibration is called *trivial*.

In more complicated cases, a fibre space is not simply the direct product of a *fiber* by a *basis* but also consists of homeomorphic fibers, and, if the latter are viewed as points of some new space, then this space can be regarded as a basis of the fiber space. The simplest fiber space of this kind is a *Möbius strip* obtained from the lateral surface of a right circular cylinder by identification of pairs of points that are symmetric with respect to its center, or from a rectangle (which may be thought of as the application of half of the preceding cylinder to a plane) by gluing the points of a pair of its opposite sides that are symmetric with respect to its center. (Hence the name *skew products* for general fibrations of a space used in the Russian translation of N. Steenrod's book *[560]*). One usually considers also the group of topological mappings of a fiber onto itself that preserves a certain structure of these fibers and mappings of fibers, one onto another, that preserve this structure.

The most important fiber spaces are the *tangent plane-bundles* defined by Whitney for differentiable manifolds. Now they are called simply *tangent bundles* of differentiable manifolds. The bases of these fiber spaces are the differentiable manifolds, and the fibres are their tangent spaces. To the class of fiber spaces there belong Riemannian spaces, pseudo-Riemannian spaces, and spaces with an affine connection in the large together with their tangent spaces that are, respectively, Euclidean, pseudo-Euclidean, and affine, as well as spaces with a projective, conformal, and arbitrary homogeneous connection together with the corresponding homogeneous spaces that also form *fibers*. The groups of transformations of the *fibers* of these spaces are, respectively, the groups of Euclidean and pseudo-Euclidean motions, of affine, projective, conformal, and other transformations.

Exterior Forms, Curvature and Betti Numbers

The field of a skew-symmetric covariant tensor $a_{i_1 i_2 \ldots i_k}$ in a domain of a differentiable manifold defines at every point of this domain an exterior differential form

$$\omega_k = \sum_{i_1} \cdots \sum_{i_k} a_{i_1 i_2 \ldots i_k} dx^{i_1} \wedge dx^{i_2} \wedge \cdots \wedge dx^{i_k},$$

where $\wedge$ denotes exterior multiplication. The form is invariant under even permutations of the dx^{i_α} and changes sign under odd permutations of the dx^{i_α} (in virtue of the skew symmetry of $a_{i_1 \ldots i_k}$ the ordinary differential form $\sum_{i_1} \ldots \sum_{i_k} a_{i_1 i_2 \ldots i_k} dx^{i_1} dx^{i_2} \ldots dx^{i_k}$ is equal to zero). For exterior forms we define the operations of exterior multiplication

$$\omega_{k+l} = \omega_k \wedge \omega_l$$

and exterior differentiation

$$\omega_{k+1} = \mathscr{D}\omega_k = \sum_{i_1} \cdots \sum_{i_k} da_{i_1 \ldots i_k} \wedge dx^{i_1} \wedge \cdots \wedge dx^{i_k}.$$

The differential forms in multiple integrals defining areas and volumes are exterior forms, and the Ostrogradskiĭ formula in the beginning of chapter 7 can be written as

$$\int_{\partial M} \omega = \int_M \mathscr{D}\omega,$$

where M is a bounded domain and ∂M is its boundary.

The theory of exterior forms was founded by É. Cartan in the paper *On certain differential expressions and the Pfaff problem* (Sur certaines expressions différentielles et le problème de Pfaff. Paris, 1899) *[96, part 2, pp. 303–396]*. It was extensively developed by É. Cartan (see his book *Exterior differential systems and their geometrical applications* (Les systèmes différentiels extérieurs et leurs applications géométriques. Paris, 1945) *[97]*, by the Soviet geometer Sergeĭ Pavlovič Finikov (1883–1964), and by their students.

If a moving orthonormal frame $\{\mathbf{e}_i\}$ is associated with every point of a curve or surface in the space R_n or with every figure of a family of figures in this space, then the differentials of the radius vector $\mathbf{x}$ and of the vectors $\mathbf{e}_i$ of the frame can be written as

$$d\mathbf{x} = \mathbf{e}_i \omega^i, \qquad d\mathbf{e}_i = \mathbf{e}_j \omega_i^j, \tag{8.16}$$

where

$$\omega_j^i = -\omega_i^j, \tag{8.17}$$

and the exterior differentials of the forms ω^i and ω_j^i satisfy the *equations of structure*

$$\mathscr{D}\omega^i = \sum_k \omega^k \wedge \omega_k^i, \qquad \mathscr{D}\omega_j^i = \sum_k \omega_j^k \wedge \omega_k^i. \tag{8.18}$$

A curve, surface or family of figures is defined by a system of Pfaff equations $\theta^1 = \theta^2 = \cdots = \theta^r = 0$, where the forms θ^A are linear combinations of the forms ω^i, ω_j^i. For a curve with arc length s and tangent vector $\mathbf{e}_1$ these equations are $\omega^2 = \cdots = \omega^n = 0$ and for a hypersurface with normal vector $\mathbf{e}_n$ the equation is $\omega^n = 0$. If for the curve we put $d\mathbf{e}_1/ds = k_1\mathbf{e}_2$ and choose vectors $\mathbf{e}_3, \ldots, \mathbf{e}_n$ so that $d\mathbf{e}_i/ds$ is a linear combination of $\mathbf{e}_1, \ldots, \mathbf{e}_{i+1}$, then $\omega_i^{i+1}/ds = -\omega_{i+1}^i/ds = k_i$ are curvatures of the curve and the remaining ω_j^i are zeros. In this way we obtain the *Frenet formulas*

$$\begin{aligned} &d\mathbf{e}_1/ds = k_1\mathbf{e}_2, \\ &d\mathbf{e}_2/ds = -k_1\mathbf{e}_1 + k_2\mathbf{e}_3, \ldots, \\ &d\mathbf{e}_i/ds = -k_{i-1}\mathbf{e}_{i-1} + k_i\mathbf{e}_{i+1}, \ldots, d\mathbf{e}_n/ds = -k_{n-1}\mathbf{e}_{n-1} \end{aligned}$$

discovered for R_3 in 1847 by Frederic Frenet (1816–1900) and for R_n in 1874 by C. Jordan. The curvatures k_i define the curve up to a motion of R_n.

For a hypersurface we direct the vectors $\mathbf{e}_1, \ldots, \mathbf{e}_{n-1}$ along curvature lines of the hypersurface and the vector $\mathbf{e}_n$ along its normal. Exterior differentiation of the Pfaff equation $\omega^n = 0$ gives, in view of (8.18), $\mathscr{D}\omega^n = \sum_k \omega^k \wedge \omega_k^n = 0$. Hence $\omega_\alpha^n = \sum_\beta b_{\alpha\beta}\omega^\beta$ $(\alpha, \beta = 1, 2, \ldots, n-1)$. We note that the analogues of Gauss's quadratic forms for surfaces in R_3 and for hypersurfaces in R_n are

$$d\mathbf{x}^2 = \sum_\alpha (\omega^\alpha)^2,$$

$$\mathbf{e}_n d^2\mathbf{x} = -d\mathbf{e}_n d\mathbf{x} = -\left(-\sum_\alpha \omega_\alpha^n \mathbf{e}_\alpha\right)\left(\sum_\beta \omega^\beta \mathbf{e}_\beta\right) = \sum_\alpha \sum_\beta b_{\alpha\beta}\omega^\alpha\omega^\beta.$$

In our basis $b_{\alpha\beta} = b_\alpha\delta_{\alpha\beta}$, $-b_\alpha = k_\alpha$ are main curvatures of the hypersurface; they are differential invariants of the hypersurface. Exterior differentiation of other forms yields a complete system of differential invariants of the hypersurface which defines it up to a motion of the space R_n.

Formulas (8.16) and (8.18) also hold in the affine space E_n and in the pseudo-Euclidean space ${}^lR_n$. In the case of E_n the forms ω_j^i are not connected by any condition. In the case of ${}^lR_n$ with scalar square of a vector $\mathbf{x}^2 = \sum_i \varepsilon_i (x^i)^2$ the conditions (8.17) become

$$\varepsilon_i \omega_j^i = -\varepsilon_j \omega_i^j. \tag{8.19}$$

In the spaces P_n, S_n and ${}^lS_n$ the points are represented by vectors of the spaces E_{n+1}, R_{n+1} and ${}^lR_{n+1}$, respectively. In these spaces the role of the radius vector $\mathbf{x}$ is played by e_0. In these spaces hold the second formulas (8.16) and (8.18). In P_n the forms ω_j^i are connected by the condition $\sum_i \omega_i^i = 0$, in S_n by the condition (8.17), and in ${}^lR_n$ by the condition (8.19).

Analogous methods can be applied in all homogeneous spaces.

These methods can also be applied in spaces with affine connection and in Riemannian and pseudo-Riemannian spaces. In these spaces the vectors $\mathbf{e}_i$ are vectors of the tangent spaces of E_n, R_n and ${}^lR_n$ respectively. In these spaces hold formulas (8.16) and in Riemannian and pseudo-Riemannian spaces formulas (8.17) and (8.19), respectively. The equations of structure there have the form

$$\mathscr{D}\omega^i = \sum_k \omega^k \wedge \omega_k^i + \sum_j \sum_k S_{jk}^i \omega^j \wedge \omega^k,$$
$$\mathscr{D}\omega_j^i = \sum \omega_j^k \wedge \omega_k^i + \sum_k \sum_h R_{jkh}{}^{\cdot\cdot\cdot i} \omega^k \wedge \omega^h$$

where S_{jk}^i is the *torsion tensor* (equal to zero in spaces without torsion, in particular, in Riemannian and pseudo-Riemannian spaces), $R_{jkh}{}^{\cdot\cdot\cdot i}$ is the *curvature tensor* (in Riemannian spaces $R_{ijkl} = g_{hl} R^h{}_{ijk}$ is the Riemann tensor).

An exterior differential form ω is called *closed* if $\mathscr{D}\omega = 0$ and *exact* if $\omega = \mathscr{D}\omega'$. Every exact form is closed since $\mathscr{D}(\mathscr{D}\omega) = 0$. Exterior differentiation is similar to the taking of a boundary, except that in the latter case the dimension of a manifold decreases and in the former case the "order" of a form increases. This analogy was made use of in the paper *On analysis situs* [i.e. topology] *of n-dimensional manifolds* (Sur l'analysis situs des variétés à n-dimensions. Paris, 1931) *[452]* by the Belgian mathematician Georges de Rham (1903 1969). In this paper de Rham defined the *cohomology groups*, in a certain sense dual to Betti's *homology groups*, and applied exterior differential forms for the calculation of Betti numbers. The integral of a closed form is said to be homologous to zero, and h integrals of closed forms on a p-dimensional submanifold which are independent in the usual topological sense are said to be homologically independent if no linear combination of these integrals with constant coefficients not all zero is homologous to zero. De Rham has shown that the Betti number b_p is equal to the number of homologically independent integrals of exact differential forms of order p. This method of calculation of Betti numbers was applied by Cartan in his *Topology of compact homogeneous spaces* (La topologie des espaces homogènes clos. Moscow, 1937) *[96, part 1, pp. 1331 -1338]* and by his student Charles Ehresmann in the paper *On the topology of certain homogeneous spaces* (Sur la topologie de certains espaces homogènes. Princeton, 1934) *[164]*.

The Betti numbers are connected with the Gaussian curvature of a surface: if the Gaussian integral curvature $\int K d\sigma$ is taken over a closed compact surface in R_3, then this integral is equal to $4\pi\left(1-\frac{b_1}{2}\right)$, where b_1 is the first Betti number of the surface. This number is equal to double the number of handles of the surface ($b_1 = 0$ for a sphere and $= 2$ for a torus). About this problem see the book of Kentaro Yano and Salomon Bochner *Curvature and Betti numbers* (Princeton, 1953) *[645]*.

lichen Ergebnisse eintreten. Einen Fall, bei dem de Mérés Fehleinschätzung in spektakulärer Weise übertroffen wurde, erwähnt der amerikanische Glücksspielexperte John Scarne in seinem Buch *Complete guide to gambling*[14]: So soll ein Spieler – sich selbst im Vorteil wähnend – 1952 innerhalb von zwölf Stunden insgesamt 49000 Dollar bei Wetten darauf verloren haben, in jeweils 21 Würfen mindestens eine Doppel-Sechs zu erzielen. Tatsächlich ist die Gewinnwahrscheinlichkeit in Höhe von $1 - (35/36)^{21} = 0{,}4466$ deutlich geringer, als man vermutlich schätzen würde.

1.3 Lottotipps – „gleicher als gleich“?

Eine statistische Auswertung der insgesamt 1433 deutschen Lotto-Ausspielungen, die vom Oktober 1955 bis Anfang 1983 erfolgten, ergibt, dass – ohne Berücksichtigung der Zusatzzahlen – bei 76,4% der Ausspielungen mindestens eine der Zahlen von 1 bis 10 gezogen wurde. Getippte Zahlenreihen, die keine der Zahlen 1 bis 10 enthielten, hatten also allein aufgrund dieser Tatsache in 76,4% der Fälle keine Chance, einen Haupttreffer mit „Sechs Richtigen“ zu erzielen. Sollte man deshalb immer mindestens eine der Zahlen 1 bis 10 in seinem Lotto-Tipp berücksichtigen?

Das Zahlenlotto, das in Deutschland und in einigen anderen Ländern in der Form „6 aus 49“ gespielt wird, gehört heute zu den populärsten Glücksspielen. Und das nicht nur beim Publikum, sondern auch beim Staat, dessen Gewinn in der ungefähren Höhe des halben Einsatzes schon vor der Ziehung sicher ist. Entstanden ist das Lotto übrigens im 16. Jahrhundert in der Stadt Genua, wo damals jährlich fünf Senatoren per Los bestimmt wurden. Gleichzeitig konnte auf die zur Auswahl stehenden 110 Namen gewettet werden. Mit der Zeit verselbstständigte sich das Spiel und wurde dabei abstrahiert. Statt auf Namen setzte man nun auf Zahlen. Dem Siegeszug des Lottos konnten sich selbst die Regierungen des ehemaligen Ostblocks nicht entziehen[15]. Auch dort wurde das ursprünglich als kapitalistisch gebrandmarkte Spiel veranstaltet.

Aufgrund seiner Beliebtheit wurde das Lotto auch zum Gegenstand vieler Publikationen. In einem Lotto-Buch[16] wird die in der Fragestellung zitierte Auswertung wie folgt kommentiert:

> So gesehen muß man feststellen, daß Lotto eigentlich unlogisch ist. Wenn man darüber nachdenkt, ist es ganz einfach. Es haben nicht alle Zahlen beziehungsweise alle möglichen „Anfangszahlen“[17], die von 1 bis 44, die gleichen Chancen.
> Weil das so ist, haben nicht alle Tippreihen im Lottospiel die gleichen Chancen.
> ... wer Lotto spielt und dabei Reihen zusammenstellt, die mit einer Anfangszahl 11 und höher beginnen, verschenkt mehr als drei Viertel der Chancen, einen Sechser zu treffen. Selbst dann, wenn das Glück ihm eigentlich hold wäre. Er kann den Sechser deshalb nur

E. Behrends, G.M. Ziegler, P. Gritzmann (Hrsg.), *Pi und Co.*, DOI 10.1007/978-3-662-48872-0_22

> in einem knappen Viertel aller Ausspielungen treffen, weil seine Spielreihe nach der Formel „6 aus 49“ schlicht unvollständig ist. Der Spieler, der hohe Anfangszahlen für seine Reihe wagt, gleicht dem Lotteriespieler, der mit einem Viertellos die auf ein ganzes Los entfallende Million gewinnen will. Er kann sie einfach nicht bekommen.

Fast ist man geneigt, den Argumenten Glauben zu schenken und seine Tippreihen immer mit einer der Zahlen 1 bis 10 anfangen zu lassen. Andererseits ist aber jede Zahl und damit auch jede Lottoreihe theoretisch „gleichmöglich“, wie Laplace formulierte. Und warum sollten gerade die Zahlen von 1 bis 10 und nicht andere Zehner-Gruppen wie

- 34 bis 43 oder
- 4, 9, 14, 19, 24, 29, 34, 39, 44 und 49 oder
- 11, 16, 17, 22, 23, 25, 29, 32, 36 und 48

eine besondere Rolle spielen? Alles gut und schön, aber vielleicht doch nur graue Theorie? Schließlich kann das Ergebnis der statistischen Untersuchung doch nicht einfach ignoriert werden! Aber ist es wirklich so außergewöhnlich, wie es scheint? Und kann das statistische Ergebnis wirklich als Argument für die gegebene Empfehlung dienen?

Vergessen wir für einen Moment, dass die statistische Auswertung bereits vorliegt. Welches Ergebnis würden wir dann ungefähr erwarten? Das heißt, wie groß ist die Wahrscheinlichkeit und damit ungefähr die relative Häufigkeit dafür, dass eine Lottoausspielung mindestens eine der Lottozahlen 1 bis 10 enthält? Für eine Antwort könnte man einen Computer so programmieren, dass er alle Möglichkeiten und darunter die für das Ereignis „günstigen“ durchzählt. Dass es auch einfacher geht, verdanken wir einigen Formeln der **Kombinatorik**, einer mathematischen Teildisziplin, die sich mit den Möglichkeiten befasst, Dinge miteinander zu kombinieren oder anzuordnen. Der denkbar einfachste Fall betrifft die völlig freie Kombination von Merkmalen, etwa den Ergebnissen von zwei Würfeln: Jedes Ergebnis des einen Würfels kann mit jedem Ergebnis des anderen zusammentreffen, so dass es 6·6 = 36 Kombinationen gibt, wobei Würfelkombinationen wie 2-6 und 6-2 unterschieden sind.

Etwas komplizierter wird es, wenn Karten gemischt werden. Wie viele Möglichkeiten gibt es dafür, eine vorgegebene Anzahl von unterschiedlichen Karten anzuordnen? Handelt es sich nur um drei Karten, hier einfach 1, 2 und 3 genannt, dann sind die folgenden Reihenfolgen möglich:

1 2 3   1 3 2   2 3 1   2 1 3   3 1 2   3 2 1

Drei Karten lassen sich also auf 6 Arten sortieren, es gibt also 6 so genannte **Permutationen**. Bei 4 Karten gibt es bereits 24 und bei 5 Karten schon 120 Permutationen. Um diese Zahlen zu finden, müssen keineswegs alle Permutationen aufgelistet werden. So gibt es bei 5 Karten 5 Möglichkeiten für die erste Karte. Ist die erste Karte gewählt, kann die zweite Karte aus dem Rest von 4 Karten gewählt werden. Für die dritte Karte gibt es dann 3 und für die vierte Karte noch 2 Möglichkeiten. Am Schluss muss schließlich die einzig noch verbliebene Karte genommen werden. Die Zahl der Permutationen von 5 Karten oder anderen unterscheidbaren Dingen ist also gleich $5 \cdot 4 \cdot 3 \cdot 2 \cdot 1 = 120$.

Die Anzahl von Permutationen hat eine so große Bedeutung, dass sie als eigenständige mathematische Operation interpretiert wird. Diese so genannte **Fakultät** wird mit einem Ausrufungszeichen „!“ abgekürzt: n!, gesprochen „n Fakultät“, steht für die Anzahl von Permutationen, die mit n unterschiedlichen Dingen gebildet werden können. Wie im Fall $n = 5$ berechnet man n Fakultät allgemein mit der Formel

$$n! = n \cdot (n-1) \cdot (n-2) \ldots 4 \cdot 3 \cdot 2 \cdot 1,$$

was für die Zahlen n = 1, 2, 3, 4, 5, 6 die Werte

$$1! = 1,\ 2! = 2,\ 3! = 6,\ 4! = 24,\ 5! = 120,\ 6! = 720$$

ergibt. Als praktisch hat sich die Festlegung des Wertes 1 für die Fakultät der Null erwiesen, das heißt

$$0! = 1.$$

Die 32 Karten eines Skatspiels können auf 32! = 32·31·... 4·3·2·1 verschiedene Arten gemischt werden, das ist eine immerhin 35-stellige Zahl, die selbst die vermutlich seit dem Urknall des Universums vergangenen Sekunden, eine 18-stellige Zahl, weit übertrifft:

$$32! = 263\ 130\ 836\ 933\ 693\ 530\ 167\ 218\ 012\ 160\ 000\ 000$$

So astronomisch diese Zahl ist, im Vergleich zu den 52! Permutationen eines Rommé- oder Poker-Spiels ist sie verschwindend klein: 52! ist nämlich eine 67-stellige Zahl – etwa so viel, wie es nach einer Schätzung Atome im gesamten Universum geben soll[18].

Beim Lotto werden, sieht man von der Zusatzzahl erst einmal ab, 6 von 49 Zahlen gezogen. Vergleichbare Auswahlen sind auch bei anderen Spielen üblich: Beim Pokern erhält ein Spieler 5 der 52 Karten, ein Skatspieler erhält 10 von 32 Karten. Allen Situationen gemeinsam ist, dass aus einer Gesamtzahl von unterscheidbaren Dingen eine festgelegte Zahl von Dingen zufällig ausgewählt wird. Auf die Reihenfolge, in der diese Dinge ausgewählt werden, kommt es dabei nicht an. Man spricht in solchen Fällen von **Variationen**.

Die Anzahl von möglichen Variationen kann ähnlich wie die von Permutationen bestimmt werden: Für die erste Kugel bei einer Lottoausspielung gibt es 49 Möglichkeiten. Wird die zweite Zahl gezogen, gibt es für diese noch 48 Möglichkeiten. Folglich können sich die ersten beiden Zahlen auf 49·48 verschiedene Weisen miteinander kombinieren. Bei den anschließend gezogenen Zahlen verringert sich die Anzahl der Möglichkeiten jeweils um 1. Daher existieren insgesamt 49·48·47·46·45·44 Sequenzen von 6 Lottozahlen, wobei sich einige Sequenzen nur in der Reihenfolge, nicht aber in den ausgewählten Zahlen unterscheiden. Dieser Sachverhalt lässt sich noch präzisieren: Jede Auswahl von 6 Lottozahlen kann als Permutation in insgesamt 6! = 720 Ziehungssequenzen auftreten, das heißt, die Zahl der Variationen beträgt

$$\frac{49\cdot 48\cdot 47\cdot 46\cdot 45\cdot 44}{6!} = 13983816.$$

Damit gibt es knapp 14 Millionen mögliche Tippreihen beim Lotto. Folglich beträgt die Wahrscheinlichkeit, „Sechs Richtige“ zu tippen, etwa 1 durch 14 Millionen. Dass trotz der geringen Wahrscheinlichkeit fast jede Woche Glückliche zu verzeichnen sind, liegt einzig an der riesigen Zahl von abgegebenen Lottotipps, welche die Anzahl der Mitspieler aufgrund mehrfacher Tipps sogar noch übersteigt.

---

[18] Wie stark Fakultäten wachsen, kann man gut anhand der so genannten Stirling'schen Formel sehen, mit der Fakultäten näherungsweise berechnet werden können. Die Stirling'sche Formel lautet

$$n! \approx \left(\frac{n}{e}\right)^n \sqrt{2\pi n},$$

wobei der relative Fehler für größere Werte n sehr klein ausfällt. Beschreiben lässt sich die Qualität der Approximation dadurch, dass der Quotient aus n! und der Stirling-Näherung zwischen $e^{1/(12n+1)}$ und $e^{1/12n}$ liegt. Beispielsweise für n=32 erhält man die Näherung $2{,}6245\cdot 10^{35}$; das ist nur 0,26% zu wenig.

Die allgemeine Formel für die Anzahl von Variationen ergibt sich ganz analog zum Lotto-Beispiel: Werden aus n unterschiedlichen Dingen k Dinge ausgewählt, dann gibt es insgesamt

$$\frac{n(n-1)(n-2)\ldots(n-k+1)}{k\,!}$$

verschiedene Möglichkeiten einer Auswahl. Der Bruch, der sich immer zu einer ganzen Zahl kürzen lässt, wird **Binomialkoeffizient** genannt. In seiner Schreibweise

$$\binom{n}{k}$$

spricht man auch von „n über k“. Die Zahl der möglichen Lottotipps beträgt

$$\binom{49}{6},$$

was genau den schon berechneten Wert ergibt.

Das Pascal’sche Dreieck

Die Gesamtheit der Binomialkoeffizienten lässt sich übersichtlich in einem Schema anordnen, das Pascal’sches Dreieck genannt wird:

$$\begin{array}{ccccccccccc}
 & & & & & 1 & & & & & \\
 & & & & 1 & & 1 & & & & \\
 & & & 1 & & 2 & & 1 & & & \\
 & & 1 & & 3 & & 3 & & 1 & & \\
 & 1 & & 4 & & 6 & & 4 & & 1 & \\
1 & & 5 & & 10 & & 10 & & 5 & & 1 \\
\ldots & & & & & \ldots & & & & & \ldots
\end{array}$$

Dabei steht der Binomialkoeffizient $\binom{n}{k}$ in der (n+1)-Zeile an (k+1)-ter Stelle, beispielsweise findet man $\binom{4}{2} = 6$ als dritten Wert in der fünften Zeile. Der Clou des Pascal’schen Dreiecks besteht darin, dass alle Werte ohne jede Multiplikation berechnet werden können, da jede Zahl gleich der Summe der beiden über ihr stehenden Zahlen ist. Warum das funktioniert, lässt sich schnell erklären: Um von n Karten k auszuwählen, nimmt man entweder die erste Karte und wählt die anderen k-1 aus den verbleibenden n-1 Karten aus oder man nimmt die erste Karte nicht und nimmt alle k Karten aus dem Rest. Das entspricht der Gleichung

$$\binom{n}{k} = \binom{n-1}{k-1} + \binom{n-1}{k}$$

Mit Binomialkoeffizienten ist es nun ein Leichtes, Wahrscheinlichkeiten beim Lotto zu berechnen. So gibt es unter den insgesamt knapp 14 Millionen möglichen Tipreihen nur $\binom{39}{6} = 3262623$, die sich bloß aus den 39 Zahlen von 11 bis 49 zusammensetzen. Das heißt, die Wahrscheinlichkeit, dass alle sechs ausgespielten Zahlen größer oder gleich 11 sind, beträgt 0,2333. Nach dem Gesetz der großen Zahlen ist es also auf Dauer zu erwarten, dass der Anteil der Ziehungen, die mindestens eine Zahl von 1 bis 10 enthalten, etwa gleich

76,67% beträgt. Das Ergebnis der statistischen Untersuchung von 76,4% ist damit alles andere als ungewöhnlich.

Wenn das statistische Ergebnis schon nicht ungewöhnlich ist, wie sieht es dann mit der ausgesprochenen Empfehlung aus, mindestens eine der Zahlen 1 bis 10 bei einem Tipp zu berücksichtigen? Man kann sie getrost vergessen, da sie auf einem Fehlschluss beruht! Die Aussage, dass man bei einem Tipp ohne die Zahlen 1 bis 10 mit fast 77-prozentiger Wahrscheinlichkeit unter anderem deshalb keinen Sechser erzielen wird, weil mindestens eine der Zahlen 1 bis 10 gezogen wird, ist schlicht uninteressant. Damit wird nämlich nur ausgesagt, dass bei Tipps, welche die Empfehlung nicht berücksichtigen, die Wahrscheinlichkeit auf „Sechs Richtige” kleiner als 0,2333 ist. Aber das ist ohnehin klar, denn die Wahrscheinlichkeit auf einen Sechser ist noch viel kleiner, nämlich gleich 0,0000000715.

Nicht überzeugt? Stellen wir uns vor, wir hätten die Zahlen 22, 25, 29, 31, 32, 38 getippt. Da wir die Ziehung im Fernsehen nicht selbst verfolgen können, bitten wir einen Bekannten, die Lottozahlen für uns aufzuschreiben. Immer noch nicht überzeugt, ob es richtig war, keine Zahl bis 10 zu tippen, fragen wir unseren Bekannten zunächst: „Ist eine Zahl von 1 bis 10 dabei?“. In knapp 77% der Fälle ist der Traum von den Millionen mit einem „Ja“ als Antwort bereits beendet. So weit so gut. In den anderen knapp 23% – und hier irrte der zitierte Buchautor – bleibt die Gewinnhoffnung aber nicht gleich, sondern sie steigt. Schließlich haben wir ja nur noch 6 aus 39 Zahlen richtig zu tippen.

Nachdem wir uns davon überzeugen konnten, dass der aus dem Buch zitierte Ratschlag unbegründet ist, bleibt noch die Frage danach, was einen Spieler erwartet, der der Empfehlung trotzdem folgt. Zunächst ist natürlich zu bemerken, dass die entsprechenden Zahlenkombinationen zwar nicht „besser” sind, wie der Autor vermutete, aber ebenso wenig sind sie „schlechter”, das heißt unwahrscheinlicher, als die anderen. Insofern ist die Empfehlung im Hinblick auf die Gewinnwahrscheinlichkeit keineswegs schädlich. Berücksichtigt man aber, dass die Gewinnhöhen beim Lotto stets davon abhängen, wie viele Mitspieler eine Gewinnklasse treffen, dann ändert sich das Bild[19]. Jede Zahlenkombination, die häufig getippte Zahlen und Zahlenkombinationen beinhaltet, ist danach weniger empfehlenswert, da sie im Gewinnfall zu vergleichsweise niedrigen Gewinnhöhen führt. Beispielsweise ergeben, da viele Lotto-Spieler ihren Tipp aus Datumsangaben ableiten, Ziehungen mit der Zahl 19 vergleichsweise niedrige Quoten. Entsprechendes gilt für Ziehungen, in denen die Zahlen von 1 bis 12 beziehungsweise 1 bis 31 besonders oft vorkommen. Andere Vorlieben erklären sich, wie bei der Glückszahl 7, eher aus der mit der Zahl verbundenen Symbolik. Und auch die geometrische Verteilung der Zahlen auf dem Spielschein hat sicher einen Einfluss.

---

[19] Die Gewinnquoten differieren zum Teil erheblich. So hat es bei der Gewinnklasse „Sechs Richtige” bisher zweimal besonders niedrige Quoten gegeben. Bei der Ziehung am 18.6.1977 waren es 205 vermeintliche „Glückspilze”, die alle die sechs gezogenen Zahlen, nämlich 9, 17, 18, 20, 29 und 40 richtig getippt hatten. Die Gewinnquote betrug aber nicht die ersehnte Million, sondern nur vergleichsweise klägliche 30737,80 DM. Was war passiert? Viele Tipper, vor allem im nordwestdeutschen Raum, hatten es sich angewöhnt, diejenigen Zahlen zu tippen, die in Holland eine Woche zuvor gezogen worden waren. Dies war, wie sich dann zeigte, ein schwerer Fehler, natürlich nicht deshalb, weil eine direkte Wiederholung unwahrscheinlicher war als eine andere Zahlenreihe, sondern einfach deshalb, weil zu viele Mitspieler die gleiche Idee hatten. Bei einer anderen Ziehung, nämlich am 23.1.1988, ergaben sich sogar 222 Volltreffer. Dafür verantwortlich war wohl die Regelmäßigkeit der gezogenen Zahlenreihe: 24, 25, 26, 30, 31 und 32.

Die Gewinnklassen im Lotto

Auch die Chance, beim Lotto eine bestimmte Gewinnklasse zu erzielen, kann mit Hilfe von Binomialkoeffizienten leicht berechnet werden. Beispielsweise erreicht man genau dann 4 Richtige, wenn

- 4 der 6 getippten Zahlen und
- 2 der 43 nicht getippten Zahlen

gezogen werden. Dazu gibt es, kombiniert man die Möglichkeiten für die richtigen wie die falsch getippten Zahlen miteinander, insgesamt genau

$$\binom{6}{4}\cdot\binom{43}{2} = 15\cdot 903 = 13545$$

Möglichkeiten. Das ergibt eine Wahrscheinlichkeit von 0,00097, ungefähr entsprechend 1/1032. Folglich bringt noch nicht einmal jeder tausendste Tipp 4 Richtige!

Gewinnklasse	Anzahl der Kombinationen	Wahrscheinlichkeit
6 Richtige	1	1/14 Mill.
5 Richtige mit Zusatzzahl	6	1/2,3 Mill.
5 Richtige	252	1/55491
4 Richtige	13545	1/1032
3 Richtige mit Zusatzzahl	17220	1/812
3 Richtige	229600	1/61
Verlust (Rest)	13723192	0,981
	13983816	

Aufgrund der zusätzlich ausgespielten „Superzahl“ unterteilt sich die höchste Gewinnklasse im Verhältnis von 9:1, so dass die Wahrscheinlichkeit für die höchste Gewinnklasse nur noch 1 zu 140 Millionen beträgt. Trotz des gestiegenen Umsatzes, nicht zuletzt auch aufgrund der deutschen Wiedervereinigung, wird so die höchste Gewinnklasse oft über mehrere Wochen nicht erreicht. Die dann nicht ausgespielten Gewinne bleiben in Form eines Jackpots für die nächste Ziehung stehen. 1994 erreichte dieser Jackpot immerhin einen Spitzenwert von 42 Millionen DM.

Hinweise darauf, welche Zahlen besonders oft getippt werden, lassen sich indirekt dadurch erhalten, dass man die wöchentlichen Gewinnquoten darauf untersucht, bei welchen gezogenen Zahlen sie höher und bei welchen sie niedriger ausfallen. Allerdings sind so aufgrund der vielschichtigen Einflüsse, etwa durch mehr oder weniger beliebte Teilkombinationen und einem nicht bei jeder Ziehung völlig gleichem Verhalten, nur eingeschränkte Aussagen zu erzielen[20]. Weit aussagekräftiger ist eine Auswertung, in der bei einer Ziehung des Jahres 1993 alle in Baden-Württemberg abgegebene Tipps einbezogen wurden[21]. Von diesen Tipps haben 80,7% eine Anfangszahl zwischen 1 und 10. Da davon ausgegangen werden kann, dass es sich bei diesem Wert nicht nur um eine Momentaufnahme handelt, sind die Kombinationen mit einer Anfangszahl von höchstens 10 weniger empfehlenswert. Sicher würde man dem zitierten Buch zu viel Ehre antun, wenn man das Verhalten auf seine Empfehlung zurückführen würde. Ursache ist sicher eher die schon genannte Vorliebe für Datumsangaben.

[21] Karl Bosch, *Lotto und andere Zufälle*, Braunschweig 1994, S. 201 ff.; Karl Bosch, *Glücksspiele: Chancen und Risiken*, München 2000, S. 57-70. Die Auswertung erstreckte sich über knapp 7 Millionen Tippreihen, so dass bei einer zufälligen Verteilung der Tipps jede der knapp 14 Millionen

Pokern

Beim Pokern erhält ein Mitspieler fünf der insgesamt 52 Karten, dafür gibt es

$$\binom{52}{5} = \frac{52\cdot 51\cdot 50\cdot 49\cdot 48}{1\cdot 2\cdot 3\cdot 4\cdot 5} = 2598960$$

Möglichkeiten. Will man unter diesen knapp 2,6 Millionen Kartenkombinationen beispielsweise die Anzahl der „Doppel-Zwillinge“ bestimmen, geht man am besten wie folgt vor: Ein Doppel-Zwilling besteht aus 5 Karten mit insgesamt 3 unterschiedlichen Kartenwerten, von denen 2 zweimal vorkommen. Ein Beispiel ist

- Herz-*Vier*, Kreuz-*Vier*, Herz-*Bube*, Pik-*Bube*, Pik-Dame.

Eindeutig bestimmt wird ein Doppel-Zwilling durch die folgenden Angaben:

- Die beiden Kartenwerte der Zwillinge (im Beispiel Vier, Bube),
- der einmal vorkommende Wert (Dame),
- die beiden Farben des niedrigwertigen Zwillings (Herz, Kreuz),
- die beiden Farben des höherwertigen Zwillings (Herz, Pik),
- die Spielfarbe des einmal vorkommenden Wertes (Pik).

Die Zahl der möglichen Kombinationen erhält man nun, wenn man die Anzahlen, die sich für diese Merkmale ergeben, miteinander multipliziert. Zu berücksichtigen dabei ist, dass nicht alle Merkmale frei miteinander kombinierbar sind. Im Einzelnen gibt es

- zunächst $\binom{13}{2} = 78$ Möglichkeiten für die Kartenwerte der beiden Zwillinge,
- dazu jeweils 11 Möglichkeiten für den einmal vorkommenden Wert,
- für die beiden Farben des ersten Zwillings $\binom{4}{2} = 6$ Möglichkeiten,
- für die Farben des zweiten Zwillings ebenfalls 6 Möglichkeiten und
- 4 Möglichkeiten für die Farbe des einmal vorkommenden Wertes.

Zahlenkombinationen etwa 0,5-mal zu erwarten ist. Allerdings gibt es bei den Tippreihen stark ausgeprägte Favoriten, von denen 24 mehr als tausend mal getippt wurden. Die häufigste Tippreihe, bestehend aus den Zahlen 7, 13, 19, 25, 31 und 37, wurde sogar 4004-mal getippt! Weniger die Zahlen selbst – bis auf die 25 allesamt Primzahlen – dürften für diese Vorliebe verantwortlich sein. Vielmehr bilden diese Zahlen auf dem Spielschein eine fast vollständige Diagonale, die oben rechts beginnt. Hochgerechnet auf ganz Deutschland dürfte diese Tippreihe bei jeder Ziehung über 30000-mal getippt werden. Kaum einer der betreffenden Spieler wird wohl ahnen, wie gering seine Gewinnaussichten sind.

Ähnliche Ergebnisse in anderen Ländern wurden von H. Riedwyl gefunden. Siehe: Hans Riedwyl, *Zahlenlotto – Wie man mehr gewinnt*, Bern 1990; Norbert Henze, Hans Riedwyl, *How to win more*, Natick 1998; Hans Riedwyl, *Gewinnen im Zahlenlotto*, Spektrum der Wissenschaft, 2002/3, S. 114-119.

Insgesamt existieren daher 78·11·6·6·4 = 123552 Doppel-Zwillinge. Werden aus einem gut gemischten Kartenblatt fünf Karten zufällig ausgeteilt, dann ist die Wahrscheinlichkeit, einen Doppel-Zwilling zu erhalten, gleich

$$123552/2598960 = 0{,}04754,$$

das heißt, etwa jedes 21. zufällig gezogene Blatt ergibt einen Doppel-Zwilling.

Die folgende Tabelle umfasst in der Reihenfolge der Wertigkeit die Anzahlen aller Poker-Kombinationen. Mit berücksichtigt ist auch die Würfelvariante, die mit fünf Würfeln gespielt wird, welche mit den Symbolen (Pik-)Neun, (Karo-)Zehn, Bube, Dame, König und (Kreuz-)Ass gekennzeichnet sind:

Poker-Kombination	**Anzahl bei ...**	
	5 Karten	**5 Würfeln**
Fünfling		6
Royal Flush (Zehn bis Ass einer Farbe)	4	
Straight Flush	36	
Vierling	624	150
Full House (Drilling und Zwilling)	3744	300
Flush (eine Farbe)	5108	
Straight (Straße: Werte in Reihenfolge)	10200	240
Drilling	54912	1200
Doppel-Zwilling	123552	1800
Zwilling	1098240	3600
Rest	1302540	480
	2598960	7776

SOME GEOMETRIC PROPERTIES AND OBJECTS RELATED TO BÉZIER CURVES

M. J. HRISTOV

"St. Cyril and St. Methodius" University of Veliko Tarnovo,
Faculty of Education, Department of Algebra and Geometry
E-mail: m.hristov@uni-vt.bg

Classical Bézier curves (the parabolic case) with the natural barycentric description are considered. The explicit expressions for lenght, curvature, shape etc. are given. It is introduced the notion trajectory of Bézier curve and by means of the projective isotomic conjugation the corresponding envelope conic surfaces in the space are obtained.

Keywords: Barycentric coordinates and orbits; Projective isotomic conjugation; Bézier curves; Curvature; Shape; Envelope.

1. Preliminaries

1.1. *Barycentric coordinates and barycentric trajectories*

Let α be fixed euclidean plane, $\triangle ABC$ be fixed triangle in λ and $\mathbb{E}_2^*(\alpha)$ be the extended euclidean plane — the basic model of the real projective plane $\mathbb{RP}_2$. The set of points (resp. lines) in $\mathbb{E}_2^*(\alpha)$ will be denoted by Σ (resp. Λ). For $G \in \Sigma$, Λ_G will stand for the set of lines, incident (z) with G (known as star of lines with center G), for $g \in \Lambda$, Σ_g will stand for the set of points z g and U_g denotes the infinity (unproper) point of g. The infinity line in α is the set of all infinity points and will be denoted by ω.

For any point $P \in \Sigma$ and $p \in \mathbb{R}$ there exist unique $x, y, z \in \mathbb{R}$, so that

$$\begin{cases} p \cdot \overrightarrow{OP} = x \cdot \overrightarrow{OA} + y \cdot \overrightarrow{OB} + z \cdot \overrightarrow{OC} \\ x + y + z = p. \end{cases}$$

The ordered triple (x, y, z) is said to be triple of barycentric coordinates (b-coordinates) [4–6] of P with respect to basic Möbius triangle ABC and it will be written $P(x, y, z)$. The case $p = 0$ corresponds to $P \in \omega$ and $p \neq 0$ describes finite euclidean points. From projective point of view, b-coordinates of P are the affine coordinates with respect to space coordinate system

$$\mathcal{K} = \{O(\not\in\alpha), a_1(\|\overrightarrow{OA}), a_2(\|\overrightarrow{OB}), a_3(\|\overrightarrow{OC})\},$$

of a vector $p\|\overrightarrow{OP}$ and $\alpha : x + y + z = p$. That is why we do not use the terminology "homogeneous relative (absolute) b-coordinates" [4–6].

From algebraic point of view b-coordinates x, y, z of finite $P \in \Sigma$ are the unique solution of the system of linear equations (SLE)

$$\left\{\begin{array}{llll} & \lambda y & + z & = 0 \\ \mu x & + (1-\lambda)y & & = 0\ , \\ (1-\mu)x & & & = p \end{array}\right. \tag{1}$$

where $\lambda = (BCA') \overset{\mathrm{def}}{=} \dfrac{\overline{BA'}}{\overline{CA'}}$ and $\mu = (AA'P)$ are the affine ratios, always $\neq 1$ for each finite points P and $A' = PA \cap BC$ (it is assumed) and $\lambda = 1 \iff A' = U_{BC}$. We rewrite (1) in the matrix form $A.X_1 = B$, where

$$A = \begin{pmatrix} 1 & \lambda & 0 \\ 0 & 1-\lambda & \mu \\ 0 & 0 & 1-\mu \end{pmatrix}, \qquad B = \begin{pmatrix} 0 \\ 0 \\ p \end{pmatrix}, \qquad X_1 = \begin{pmatrix} z_1 \\ y_1 \\ x_1 \end{pmatrix}.$$

Thus, in transposed form,

$$X_1^T = B^T (A^{-1})^T = \left(\frac{p\lambda\mu}{(1-\lambda)(1-\mu)}; -\frac{p\mu}{(1-\lambda)(1-\mu)}; \frac{p}{1-\mu} \right).$$

The triangle matrix A is of stochastic type by columns (left(L)-stochastic-like) and generates the affine transfomation φ_A in $\mathbb{E}_2^*(\alpha)$. The reason to use "-like" is that A is not non-negative. The set $\mathcal{A}$ of all such matrixes is multiplicative, non-commutative group. We express the commutator $[A_1, A_2]$ of such matrixes in the form

$$[A_1, A_2] = \begin{vmatrix} \lambda_1 & \lambda_2 \\ \mu_1 & \mu_2 \end{vmatrix} \cdot D \tag{2}$$

where

$$D = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & -1 \\ 0 & 0 & 0 \end{pmatrix}, \qquad A_i = \begin{pmatrix} 1 & \lambda_i & 0 \\ 0 & 1-\lambda_i & \mu_i \\ 0 & 0 & 1-\mu_i \end{pmatrix}.$$

Moreover $\mathcal{A}$ is Lie group. We call $\mathcal{A}$ *L-stochastic-like Lie group with basic Möbius triangle* ABC.

By the consideration of the powers of $A \in \mathcal{A}$, we get the following

Definition 1.1. The orbit of the point $P(x, y, z)$ under the action of the matrix $A \in \mathcal{A}$, i.e. the set of points $\{P_n(x_n, y_n, z_n) = \varphi_A^{1-n}(P),\ n \in \mathbb{N}\}$, such that (x_n, y_n, z_n) is the unique solution of SLE

$$A^n X_n = B, \qquad X_n = \begin{pmatrix} z_n \\ y_n \\ x_n \end{pmatrix}, \quad B = \begin{pmatrix} 0 \\ 0 \\ p \end{pmatrix}$$

is said to be *barycentric trajectory (b-trajectory)* of the point $P(\equiv P_1)$ with respect to basic $\triangle ABC$.

We get the explicit form of the b-trajectory in the form

$$\begin{aligned} z_n &= p + \frac{p}{\lambda - \mu}\left[\frac{\mu}{(1-\lambda)^n} - \frac{\lambda}{(1-\mu)^n}\right], \\ y_n &= \frac{p\mu}{\lambda - \mu}\left[\frac{1}{(1-\mu)^n} - \frac{1}{(1-\lambda)^n}\right], \\ x_n &= \frac{p}{(1-\mu)^n}. \end{aligned} \tag{3}$$

Any point $P_n(x_n, y_n, z_n) \in \alpha : x + y + z = p$ and determines

$$\lambda_n = (BCA_n) = -\frac{z_n}{y_n}, \qquad \mu_n = (AA_nP_n) = -\frac{y_n + z_n}{x_n}$$

where $A_n = AP_n \cap BC$. Thus, the position of P_n is determined by

$$\overrightarrow{CP_n} = \frac{1}{1-\mu_n}\overrightarrow{CA} - \frac{\mu_n}{1-\mu_n}\frac{1}{1-\lambda_n}\overrightarrow{CB}.$$

1.2. *Barycentric characterization of the duality in the projective plane. Projective isotomic conjugation*

Further we assume $P(x, y, z) : x + y + z = 1$, i.e. $\alpha : x + y + z = 1$.

In the following theorem we resume some well known facts from the analytic geometry of $\mathbb{E}_2^*(\alpha)$.

Theorem 1.1. *Let in the plane α of a basic $\triangle ABC$ be given in b-coordinates the points $A'(a_1, a_2, a_3)$, $B'(b_1, b_2, b_3)$ and $C'(c_1, c_2, c_3)$. Let*

$$\mathcal{M}(A'B'C') = \begin{pmatrix} a_1 & a_2 & a_3 \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{pmatrix} \qquad \textit{and} \qquad \Delta' = \det \mathcal{M}(A'B'C')$$

be the matrix and it's determinant, formed by the ordered triple (A', B', C'). Then:

(i) *A', B', C' are incident with a line* $\iff \Delta' = 0$;

(ii) *the ratio of the areas* $\dfrac{S_{A'B'C'}}{S_{ABC}} = |\Delta'|$;

(iii) *the barycentric equation of the line* $a' : \begin{cases} \mathsf{z}\ B'(b_1, b_2, b_3) \\ \mathsf{z}\ C'(c_1, c_2, c_3) \end{cases}$ *is*

$$a' : \begin{vmatrix} x & y & z \\ b_1 & b_2 & b_3 \\ c_1 & c_2 & c_3 \end{vmatrix} = 0 \iff a' : \mathcal{A}_{23}.x + \mathcal{A}_{31}.y + \mathcal{A}_{12}.z = 0.$$

The minors $\mathcal{A}_{ij}$ are called b-coordinates of the line a' and it is written $a'[\mathcal{A}_{23},\, \mathcal{A}_{31},\, \mathcal{A}_{12}]$;

(iv) *the b-coordinates of the intersect point* $P = m \cap n$ *of the lines* $m[\mathcal{M}_1,\, \mathcal{M}_2,\, \mathcal{M}_3]$ *and* $n[\mathcal{N}_1,\, \mathcal{N}_2,\, \mathcal{N}_3]$ *are* $P\left(\dfrac{p_{23}}{\Delta}, \dfrac{p_{31}}{\Delta}, \dfrac{p_{12}}{\Delta}\right)$, *where* p_{ij} *are the minors, formed with $\{i, j\}$-columns of the matrix*

$$\mathcal{P}(m, n) = \begin{pmatrix} \mathcal{M}_1 & \mathcal{M}_2 & \mathcal{M}_3 \\ \mathcal{N}_1 & \mathcal{N}_2 & \mathcal{N}_3 \end{pmatrix} \qquad \text{and} \qquad \Delta = \begin{vmatrix} 1 & 1 & 1 \\ \mathcal{M}_1 & \mathcal{M}_2 & \mathcal{M}_3 \\ \mathcal{N}_1 & \mathcal{N}_2 & \mathcal{N}_3 \end{vmatrix};$$

(v) *the b-equation of a conic $\mathcal{C}$ is* $\mathcal{C} : (x, y, z).A.(x, y, z)^T = 0$, *where A is 3×3 real symmetric matrix. In particular, $\mathcal{C}$ passes through the vertexes of the basic triangle iff* $a_{ii} = 0$, $i = 1, 2, 3$.

There are several kinds of conjugate maps (isogonal, isotomic) with respect to fixed triangle, defined as colineations over $\mathbb{E}_2^*$, for example by means of point multiplication [6]. The theorems of Ceva and Menelaus give rise

Definition 1.2. *Projective* ($\mathbb{RP}_2$-) *isotomic conjugation* with respect to basic $\triangle ABC$ is the map

$$\begin{aligned} \pi\ : \Sigma \backslash \{\Sigma_{AB} \cup \Sigma_{BC} \cup \Sigma_{CA}\} &\longrightarrow \Lambda \backslash \{AB \cup BC \cup CA\} \\ P = AA' \cap BB' \cap CC' &\longmapsto \pi(P) = p\ \mathsf{z}\ A^*, B^*, C^*, \end{aligned}$$

where the points I', I^* are harmonically-conjugated to the pair (J, K), i.e. $I', I^*\, \mathsf{z}\ JK$ and $(JKI') = -(JKI^*)$ for $I, J, K \in \{A,\, B,\, C\}$. The Ceva point P is called *pole*, the Menelaus line $p = \pi(P)$ is called *polar line* and the map π is known also as *polarity* w.r. to $\triangle ABC$.

The image of the medicenter G is $\pi(G) = \omega$.

The following theorem is easy to check by using Theorem 1.1.

Theorem 1.2.

(i) *The* $\mathbb{RP}_2-$*isotomic conjugation is involutive corelation, i.e.* $\pi \neq \mathrm{id}$ *(the identity),* $\pi^2 = \mathrm{id}$ *(or* $\pi^{-1} \equiv \pi$*) and analytically in b-coordinates*

$$\Sigma \ni P(p_1,\, p_2,\, p_3) \xmapsto{\pi} \pi(P) = p\,[p_2p_3,\, p_3p_1,\, p_1p_2\,] \in \Lambda.$$

(ii) *The sets of stars of lines in the plane of basic* $\triangle ABC$ *and the set of conics, incident with the vertexes* A, B, C *are equivalent in the sence of the* $\mathbb{RP}_2$*-isotomic conjugation.*

2. Bézier curves and related geometric properties and objects

Bézier curves, as basic tools for Computer Aided Geometric Design [1], are intensively studied by many autors. We recall the well known

Definition 2.1. Let $\triangle A_0A_1A_2$ be fixed triangle with vertex-vector-positions $a_i = \overrightarrow{OA_i}$, $i = 0, 1, 2$. The polynomial curve of second degree

$$\mathcal{C} : r(t) = (1-t)^2 a_0 + 2t(1-t)a_1 + t^2 a_2, \quad 0 \leq t \leq 1$$

is said to be *Bézier curve* of $2^{-\mathrm{d}}$ power with basic $\triangle A_0A_1A_2$. It is also in use the denotation $\mathcal{C}_{\{A_0A_1A_2\}}$.

Generally, $\mathcal{C}_{\{A_0A_1\ldots A_n\}} : r(t) = \sum\limits_{k=0}^{n} \binom{n}{k} t^k (1-t)^{n-k}.a_k,\ t \in [0,1]$ is Bézier curve of $n^{-\mathrm{th}}$ power with basic symplex $A_0A_1\ldots A_n$, formed as the linear combination of $a_k = \overrightarrow{OA_k}$ with coefficients the basic Bernstein's polynomials $B_{k,n} = \binom{n}{k} t^k (1-t)^{n-k}$, $k = 0, 1, \ldots, n$. Point A_0 is called *initial*, A_n — *end-point*, all the rest A_k — *control points*. Any Bézier curve is invariant under the action of any affine transformation.

We use the following matrix forms for $\mathcal{C}_{\{A_0A_1A_2\}}$

$$\mathcal{C}_{\{A_0A_1A_2\}} : r(t) = (1,\, t,\, t^2) \cdot \begin{pmatrix} \overrightarrow{OA_0} \\ 2\overrightarrow{A_0A_1} \\ \overrightarrow{A_1A_0} + \overrightarrow{A_1A_2} \end{pmatrix} = (1,\, t,\, t^2) \cdot \begin{pmatrix} \overrightarrow{OA_0} \\ 2\overrightarrow{A_0A_1} \\ 2\overrightarrow{A_1M_1} \end{pmatrix},$$

where M_1 is the midpoint of A_0A_2, from which it's easy to calculate the derivatives $\dot{r}(t) = \frac{dr(t)}{dt}$ ets. and to proove the well known properties, used in the De'Casteljau algorithm:

Lemma 2.1. *Arbitrary Bézier curve* $\mathcal{C}_{\{A_0A_1A_2\}}$ *passes through* $A_0(t = 0)$ *and* $A_2(t = 1)$*, tangent to* $\overrightarrow{A_0A_1} \| \dot{r}(0)$*,* $\overrightarrow{A_1A_2} \| \dot{r}(1)$*, with curvatures at the* *initial point* A_0 *and the end-point* A_2

$$\varkappa(0) = \frac{S_{\triangle A_0A_1A_2}}{|\overrightarrow{A_0A_1}|^3}, \qquad \varkappa(1) = \frac{S_{\triangle A_0A_1A_2}}{|\overrightarrow{A_1A_2}|^3},$$

respectively, where $S_{\triangle A_0A_1A_2}$ *is the area of* $\triangle A_0A_1A_2$. *Moreover* $\mathcal{C}_{\{A_0A_1A_2\}}$ *intersects the median* A_1M_1 *at the midpoint* $M(t=\frac{1}{2})$ *and is tangent at* M *to the midsegment:* $\dot{r}(\frac{1}{2}) \| A_0A_2$.

From barycentric point of view any Bézier curve $\mathcal{C}_{\{A_0A_1A_2\}}$ is the set of points P with b-coordinates with respect to basic $\triangle A_0A_1A_2$ — the basic Bernstein polinomials of second degree $P\Big((1-t)^2,\, 2t(1-t),\, t^2\Big)$, $t \in [0,1]$.

Lemma 2.2.

(i) *Let* $P\Big((1-t)^2,\, 2t(1-t),\, t^2\Big)$, $t \in [0,1]$ *be arbitrary point of the Bézier curve* $\mathcal{C}_{\{A_0A_1A_2\}}$. *The b-coordinates of the points:* $B_0 = A_0P \cap A_1A_2$, $B_1 = A_1P \cap A_0A_2$, $B_2 = A_2P \cap A_1A_0$ *are*

$$B_0\left(0;\, \frac{2(1-t)}{2-t};\, \frac{t}{2-t}\right), \qquad B_1\left(\frac{(1-t)^2}{2t^2-2t+1};\, 0;\, \frac{t^2}{2t^2-2t+1}\right),$$
$$B_2\left(\frac{1-t}{1+t};\, \frac{2t}{1+t};\, 0\right).$$

(ii) *Any Bézier curve* $\mathcal{C}_{\{A_0A_1A_2\}}$ *generates the functional matrix* $A(t)$ *from the L-stochastic-like Lie group* $\mathcal{A}$ *with*

$$\lambda(t) = \frac{t}{2(t-1)} \qquad \text{and} \qquad \mu(t) = \frac{t(t-2)}{(t-1)^2}, \qquad t \in [0,\, 1).$$

Proof. The statement (i) follows by applying Theorem 1.1. and (ii) — by calculating the affine ratios $\lambda(t) = (A_2A_1B_0)$ and $\mu(t) = (A_0B_0P)$. □

For $\triangle A_0A_1A_2$ we denote: $l_i = |\overrightarrow{A_jA_k}|$, $m_i = |\overrightarrow{A_iM_i}|$, M_i — the midpoints of A_jA_k for $i \neq j \neq k \in \{0,1,2\}$, $\varphi = \measuredangle A_0A_1A_2$ and $\psi = \measuredangle A_0A_1M_1$.

Theorem 2.1. *Let* $\mathcal{C}_{\{A_0A_1A_2\}}$ *be Bézier curve.*

(i) *For any* $P \in \mathcal{C}_{\{A_0A_1A_2\}}$ *the ratio of the areas*

$$s(t) = \frac{S_{\triangle B_0B_1B_2}}{S_{\triangle A_0A_1A_2}} = \frac{4t^2(1-t)^2}{(2-t)(1+t)(2t^2-2t+1)} \in \left[0;\, \frac{2}{9}\right],$$

$\max\limits_{[0,1]} s = s(\frac{1}{2}) = \frac{2}{9} \iff P \equiv M(\frac{1}{4};\, \frac{1}{2};\, \frac{1}{4})$ — *the midpoint of the median* A_1M_1 *for* $\triangle A_0A_1A_2$;

(ii) *The length of the curve is*

$$l_{\mathcal{C}} = \frac{2m_1 - l_2\cos\psi}{2m_1}\sqrt{(2m_1 - l_2\cos\psi)^2 + l_2^2\sin^2\psi} + \frac{l_2^2\cos\psi}{2m_1} + \frac{l_2^2\sin^2\psi}{2m_1}\ln\frac{\sqrt{(2m_1 - l_2\cos\psi)^2 + l_2^2\sin^2\psi} + 2m_1 - l_2\cos\psi}{l_2(1-\cos\psi)}.$$

Proof. The statement (i) follows from Theorem 1.1.-(ii) and standard obtaining of the $\max s(t)$ over $[0,1]$. For (ii) we apply the lenght-formula

$$l_{\mathcal{C}} = \int_0^1 |\dot{r}(t)|dt \qquad \text{for} \qquad |\dot{r}(t)| = 2\sqrt{(1,2t).\Gamma(\overrightarrow{A_0A_1}\overrightarrow{A_1M_1}).\begin{pmatrix}1\\2t\end{pmatrix}}$$

where $\Gamma(\overrightarrow{A_0A_1}\overrightarrow{A_1M_1})$ is the Gramm-matrix for the pair $\{\overrightarrow{A_0A_1}, \overrightarrow{A_1M_1}\}$. □

Theorem 2.2. *The curvature $\varkappa(t)$ of any Bézier curve $\mathcal{C}_{\{A_0A_1A_2\}}$ is*

$$\varkappa(t) = S_{\triangle A_0A_1A_2}.[g(t)]^{-3/2},$$

where the function $g(t)$, defined over $[0,1]$, is of the form

$$g(t) = |(t-1)\overrightarrow{A_1A_0} + t\overrightarrow{A_1A_2}|^2 = (t-1\,;t)\begin{pmatrix} l_2^2 & l_0l_2\cos\varphi \\ l_0l_2\cos\varphi & l_0^2\end{pmatrix}\begin{pmatrix}t-1\\t\end{pmatrix}.$$

Proof. It follows by direct calculations, analogous to Theorem 2.1.-(ii), over the well known formula $\varkappa(t) = \dfrac{|\dot{r}\times\ddot{r}|}{|\dot{r}|^3}$. □

Theorem 2.2. implies immediately the well known

Corollary 2.1. *The Bézier curve $\mathcal{C}_{\{A_0A_1A_2\}}$ is a parabola with vertex at point K, such that $\overrightarrow{OK} = r(t_0)$, where*

$$t_0 = \frac{l_2^2 + l_0l_2\cos\varphi}{l_2^2 + 2l_0l_2\cos\varphi + l_0^2}$$

is the unique (global) maximum for $\varkappa(t)$: $\varkappa_{|_K} = \varkappa(t_0) = \max\limits_{[0,1]}\varkappa(t)$.

Moreover, the result of Theorem 2.2. gives additional geometric information of the shape of Bézier curve $\mathcal{C}_{\{A_0A_1A_2\}}$, considered and discussed in [2] and generalized in [3] for cubic Bézier curve.

By cosidering the action of $\mathbb{RP}_2$-isotomic conjugation over each point of $\mathcal{C}_{\{A_0A_1A_2\}}\setminus\{A_0, A_2\}$, jointly with Lemma 2.2. (i), we get

Theorem 2.3. *The* $\mathbb{RP}_2$*-isotomic-conjugated image of* $\mathcal{C}_{\{A_0A_1A_2\}}$ *is*

$$\pi(\mathcal{C}_{\{A_0A_1A_2\}}) = \Big\{p\,[2t^2;\ t(1-t);\ 2(1-t)^2]\ :\ t \in (0,1)\Big\},$$

i.e. is the 1-parameter set of polar lines

$$p = \pi(P) : 2t^2 \cdot x + t(1-t) \cdot y + 2(1-t)^2 \cdot z = 0, \quad t \in (0,1),\ u, v \in \mathbb{R}.$$

The lines, corresponding to $t = \frac{1}{3}, \frac{1}{2}, \frac{2}{3}$*, are the polar lines of the intersecting points of* $\mathcal{C}_{\{A_0A_1A_2\}}$ *with the medians through* A_2, A_1, A_0 *and are parallel to* A_1A_0*,* A_0A_2*,* A_2A_1*, respectively.*

From projective point of view w.r. to the space coordinate system $\mathcal{K} = \{O, a_1, a_2, a_3\}$ the obtained 1-parameter family of lines p, give rise 1-parameter family of the planes $\sigma : \begin{cases} \mathsf{z}\ O \\ \mathsf{z}\ p \end{cases}$. The envelope of the last one is conic surface $\mathcal{S}$ with vertex O and generator $\mathcal{E}_{\pi(\mathcal{C})} = \mathcal{S} \cap \alpha : x + y + z = 1$ — the envelope of $\pi(\mathcal{C}_{\{A_0A_1A_2\}})$. More precisely, after standard calculations, we get the following

Theorem 2.4. *The envelope* $\mathcal{S}$ *of the set of planes* $\sigma : \begin{cases} \mathsf{z}\ O \\ \mathsf{z}\ \pi(\mathcal{C}_{\{A_0A_1A_2\}}) \end{cases}$ *with respect to* $\mathcal{K} = \{O, a_1, a_2, a_3\}$ *is the real hyperbolic conic surface*

$$\mathcal{S} : 16xz - y^2 = 0$$

with generator in the basic plane $\alpha :\ x + y + z = 1$*, the envelope*

$$\mathcal{E}_{\pi(\mathcal{C})} : \left(x = \frac{(1-t)^2}{6t^2 - 6t + 1}; y = \frac{4t(t-1)}{6t^2 - 6t + 1}; z = \frac{t^2}{6t^2 - 6t + 1} \right)$$

(in b-coordinates) and $t \in (0,\ 1) \backslash \{\frac{1}{2} \pm \frac{1}{2\sqrt{3}}\}$.

Proof. From Theorem 2.3. the b-equation $F(x, y, z, t) = 0$, where $F(x, y, z, t) = 2t^2.x + t(1-t).y + 2(1-t)^2.z$ for $t \in (0,1)$ describes the 1-parameter set of polar lines. Then the envelope is obtained by the solutions of

$$\mathcal{E}_{\pi(\mathcal{C})} : \begin{cases} F(x, y, z, t) = 0 \\ \dfrac{\partial F}{\partial t}(x, y, z, t) = 0 \\ x + y + z = 1 \end{cases} \iff \begin{pmatrix} 2t^2 & t(1-t) & 2(1-t)^2 \\ 4t & 1-2t & 4(t-1) \\ 1 & 1 & 1 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}.$$

By solving the SLE with respect to x, y, z we proof the theorem. □

Analogous to Lemma 2.2, we get

Lemma 2.3. *The envelope* $\mathcal{E}_{\pi(\mathcal{C})}$ *of* $\mathbb{RP}_2$*-isotomic image of any Bézier curve* $\mathcal{C}_{\{A_0A_1A_2\}}$ *generates the functional L-stochastic-like matrix* $A_\varepsilon(t)$ *with*

$$\lambda(t) = \frac{t}{4(1-t)}, \qquad \mu(t) = \frac{t(4-5t)}{(t-1)^2}, \qquad t \in (0,\,1) : t \neq \frac{4}{5},\ \frac{1}{2} \pm \frac{1}{2\sqrt{3}}.$$

By applying (2) to Lemma 2.2 (ii) and Lemma 2.3, we calculate the commutators and obtaine

Lemma 2.4. *Let* $A(t)$ *and* $A_\varepsilon(t)$ *be the functional matrices in* $\mathcal{A}$ *of* $\mathcal{C}_{\{A_0A_1A_2\}}$ *and* $\mathcal{E}_{\pi(\mathcal{C})}$ *respectively. For* $t_1 \neq t_2$ *in* $(0,1)$*, the following relations for the commutators are valid*

$$[A(t_1),\, A(t_2)] = -2[A_\varepsilon(t_1),\, A_\varepsilon(t_2)] = \frac{t_1t_2(t_2-t_1)}{2(1-t_1)^2(1-t_2)^2}.D.$$

By the notion *b-trajectory* of a point we consider *b-trajectories* of the Bézier curve $\mathcal{C}_{\{A_0A_1A_2\}}$ as the family of lines $\mathcal{C}^{(n)}_{\{A_0A_1A_2\}}$ formed by the n^{th}–b-image of any point of $\mathcal{C}_{\{A_0A_1A_2\}}$, $\forall\, n \in \mathbb{N}$.

Theorem 2.5. *The b-trajectories of the Bézier curve* $\mathcal{C}_{\{A_0A_1A_2\}}$ *are the elements of the sequence of curves*

$$\mathcal{C}^{(n)}_{\{A_0A_1A_2\}} : r_n(t) = x_n(t).a_0 + y_n(t).a_1 + z_n(t).a_2, \quad t \in [0,\,1],$$

with

$$\begin{aligned}&\big(x_n(t); y_n(t); z_n(t)\big)\\ &= \left((t-1)^{2n};\ 2f(t)\begin{vmatrix}(t-1)^n & 2^n\\ 1 & (t-2)^n\end{vmatrix}; 1-f(t)\begin{vmatrix}(t-1)^{n+1} & 2^{n+1}\\ 1 & (t-2)^{n-1}\end{vmatrix}\right)\end{aligned} \tag{4}$$

and where $f(t) = \dfrac{(1-t)^n}{(t-3)(2-t)^{n-1}}$.

(i) *For arbitrary* $n \in \mathbb{N}$, $r_n(0) = a_0$, *i.e.* $A_0 \in \mathcal{C}^{(n)}_{\{A_0A_1A_2\}}$, $r_n(1) = a_2$ *and* $A_2 \in \mathcal{C}^{(n)}_{\{A_0A_1A_2\}}$.

(ii) *The tangent vectors to each* $\mathcal{C}^{(n)}_{A_0A_1A_2}$ *at* A_0 *and* A_2 *are*

$$\dot{r}_n(0) = 2n \cdot (a_1 - a_0) = 2n \cdot \overrightarrow{A_0A_1}, \qquad \forall n \in \mathbb{N},$$

$$\dot{r}_n(1) = \dot{f}(1).2^{n+1}(a_2 - a_1) = \begin{cases} 0, & \textit{for} \quad n \geq 2\\ 2(a_2 - a_1) = 2.\overrightarrow{A_1A_2}, & \textit{for} \quad n = 1.\end{cases}$$

(iii) *The envelope* $\mathcal{E}_n$ *of* $\pi(\mathcal{C}^{(n)}_{A_0A_1A_2})$, *in b-coordinates, is*

$$\mathcal{E}_n : \begin{cases} x = \Delta_1.\Delta^{-1} \\ y = \Delta_2.\Delta^{-1}, \\ z = \Delta_3.\Delta^{-1} \end{cases}$$

for all (t, n) *in order to have well defined*

$$\Delta_1 = \frac{-1}{y_n^2}\left(\frac{y_n}{z_n}\right)^{\bullet}, \quad \Delta_2 = \frac{-1}{z_n^2}\left(\frac{z_n}{x_n}\right)^{\bullet}, \quad \Delta_3 = \frac{-1}{x_n^2}\left(\frac{x_n}{y_n}\right)^{\bullet},$$

and $\Delta = \sum_{i=1}^{3} \Delta_i$.

Proof. By applying Lemma 2.2.(ii) jointly with (3) we get (4) and calculate (i). We express the derivatives $\dot{x}_n$, $\dot{y}_n$, $\dot{z}_n$ of (4) are as follows:

$$\dot{x}_n = 2n(t-1)^{2n-1},$$

$$\dot{y}_n = \frac{2f(t)}{(t-1)(t-2)(3-t)} \begin{vmatrix} (t-1)^n(t-2)^n & 2^n \\ t-1+n(t-3) & t-1+2n(t-2)(3-t) \end{vmatrix},$$

$$\dot{z}_n = \frac{2f(t)}{(t-1)(t-2)(3-t)} \begin{vmatrix} (t-1)^{n+1}(t-2)^{n-1} & -2^n \\ t-1+n(t-3) & (3-t)[1-n(t-2)]-1 \end{vmatrix}.$$

Thus we calculate (ii).

(iii) The $\mathbb{RP}_2-$ isotomic conjugated image of each $\mathcal{C}^{(n)}_{\{A_0A_1A_2\}}$ is the 1-parameter family of lines

$$\pi(\mathcal{C}^{(n)}_{\{A_0A_1A_2\}}) = p_n : \underbrace{\frac{1}{x_n(t)} \cdot x + \frac{1}{y_n(t)} \cdot y + \frac{1}{z_n(t)} \cdot z}_{=F_n(x,y,z,t)} = 0.$$

The envelope $\mathcal{E}_n$ of $\pi(\mathcal{C}^{(n)}_{\{A_0A_1A_2\}})$ is obtained by the solutions of the system

$$\mathcal{E}_n : \begin{cases} x+y+z=1 \\ F_n(x,y,z,t)=0 \\ \dfrac{\partial F_n}{\partial t}(x,y,z,t)=0 \end{cases} \iff \mathcal{E}_n : \begin{cases} x+y+z=1 \\ x_n^{-1}\cdot x + y_n^{-1}\cdot y + z_n^{-1}\cdot z = 0 \\ \dot{x}_n x_n^{-2}\cdot x + \dot{y}_n y_n^{-2}\cdot y + \dot{z}_n z_n^{-2}\cdot z = 0. \end{cases}$$

By applying the Cramer's rule for all t and n, each determinant to be well defined, we get the evelope $\mathcal{E}_n$ in b-coordinates. □

By (iii) of Theorem 2.5 in the space arises the sequence of conic surfaces $\mathcal{S}_n$ with vertex O and generators $\mathcal{E}_n$ — the envelopes of $\pi(\mathcal{C}^{(n)}_{\{A_0A_1A_2\}})$.

téristique en fonction de la vitesse de la lumière sous la forme $w = \alpha_G c$, on peut faire apparaître, comme l'ont proposé Agnese et Festa en 1997, une constante de couplage gravitationnelle α_G qui a un statut en partie semblable, pour chaque sous-système auquel elle s'applique, à celui de la constante de structure fine de l'électromagnétisme.

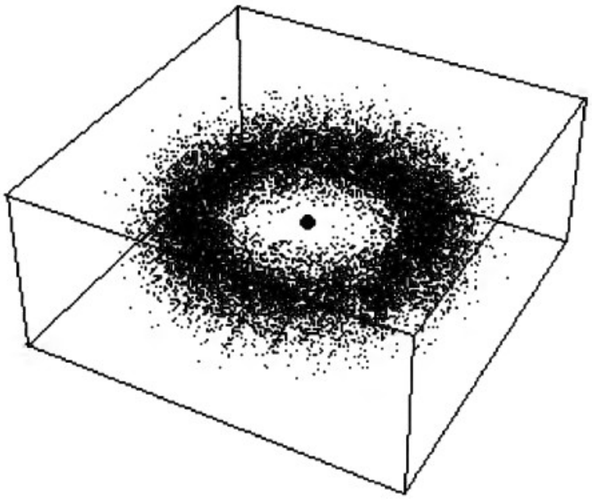

Figure 1.1. Exemple de sous-structure formée dans un disque protoplanétaire selon l'approche relativiste d'échelle.
(Transformation de l'équation fondamentale de la dynamique en une équation de forme schrödingerienne sous des conditions de fractalité.)

La résolution de l'équation de Schrödinger fondée sur un tel paramètre fournit des fonctions d'onde dont le carré du module donne la densité de probabilité attendue pour la distribution des corps dont on a ainsi décrit le mouvement. Cette distribution n'est pas plate, mais montre au contraire des pics de probabilité correspondant à des valeurs particulières des quantités conservatives comme l'énergie, le moment angulaire ou le vecteur de Runge-Lenz. Ainsi le disque initial est amené à s'organiser en sous-structures (fig. 1.1). Les planètes qui se formeront ensuite à partir de ces structures auront (une fois que le système se sera stabilisé, agrandissant ainsi l'horizon de prédictibilité) des éléments orbitaux plus probables qui pourront être calculés en fonction de ces quantités conservatives (qui sont donc communes aux deux régimes, classique et macroquantique).

On prédit ainsi que les demi-grands axes doivent montrer des pics de probabilité pour des valeurs : $a_n = (GM/w^2)\, n^2$

– où n est un entier, et que les excentricités sont elles-mêmes appelées à montrer des valeurs préférentielles données par : $e_{kn} = k/n$

1.4 Broken Surfaces Diagrams

Let a knotted surface $K = f(F)$ be given. Consider a 3-dimensional hyperplane $H \subset \mathbb{R}^4$ which we identify with $\mathbb{R}^3$ once and for all. The hyperplane H is thought of as the orthogonal complement to a vector $\mathbf{v} \in \mathbb{R}^4$, and the knotted surface K may be translated to be disjoint from H. The knotted surface K may also be perturbed slightly so that its projection p into $H = \mathbb{R}^3$ is a generic surface. Note that the projection p in this section is different from the projection $p_{\mathbf{v}}$ used in the previous sections.

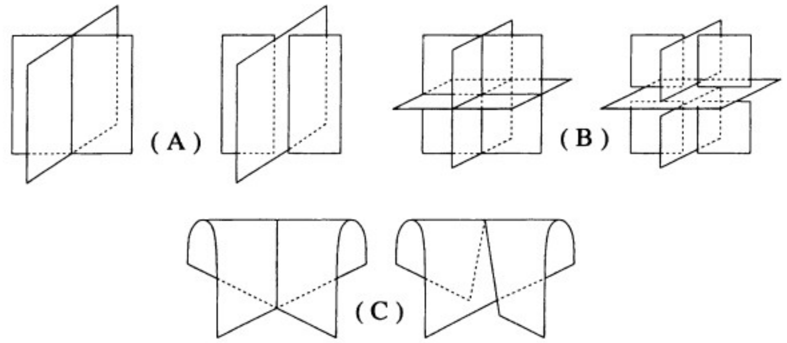

Fig. 1.9. Broken surface diagrams near singular points

This means that the image $p(f(F))$ has generic double points, triple points and branch points. That is, for any $y = p(f(x))$ there is a neighborhood N_y in $\mathbb{R}^3$ and a diffeomorphism $\psi : N_y \to \mathbb{R}^3$ such that the image of F under ψ looks like the intersection of 1, 2, or 3 coordinate planes or the cone on a figure 8 (Whitney umbrella). In these cases the point y is said to be a *non-singular point*, *a double point*, a *triple point*, or a *branch point*, respectively. Neighborhoods of double, triple, and branch points are depicted in Fig. 1.9, at the left of (A), (B), (C) respectively.

In N_y, when y is a double point, we can distinguish the relative height (with respect to the direction $\mathbf{v}$) of the two sheets in N_y as upper and lower. At a triple point we have an upper (top), middle, and lower (bottom) sheet. And at a branch point the upper and lower sheet converge at the branch point.

Now we describe the preimage of singular points

$$\{ \ x \in K \mid p(x) = p(y) \text{ for some } y \in K, x \neq y \ \}.$$

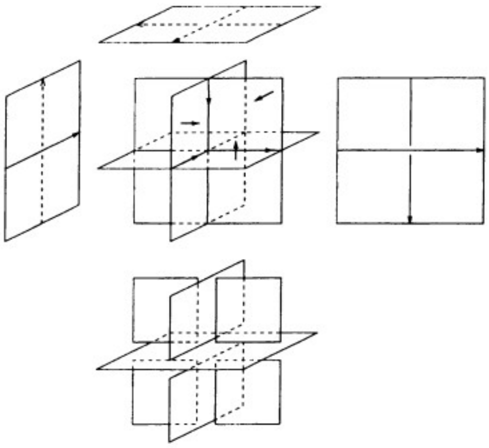

Fig. 1.10. Decker curves around a triple point

We let D, T, and B denote the sets of double, triple, and branch points in $\mathbb{R}^3$, respectively. We regard T and B as subsets of D. The preimages on K of the double points are denoted by D_a and D_b with labels representing above and below sheets. Thus D_b is lower with respect to the height direction $\mathbf{v}$ than D_a. The sets D_a and D_b are called upper and lower decker sets, respectively. We use the same terminology for the preimages in F, where $K = f(F)$, and call $f^{-1}(D_a)$ and $f^{-1}(D_b)$ the upper and lower decker sets as well. The transverse components of D_a and D_b are arcs that intersect at the preimages of triple points or branch points. The preimage on K of a branch point is a point that is in the common boundary of D_a and D_b. We use the same letter B to denote the branch points in $\mathbb{R}^3$ and on the knotted surface K. The preimage of a triple point, x, consists of three points x_t, x_m and x_b that lie in the top, middle, and bottom sheet, respectively. The preimage of the set T is the union of the three sets T_t, T_m, and T_b, where these are the collections of such top, middle, and bottom preimages of triple points, respectively. A point x_t is the interesction of two sub-arcs of D_a. The corresponding point x_m in the middle sheet is the intersection of an arc in D_a and an arc in D_b. The corresponding point x_b in the bottom sheet is the intersection of two arcs in D_b. Moreover, these six arcs are paired (top to middle, top to bottom, and middle to bottom) and project to the three arcs in the double point set that intersect at x. The situation at a triple point is depicted in Fig. 1.10. In the middle of the figure, a neighborhood of a triple point is depicted. The preimages for each sheet are depicted around it. The decker sets D_a and D_b are represented by dotted and solid lines, respectively. At the bottom of the figure, a broken surface diagram at a triple point is shown, which we explain below.

Now we generalize the convention for classical knot diagrams, where the under-arc is broken to indicate crossing information, to knotted surfaces. Let

N be a thin open neighborhood of $D_b \setminus B$, such that $B \subset \overline{N}$; where $\overline{N}$ denotes the closure. In other words, N is a thin strip along D_b, such that if an end point of an arc of D_b is a branch point, then the branch point is on the boundary of $\overline{N}$. Let $K' = K \setminus N$. Then the image $p(K)$ is a compact surface in $\mathbb{R}^3$ where the lower sheets are consistently removed along the double point curves. Thus this gives a diagram of a surface that is analogous to a classical knot diagram.

A *broken surface diagram* consists of a generic surface in $\mathbb{R}^3$ such that one of the sheets along the double point curve are consistently broken as shown in Fig. 1.9 (A) right. At triple and branch points, the surface is locally broken as indicated in Fig. 1.9 (B) and (C) right, respectively, and consistently extended to double point curves (see [CarSai98a] for more details). We have shown, in the preceding paragraph, that we obtain a broken surface diagram from a projection of a knotted surface, by breaking $p(K)$ along D_b. Similar conventions have been known for some time, and different colors or labels were used to indicate over and under crossing information (see [Fra87, HaKaShi99, Rose93, Yaji64], for example).

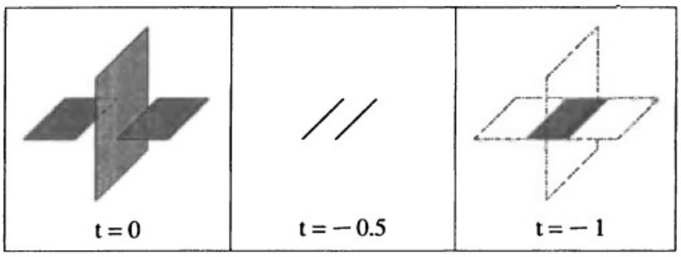

Fig. 1.11. Filling in a broken surface near a double point curve

On the other hand, given a broken surface diagram, an embedding of a surface is easy to construct as we now indicate. First we embed the broken surface, which is a surface with boundary, into $\mathbb{R}^3 = \mathbb{R}^3_0 = \{(x, y, z, 0)\}$. Next we will fill in the neighborhoods of the lower decker sets in hyperplanes $\mathbb{R}^3_t$ for $t < 0$. Figures 1.11, 1.12, and 1.13 indicate how the neighborhoods of the lower decker sets are embedded in $\mathbb{R}^3_{[0,-2]}$.

Near a double arc in the levels $\mathbb{R}^3_t$, for $t \in (-1, 0)$, a pair of arcs parallel to the boundary of the broken surface are embedded. At the level $\mathbb{R}^3_{-1}$, a strip is embedded. The union of the arcs and the strip form a 2-disk embedded in $\mathbb{R}^4$. Such a disk is embedded along any arc of double points, and these disks are chosen to match-up along closed double point arcs, or at triple points and branch points. The situation is depicted in Fig. 1.11.

Near a triple point, arcs parallel to the boundary of the broken surface are embedded in $\mathbb{R}^3_t$, for $t \in (-1, 0)$. The arcs in the bottom sheet look like the doubled "+" and the arcs in the middle sheet look like those for the

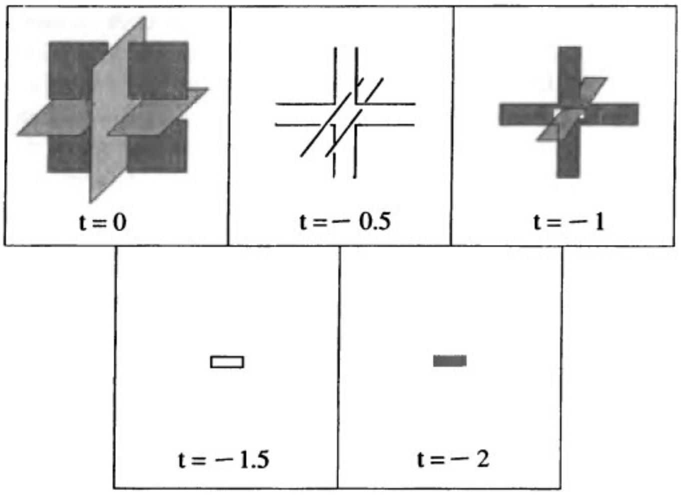

Fig. 1.12. Filling in a broken surface near a triple point

double curves described above. In Fig. 1.12, the middle picture at $t = -0.5$ depicts this situation. At the $t = -1$ level, these parallel arcs are filled in by rectangular (and "+" shaped) disks, except inside the small rectangle in the middle of "+" shaped arcs, through which the other rectangle goes. The rectangle continues in the levels $t \in (-2, -1)$, and is filled in by a smaller rectangular disk at $t = -2$ as depicted in the figure.

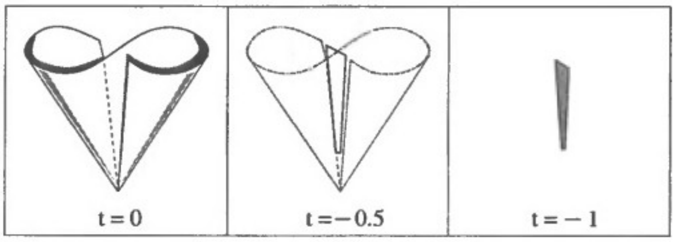

Fig. 1.13. Filling in a broken surface near a branch point

Near a branch point, an unfilled trapezoid is found in the levels $t \in (-1, 0)$, and a filled trapezoid is found in the $t = -1$ level, as depicted in Figure 1.13.

We summarize this convention as follows:

Proposition 1.21. *Any knotted surface gives rise to a broken surface diagram. Any broken surface diagram gives a knotted surface.*

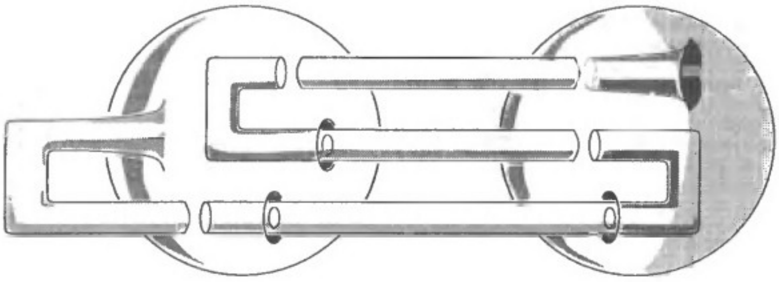

Fig. 1.14. The Fox-Milnor example as a broken surface

Example 1.22. Figure 1.14 depicts a broken surface diagram for the Fox-Milnor example in Fig. 1.1. In this figure, there are no triple points nor are there branch points.

Remark 1.23. On the other hand, it is not true that any generic surface in $\mathbb{R}^3$ is a projection of a knotted surface in $\mathbb{R}^4$. In other words, there are generic surfaces in $\mathbb{R}^3$ that do not lift to embeddings in $\mathbb{R}^4$. Such an example was described first in [Gill82]. Further criteria were found in [Ak96, CarSai98b, Sat00c], and higher (than 4) dimensional examples were given in [Oga01]. This is a phenomenon distinctive in higher dimensions, as any generically immersed circle in the plane obviously lifts to an embedding in $\mathbb{R}^3$.

Furthermore, in [Oga01], another remarkable fact was presented: there are projections of n-knots, for any $n > 2$, that do not lift to the unknot. The case $n = 2$ is open.

In case the knotted surface is oriented, the double point set D is oriented as follows. First, an orientation normal can be chosen in 3-space at every point of $p(K)$, except at branch points, in such a way that the ordered pair (tangent, normal) agrees with the fixed (say, right-handed) orientation of 3-space. A double point curve can be given an induced orientation via the triple (normal to upper sheet, normal to lower sheet, tangent to double curve) forming the right-handed orientation for 3-space.

Triple points are also oriented, in the sense that a sign, positive or negative, is assigned to each triple point as follows. A triple point is *positive* if and only if the ordered triple (normal to top sheet, normal to middle sheet, normal to bottom sheet) agrees with the orientation of 3-space.

1.5 Charts and Elementary String Interactions

In this section, we describe a planar graph, called a *chart*, that represents a given knotted surface. A chart will be a labeled planar graph. Consider a knotted surface K and perturb its image in $\mathbb{R}^4$ so that the restriction of

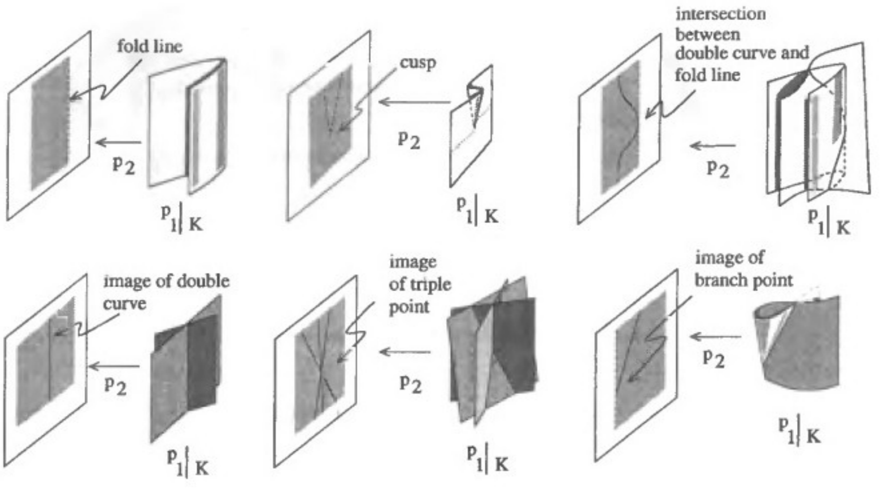

Fig. 1.15. The generic projections of knotted surfaces into planes

a projection $p : \mathbb{R}^4 \to \mathbb{R}^2$ onto a 2-dimensional affine subspace is a generic map between surfaces. The projection p can be factored (after a small perturbation if necessary) as the composition of a projection p_1 from $\mathbb{R}^4$ onto a 3-dimensional subspace $\mathbb{R}^3$ and another projection p_2 from $\mathbb{R}^3$ onto a 2-dimensional subspace $\mathbb{R}^2$, such that $p_1|_K$ and $p_2|_{(p_1(K))}$ are both generic.

Thus $p_1|_K$ has generic double points, triple points, and branch points. Meanwhile, the generic singularities of $p|_K$ consist of fold lines and cusps. The projection of a double point arc under p_2 is an arc in the plane. The projection of a triple point under p_2 is a valence 6 vertex, that is the intersection of three double point arcs. The double point curve could intersect with the fold lines in a single point, which looks like a point of tangency in $p|_K$ between a double point curve and a fold line. In this situation branch points are the end-points of double arcs that lie on fold lines. The situation of these projections is depicted in Fig. 1.15. In the figure, the projections of double point curves are depicted by solid lines, and those of fold lines are depicted by dotted lines.

We distinguish, in notation, the set D of double points of the projection, $p_1|_K$, from the image $p_2(D) = D^*$ which is a collection of edges in the plane. Similarly the triple point set, T, projects to $p_2(T) = T^*$ as the set of valence 6 vertices in the projection. The branch point set, B, projects to $p_2(B) = B^*$ which is the collection of boundary points of D^* that lie on the fold set $\mathcal{F}^*$. The set $\mathcal{F} = p_2^{-1}(\mathcal{F}^*)$ is called the *fold locus*. This is the union of the points at which p_2 has rank ≤ 1. The set, C, of cusps is the set of points at which the rank of p_2 is 0; its image in the plane is denoted by C^*. Also denote by DF the set of intersection $D \cap \mathcal{F}$, and $DF^* = p_2(DF)$.

In case the surface is oriented, the projection D^* of the double point set D is given an induced orientation inherited from the orientation of D. The fold lines are co-oriented as follows. The coorientation of a fold line is the image in $\mathbb{R}^2$ under p_2 of an oriented normal to the image $p_1(F) \subset \mathbb{R}^3$; see Fig. 1.17.

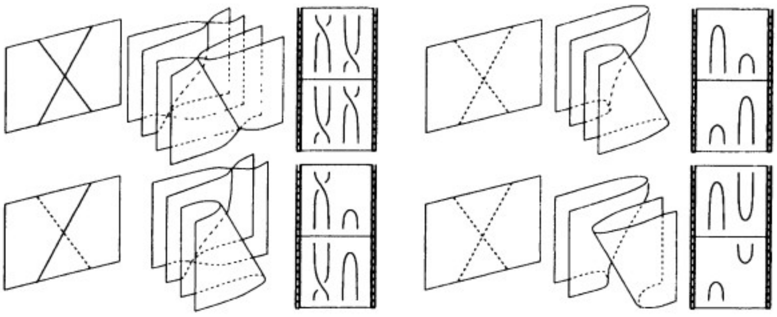

Fig. 1.16. Double intersection points of D^* and $\mathcal{F}^*$.

In summary, $D^* \cup \mathcal{F}^*$ forms a planar graph Γ with orientations for D^* and co-orientations for $\mathcal{F}^*$. The set of vertices V of such a graph Γ consists of T^*, B^*, C^*, DF^*, the double intersection points between D^* and $\mathcal{F}^*$, and double self-intersections between arcs in D^* or those in $\mathcal{F}^*$. See Fig. 1.16 for the latter double intersection points. The set E of edges are the closures of connected components of $(D^* \cup \mathcal{F}^*) \setminus V$. The types of vertices and incident edges are summarized in Table 1.1. Again, compare with Figs. 1.15 and 1.16.

Table 1.1. Vertices of a chart

Types of vertices	Valency	Types of incident edges
Cusp C^*	2	2 fold lines
Branch point B^*	3	2 fold lines, 1 double arc
Triple point T^*	6	6 double arcs
Tangential intersection of fold line and double curve DF^*	4	2 fold lines, 2 double arcs
Transverse intersection of fold line and double curve $D^* \cap \mathcal{F}^*$	4	2 fold lines, 2 double arcs
Self-intersection of double curves $D^* \cap D^*$	4	4 double arcs
Self-intersection of fold lines $\mathcal{F}^* \cap \mathcal{F}^*$	4	4 fold lines

Next, we define a label assigned to each edge of such graphs. A label (i, j) is a pair of non-negative integers. A line segment in $\mathbb{R}^3$ that is parallel to the direction p_2 intersects the surface $p_1(K)$ in a number of points. If we choose such a segment through a double point of $p_1(K)$, then we count the number of intersections of the line with the surface. The number, i, of such intersections between the double point and the plane into which the surface is projected is the first coordinate of the label on the projection of the double curve. The number, j, of points further from the plane of projection is the second coordinate of the label along the projection of the double curve. A point on the fold set is similarly labeled. This convention is slightly different from [CarSai98a] (the first and the second factors are switched). The difference in the conventions is not a problem since once a projection direction is chosen the plane can be a screen in front of or behind the surface.

Definition 1.24. A *chart* of a given knotted surface is the graph $G = (V, E)$ formed by $D^* \cup \mathcal{F}^*$, with the labels on edges, as described above.

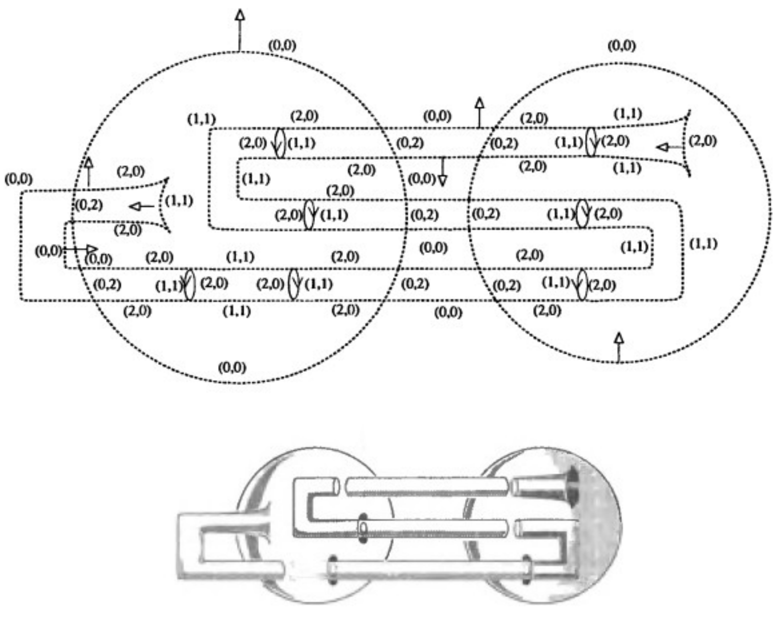

Fig. 1.17. The chart of the Fox-Milnor example

Example 1.25. A chart of the example given in Fig. 1.14 is given in Fig. 1.17.

The labels on the edges around a vertex are the same or distinct depending on the types of the vertex. The labels coincide at a double crossing of D^*, and at a branch point (on a fold line). Some labels are distinct at the rest of the vertices. At a cusp, the labels of the edges involved (fold lines) are $(i, j+1)$ and $(i+1, j)$. The six edges incident to a triple point have indices in cyclic order (i, j), $(i, j \pm 1)$, (i, j), $(i, j \pm 1)$, (i, j), and $(i, j \pm 1)$ (with all $(+)$s or all $(-)$s). At a crossing between $\mathcal{F}^*$, the labels are (i, j), (i', j'), $(i + 2, j)$, $(i', j' + 2)$, cyclically. At a crossing between D^* and $\mathcal{F}^*$, the label (i, j) on two fold lines is the same, and the labels on two edges in D^* are (i, j), $(i + 2, j)$ or (i, j), $(i, j + 2)$. At a vertex in DF^*, if the labels on the fold line are $(i, j + 1)$ and $(i + 1, j)$, then those for double arcs are $(i + 1, j)$ and $(i, j + 1)$. For the latter crossings, see Fig. 1.16.

For the rest of the section, we explain how to represent knotted surfaces as sequences of symbols (called elementary string interactions), using charts. In fact, this was a motivation for considering charts [CarSai98a].

A projection $p_3 : \mathbb{R}^3 \to \mathbb{R}$ can be chosen such that it restricts to a projection $p_3|_{\mathbb{R}^2} : \mathbb{R}^2 \to \mathbb{R}$ where $\mathbb{R}^2$ is the plane into which a chart is embedded (equivalently the plane into which the knotted surface K was projected) so that $p_3|_\Gamma$ is a generic Morse function with distinct critical values. More precisely, $p_3|_\Gamma$ satisfies the following conditions.

(i) The function $p_3|_\Gamma$ takes distinct values for vertices $V(\Gamma)$ of Γ.
(ii) Regard D^* and $\mathcal{F}^*$ as immersed 1-submanifolds. Then $p_3|_\Gamma$ has isolated non-degenerate critical points (local maxima/minima) on the interior of $(D^* \cup \mathcal{F}^*) \setminus V(\Gamma)$.
(iii) The above critical points have distinct critical values, that are also distinct from the values of $p_3(V(\Gamma))$.

Let t_i, $i = 1, \ldots, n$, be critical values of $p_3|_\Gamma$ described above, where we include $V(\Gamma)$ as the set of critical points. Let $[a_i, b_i]$ be small mutually disjoint intervals containing t_i, for $i = 1, \ldots, n$. Let $\mathbb{R}^2_t \subset \mathbb{R}^3$ denote the plane at height $t \in \mathbb{R}$, $\mathbb{R}^2_t = p_3^{-1}(t)$. The intersection $\mathbb{R}^2_t \cap \mathbb{R}^2$ (where the second $\mathbb{R}^2$ is where a chart lies) is a "horizontal" line, and the line passes through the critical points of $p_3|_\Gamma$ at $t = t_i$, $i = 1, \ldots, n$.

Let γ_t denote the immersed 1-manifold in $\mathbb{R}^2_t$ that is the intersection $p_1(K) \cap \mathbb{R}^2_t$. Then γ_{a_i} and γ_{b_i} differ by one of the small changes corresponding to the critical points of $p_3|_\Gamma$, that are called *elementary string interactions* (*ESIs*). These changes can be seen in Fig. 1.15 by looking at the top and bottom cross sections of $p_1|_K$ (right of each arrow representing p_2), and in Fig. 1.16 the changes are depicted in the form of movies. In each case, a height function on $\mathbb{R}^2_t$ is fixed for each t, in the direction parallel to the plane $\mathbb{R}^2$ in which the chart lies and perpendicular to the height function p_3. With respect to this height function, the curves γ_t have maxima and minima at fold lines. The ESIs are described in summary in Table 1.2.

The height function on the plane of the chart $p_3|_{\mathbb{R}^2}$ can be used to decompose a movie description into smaller pieces. A height function is fixed on each $\mathbb{R}^2_t$ as above, and the circles γ_t are given crossing information from a broken surface diagram of $p_1(K)$. In other words, except for $t = t_i$ $(i = 1, \cdots, n)$, $\mathbb{R}^2_t \cap p_1(K')$ is a classical link diagram γ'_t, where K' is K with a neighborhood of the lower decker set removed. The underlying immersed circles of γ'_t are γ_t.

Table 1.2. Elementary string intersections

Types of critical points	ESIs
Cusp C^*	Cancelation of local max/min
Branch point B^*	Reidemeister type I move
Triple point T^*	Reidemeister type III move
Tangential intersection of fold line and double curve DF^*	An arc going over (under) a local max (min)
Transverse intersection of fold line and double curve $D^* \cap \mathcal{F}^*$	Interchange of heights of a max or min and a crossing
Self-intersection of double curves $D^* \cap D^*$	Interchange of heights of distant crossings
Self-intersection of fold lines $\mathcal{F}^* \cap \mathcal{F}^*$	Interchange of heights of distant max and/or min
Minimum of $\mathcal{F}^*$	Birth of a circle, or a saddle
Maximum of $\mathcal{F}^*$	Death of a circle, or a saddle
Max/min of D^*	Reidemeister type II move

Right before/after a critical point $t = t_i$, the links γ'_{a_i} and γ'_{b_i} differ by an ESI.

Then each classical link diagram is represented symbolically, by using the symbols $\cup_{m,n}$, $\cap_{m,n}$, $X_{m,n}$, and $\overline{X}_{m,n}$ for a local maximum, a minimum, a positive crossing, and a negative crossing, respectively, where subscripts are the corresponding labels of the chart. Each classical link diagram is represented by a word in these symbols, and a knotted surface is represented by a sequence of words, where differences between consecutive words differ only by one of the ESIs.

The advantage to using such a movie is that no information is lost from still to still, such as rotations that we failed to describe in Remark 1.3 on Fig. 1.2. In some cases, it is necessary to explicitly mention which ESI connects two words. Specifically, there are pairs of words that can either be connected by saddles or births/deaths; in this case we must denote the ESI between them. In [CarSai98a] and [CRS97] this type of a combinatorial description of a knotted surface was given, and a complete set of moves among them that realizes equivalence was presented. Using such a combinatorial description, a 2-categorical description of knotted surfaces was obtained in [BL98].

Example 1.26. For a choice of a height function, a movie for the Fox-Milnor example is illustrated in Fig. 1.18, where changes between stills correspond to ESIs. The top still in the second film strip from the left in Fig. 1.18, for example, gives rise to a word

$$\cap_{0,0} \cap_{1,1} \overline{X}_{2,0} X_{2,0} \cup_{1,1} \cup_{0,0} \cap_{0,0} \cup_{0,0},$$

and the still below it corresponds to the word

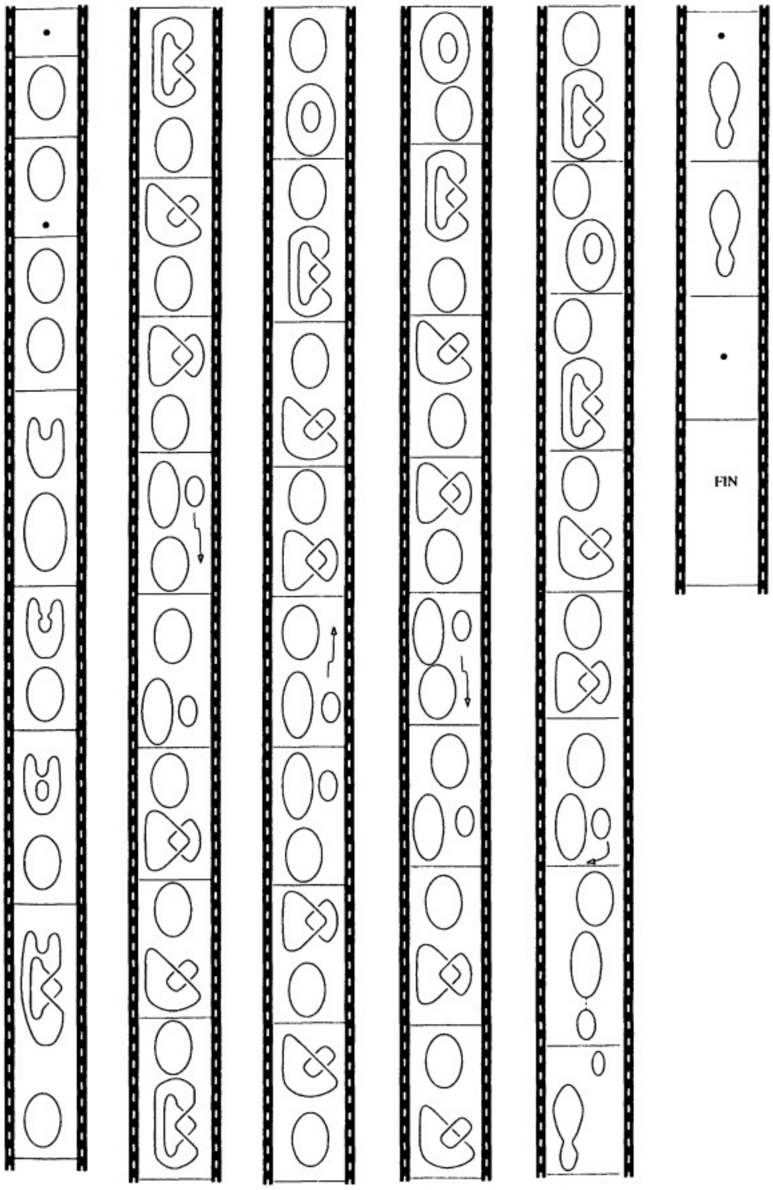

Fig. 1.18. A slow movie of the Fox-Milnor example

$$\cap_{0,0} \cap_{2.0} X_{1,1} X_{2,0} \cup_{1,1} \cup_{0,0} \cap_{0,0} \cup_{0,0}.$$

The subscripts correspond to the chart labels, and for example, $X_{1,1}$ means that there is one arc to the left and right of the crossing. The change from one of the above two words to the other corresponds to the tangential intersection of fold line and double curve, depicted in Fig. 1.15 top right.

1.6 Braids and Braid Charts

Let B and D be 2-disks. Fix a set of m interior points, $X_m = \{z_1, z_2, \ldots, z_m\}$, of B.

Definition 1.27. (cf. [CarSai94, Kama92a, Rud83, Viro90]) A *braided surface* (of degree m) is a properly embedded surface S in $B \times D$ such that

- the natural map $\pi : S \subset B \times D \to D$ is a branched covering map of D of degree m,
- ∂S is a closed braid in the solid torus $B \times \partial D$.

A *surface braid* or a *2-dimensional braid* is a braided surface such that

- ∂S is a trivial closed braid $X_m \times \partial D$ in the solid torus $B \times \partial D$.

The map $\pi : S \to D$ is called the *associated branched covering map* of S. A surface braid is *simple* if the associated branched covering is simple, i.e., $\#(\pi^{-1}(y)) = m$ or $m - 1$ for each $y \in D$.

Let S be a surface braid of degree m. Fix a bi-parametrization $I_3 \times I_4 \cong D$, where I_3 and I_4 are the unit intervals. For each $t \in I_4 = [0, 1]$, let b_t be a subset of the cylinder $B \times I_3$ such that the restriction of S to the cylinder $B \times I_3 \times \{t\} \subset B \times I_3 \times I_4 \cong B \times D$ is $b_t \times \{t\}$. The one-parameter family $\{b_t\}_{t \in [0,1]}$ is called a *motion picture* of the surface braid S.

For all t but a finite number of exceptional values, $b_t \subset B \times I_3$ is an m-braid such that $\partial b_t = X_m \times \partial I_3$. Moreover, each of b_0 and b_1 is the trivial braid $X_m \times I_3 \subset B \times I_3$. For an exceptional value t, b_t is a *singular braid* which is similar to a braid except there are intersection points among strings. Each intersection is called a *singular point* of b_t or of S, which corresponds to a singular point of the associated branched covering $S \to D$. If S is a simple surface braid, then each singular point is an intersection of two strings of b_t for some $t \in I_4$, and there are no other singular points of b_t on the same level of I_3. Conversely, if there is at least one singular point in the 2-disk $B \times (s, t)$ for each $(s, t) \in I_3 \times I_4 \cong D$ and it is the intersection of two strings of b_t, then S is simple. Deforming the bi-parametrization slightly, we may assume that there is a single singular point in b_t for each exceptional value $t \in I_4$. We sometimes assume this condition but not always. When we assume this condition and when S is simple, we call a motion picture $\{b_t\}$ a *braid movie*. See Figure 1.19. The motion picture presents a simple surface braid of degree

Si aplicamos la misma idea al número complejo

$$z = \mu(\cos 1 + i \operatorname{sen} 1),$$

de módulo $\mu \neq 1$, vemos que sus potencias

$$z^\theta = \mu^\theta (\cos \theta + i \operatorname{sen} \theta)$$

quedan representadas por un punto que describe la espiral equiangular $r = \mu^\theta$ (§ 8.6).

EJERCICIO

Por medio del teorema de de Moivre, encuéntrense
(*a*) las dos raíces cuadradas de $3 + 4i$;
(*b*) las tres raíces cúbicas de 1, denotadas por 1; ω, ω^2;
(*c*) las seis raíces sextas de 1 (con la notación de ω);
(*d*) las doce raíces duodécimas de 1.

$\sqrt[n]{z} = \rho^{1/n}$ cis $\frac{\theta + 2k\pi}{n}$

$\sqrt{3+4i} = 5^{1/2}$ cis

9.5 LA FORMULA $e^{\pi i} + 1 = 0$

> *Hay una fórmula famosa –tal vez la más compacta y famosa de todas las fórmulas– que desarrolló Euler a partir de un descubrimiento de de Moivre:* $e^{i\pi} + 1 = 0$. . . . *Es igualmente atractiva para el místico, el científico, el filósofo y el matemático. Cada uno de ellos le encuentra un significado propio. Aunque ya llevaba más de un siglo de ser conocida, la fórmula de de Moivre llegó a Benjamin Pierce como una revelación. Al descubrirla un día se volvió a sus estudiantes. . . . "Señores," les dijo, "esto es cierto con seguridad, es absolutamente paradójico; no podemos entenderlo y no sabemos lo que significa, pero lo hemos demostrado y, por lo tanto, debe ser verdad."*
>
> E. Kasner y J. Newman
>
> [1, págs. 103-104]

Puesto que hemos aceptado potencias *reales*, como lo es $\mu^\theta = e^{\theta \log \mu}$, nos preguntamos con naturalidad el significado que se puede dar a las potencias *complejas*. Una respuesta parcial proviene de la teoría de series infinitas como

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \frac{x^5}{5!} + \ldots,$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \ldots,$$

$$\operatorname{sen} x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \ldots.$$

La primera serie, que es familiar cuando x es real, nos permite *definir* e^x en otros casos; por ejemplo

$$\begin{aligned} e^i &= 1 + i + \frac{i^2}{2!} + \frac{i^3}{3!} + \frac{i^4}{4!} + \frac{i^5}{5!} + \dots \\ &= 1 + i - \frac{1}{2!} - \frac{i}{3!} + \frac{1}{4!} + \frac{i}{5!} - \dots \\ &= \left(1 - \frac{1}{2!} + \frac{1}{4!} - \dots\right) + i\left(1 - \frac{1}{3!} + \frac{1}{5!} - \dots\right) \\ &= \cos 1 + i \operatorname{sen} 1. \end{aligned}$$

Estas series nos permiten expresar 9.41 en la forma concisa de Euler

9.51 $$\cos\theta + i \operatorname{sen}\theta = e^{\theta i},$$

que es un refinamiento de la identidad

$$\theta i = \log_e(\cos\theta + i \operatorname{sen}\theta)$$

de R. Cotes* (1682–1716), de quien dijo Newton después de su muerte prematura, "Si Cotes hubiera vivido, ¡tal vez hubiéramos llegado a saber algo! "

Al llevar $\theta = \pi$ a 9.51, obtenemos la "fórmula famosa"

$$e^{\pi i} = -1,$$

que relaciona de manera tan sorprendente los tres números importantes

$$e = 2.71828\dots, \qquad \pi = 3.14159\dots,$$

e i.

EJERCICIOS

1. Evalúese $e^{i\pi i}$. ¿Es i^i real?
2. Dedúzcase de 9.51 $\cos\theta = \dfrac{e^{\theta i} + e^{-\theta i}}{2}$, $\operatorname{sen}\theta = \dfrac{e^{\theta i} - e^{-\theta i}}{2i}$,

que son las conocidas fórmulas de $\cos(\theta + \alpha)$, $\operatorname{sen}(\theta + \alpha)$, y las derivadas de $\cos\theta$, $\operatorname{sen}\theta$.

9.6 RAICES DE ECUACIONES

> *Gauss . . . fue el primer matemático que usó los números complejos de manera realmente científica y segura.*
>
> G. H. Hardy
>
> [Hardy y Wright 1, pág. 188]

En el campo de los números complejos, podemos resolver cualquier ecuación cuadrática de coeficientes reales; por ejemplo, la ecuación 9.31 tiene las dos raíces i y $-i$. Es aún más notable que podamos resolver cualquier ecuación de coeficientes complejos; y no solamente una ecuación cuadrática, sino también una ecuación cualquiera de tercer o cuarto grado. Cuando hablamos de "resolver" una ecuación queremos decir que podemos encontrar expresiones explícitas de sus raíces en términos de sus coeficientes. E. Galois (que fue asesinado en 1832 cuando solamente tenía 20 años) demostró que la ecuación algebraica general 9.21 cuando $n > 4$ no se puede resolver en este sentido [Infeld 1]. A pesar de ello, el teorema fundamental del álgebra (que Gauss demostró en 1799) afirma la *existencia* de raíces para todos los valores de n, incluso cuando no dispongamos de expresiones explícitas. (Una bonita y pulcra demostración se encuentra en Birkhoff y MacLane [1, págs. 101-103].) De hecho, se pueden encontrar soluciones *numéricas* correctas hasta un número deseado de cifras decimales.

---

* *Harmonia mensurarum*, Cambridge, 1722, pág. 28.

EJERCICIO

Una escalera de mano que mide 24 metros de largo descansa en una fachada con el apoyo adicional de un cajón cúbico cuya arista mide 7 metros, que se ha colocado al pie de la fachada con una de sus aristas horizontales en contacto con la escalera. ¿A qué altura sube la escalera sobre la fachada? (*Indicación*: tómese $7x$ como la altura desde el extremo superior de la escalera a la tapa del cajón. Obténgase una ecuación cuya raíz relevante sea $7x = 9 + 4\sqrt{2}$.)

9.7 TRANSFORMACIONES CONFORMES

Vimos, en § 9.3, que la transformación

$$z' = z + b$$

(que suma a la variable compleja z la constante compleja b) es una traslación, por lo que

$$z' = az$$

(que multiplica z por la constante compleja a) ha de ser una rotación dilatativa alrededor del punto O, donde incluimos como casos especiales una dilatación (cuando a es real) y una rotación (cuando $|a| = 1$). En consecuencia, la rotación dilatativa alrededor del punto general c es

$$z' - c = a(z - c)$$

ó

$$z' = az + (1 - a)c.$$

Así, pues, la semejanza directa general, como se describió en § 5.5, es la transformación *lineal* general

$$z' = az + b$$

[Ford 1, pág. 3]; y tenemos aquí una traslación o una rotación dilatativa según sea $a = 1$ ó $a \neq 1$. (En el último caso, $c = b/(1 - a)$.)

Como el producto de una semejanza opuesta y una reflexión es directo, una semejanza opuesta cualquiera se puede expresar como producto de una

2. Estos 12 puntos dividen las 12 aristas del octaedro

$$(\pm\tau^2, 0, 0), \quad (0, \pm\tau^2, 0), \quad (0, 0, \pm\tau^2)$$

en la razón de $\tau : 1$.

3. Obténganse las coordenadas de los 20 vértices del dodecaedro regular [Coxeter 1, pág. 53].

11.3 LA ESPIRAL AUREA

> *Arquímedes, Leonardo, Newton: todos ellos hombres con mucho sentido práctico, pero con algo más. Una vocación a la pregunta, tal vez . . . Muy misterioso todo esto, muy misterioso. Y muy emocionante. Esto es, la emoción: se obtiene al ser Dios mientras se construye, y se obtiene al observar a Dios, es decir, al observar las cosas tal como son.*
>
> J. L. Synge [2, pág. 163]

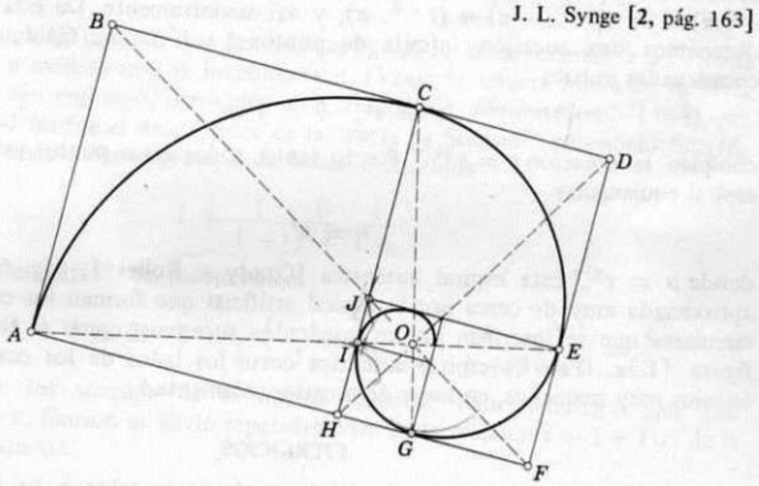

Figura 11.3a

La relación $\tau = 1 + 1/\tau$ nos señala que el rectángulo áureo $ABDF$ (figura 11.3*a*) se puede descomponer en dos piezas: el cuadrado $ABCH$ y un rectángulo áureo menor. (Se pueden identificar los puntos B, C, D con los Q, U, S de la figura 11.1*b*.) Del rectángulo pequeño $CDFH$ podemos cortar nuevamente otro cuadrado, de modo que dejemos un rectángulo aún menor, y continuar el proceso indefinidamente.

Puesto que el rectángulo $HJEF$ es homotético a $ABDF$, el vértice J del primero queda en la diagonal BF del segundo. De hecho, las rectas AE, BF, CG, DH contienen entre todas los vértices de todos los rectángulos. Para derivar $CDFH$ a partir de $ABDF$ podemos emplear una rotación dilatativa de centro O, el punto de intersección $BF \cdot DH$. Esta semejanza, que transforma cada uno de los puntos $A, C, E, G, I, \ldots$ en el siguiente, y cada uno de los puntos $B, D, F, H, J, \ldots$ en el siguiente, es el producto de un cuarto de giro negativo alrededor de O y la dilatación $O(\tau^{-1})$. Por lo tanto, DH es perpendicular a BF. La semejanza inversa, que transforma cada rectángulo en el siguiente mayor que él, es producto de un cuarto de giro positivo alrededor de O y la dilatación $O(\tau)$.

Puesto que

$$\frac{OB}{OD} = \tau = \frac{BC}{CD},$$

OC biseca el ángulo (recto) BOD. Así tenemos que las rectas CG, AE pasan por O y bisecan los ángulos entre BF, DH.

En términos de coordenadas polares con polo en O, la rotación dilatativa que transforma OE en OC transforma cualquier punto (τ, θ) en $(\tau r, \theta + \frac{1}{2}\pi)$. Si tomamos como recta inicial OE y la distancia OE como la unidad de medida, de manera que E sea $(1, 0)$, deducimos las coordenadas $(\tau, \frac{1}{2}\pi)$ de C,(τ^2, π) de A, $(\tau^3, \frac{3}{2}\pi)$ del vértice opuesto a A en el nuevo cuadrado que se colocaría sobre AF, y así sucesivamente. De la misma manera, G es $(\tau^{-1}, -\frac{1}{2}\pi)$, I es $(\tau^{-2}, -\pi)$ o (τ^{-2}, π), y así sucesivamente. De esta manera, obtenemos una sucesión infinita de puntos $\ldots, I, G, E, C, A, \ldots$ cuyas coordenadas polares

$$r = \tau^n, \quad \theta = \tfrac{1}{2}\pi n$$

cumplen la ecuación $r = \tau^{2\theta/\pi}$. Por lo tanto, todos estos puntos están en la espiral equiangular

$$r = \mu^\theta,$$

donde $\mu = \tau^{2/\pi}$ Esta espiral auténtica [Cundy y Rollet **1**, pág. 64] se ve aproximada muy de cerca por la espiral artificial que forman los cuadrantes circulares que se inscriben en los cuadrados sucesivos, como se tiene en la figura 11.3*a*. (Pero la espiral auténtica corta los lados de los cuadrados a ángulos muy pequeños, en lugar de tocarlos solamente.)

EJERCICIOS

1. Verifíquese la conclusión de § 5.4 cuando se la aplica a los rectángulos semejantes $ABDF$ y $CDFH$ de la figura 11.3*a*.
2. Obténganse coordenadas polares para los puntos J, H, F, D, B. Se encuentran en otra espiral equiangular que es congruente (¿mediante qué ángulo de rotación?) y homotética (¿mediante qué razón de amplificación?) con respecto a la espiral $IGECA$.

11.4 LOS NUMEROS DE FIBONACCI

> *Sint minim 1 et 1 quos imaginaberis inaequales. Adde, fient 2. cui adde maiorem 1 fient 3. cui adde 2 fient 5. cui adde 3 fient 8. cui adde 5 fient 13. cui adde 8 fient 21.*
>
> J. Kepler [**1**, pág. 270]

En 1202, Leonardo de Pisa, apodado Fibonacci ("hijo de buen carácter"), se encontró con su célebre sucesión de enteros f_n en relación con la cría de conejos.* Supuso que los conejos vivían para siempre y que cada mes una pareja procrea una nueva pareja que se vuelve productiva a la edad de dos meses. En el primer mes el experimento comienza con una pareja de recién nacidos. En el segundo mes, todavía hay una sola pareja. En el tercer mes, hay 2; en el cuarto, 3; en el quinto, 5; y así sucesivamente. Sea f_n el número de parejas de conejos en el enésimo mes. Los primeros valores (y sus razones sucesivas) se pueden tabular de la manera siguiente:

n:	0	1	2	3	4	5	6	7	8	9	10	. . .
f_n:	0	1	1	2	3	5	8	13	21	34	55	. . .
f_{n+1}/f_n:	∞	1	2	1.5	$1.\dot{6}$	1.6	1.625	1.6154	1.6190	1.6176	1.6182	. . .

Cuatro siglos después, Kepler afirmaba explícitamente lo que Fibonacci seguramente advirtió: que la suma de dos f cualquiera es igual a la siguiente, de manera que la sucesión queda determinada por la fórmula de recursión

11.41 $$f_0 = 0, \quad f_1 = 1, \quad f_k + f_{k+1} = f_{k+2}.$$

Kepler también observó que las razones $f_n : f_{n+1}$ se aproximan a $1 : \tau$ cada vez más, a medida que se incrementa n. (Véase la tercera hilera en la tabla anterior.) Sin embargo, otros cien años después, R. Simson (1687–1768), que en realidad no fue el descubridor de la "recta de Simson") reconoció f_{n+1}/f_n como el enésimo convergente de la fracción continua

$$1 + \frac{1}{1+}\,\frac{1}{1+}\,\frac{1}{1+}\cdots.$$

(Los "convergentes" son los números

$$1, \quad 1 + 1 = 2, \quad 1 + \frac{1}{1+1} = \frac{3}{2}, \quad 1 + \frac{1}{1+}\,\frac{1}{1+1} = \frac{5}{3},$$

y los que los suceden de la misma manera.) Para demostrar que lím $(f_{n+1}/f_n = \tau$, Simson se sirvió repetidamente de la relación $\tau = 1 + 1/\tau$, de la manera siguiente:

$$\tau = 1 + \frac{1}{\tau} = 1 + \frac{1}{1+}\,\frac{1}{\tau} = 1 + \frac{1}{1+}\,\frac{1}{1+}\,\frac{1}{\tau} = \cdots$$

Con respecto a f_n, E. Lucas (1842–1891) tomó en consideración los números relacionados g_n, que se definen por medio de

$$g_0 = 2, \quad g_1 = 1, \quad g_k + g_{k+1} = g_{k+2}.$$

Los primeros valores que obtuvo eran los siguientes:

n:	0	1	2	3	4	5	6	7	8	9	10	. . .
g_n:	2	1	3	4	7	11	18	29	47	76	123	. . .

Se demuestra facilmente por inducción que (cuando $n > 0$)

11.42 $$g_n = f_{n-1} + f_{n+1}.$$

---

* R. C. Archibald, Golden Section, *American Mathematical Monthly*, 25 (1918), págs. 232–238.

Dejemos esto como ejercicio para el lector y prosigamos para establecer las identidades de Lucas

11.43
$$f_{2n} = f_n\, g_n,$$

11.44
$$f_{2n+1} = f_n^2 + f_{n+1}^2,$$

que son obvias cuando $n = 0$ o 1. Para demostrar ambas por inducción, sumaremos las relaciones tentativas

$$f_{2k-1} = f_{k-1}^2 + f_k^2 \quad \text{y} \quad f_{2k} = f_k g_k,$$

con lo que obtenemos
$$\begin{aligned} f_{2k+1} &= f_{k-1}^2 + f_k(f_{k-1} + f_{k+1}) + f_k^2 \\ &= (f_{k-1} + f_k)f_{k+1} + f_k^2 \\ &= f_k^2 + f_{k+1}^2, \end{aligned}$$

y entonces sumamos

$$f_{2k} = f_k g_k \quad \text{y} \quad f_{2k+1} = f_k^2 + f_{k+1}^2\,,$$

con lo que obtenemos
$$\begin{aligned} f_{2k+2} &= f_k^2 + f_k(f_{k-1} + f_{k+1}) + f_{k+1}^2 \\ &= f_k f_{k+1} + f_{k+1} f_{k+2} \\ &= f_{k+1}\, g_{k+1}. \end{aligned}$$

De la misma manera, para establecer la identidad

11.45
$$\tau^n = f_n\tau + f_{n-1},$$

que es obvia cuando $n = 1$ ó 2, sumamos
$$\tau^k = f_k\tau + f_{k-1} \quad \text{y} \quad \tau^{k+1} = f_{k+1}\tau + f_k,$$
de modo que obtenemos
$$\tau^{k+2} = f_{k+2}\tau + f_{k+1}.$$

La identidad 11.45 sigue siendo válida cuando n es negativo, siempre y cuando definamos $f_{-k} = f_{-k+2} - f_{-k+1}$ (cuando $k > 0$), de manera que

$$f_{-k} = (-1)^{k+1} f_k.$$

Así,
$$\tau^{-k} = f_{-k}\tau + f_{-k-1}$$

11.46
$$= (-1)^{k+1}(f_k\tau - f_{k+1}).$$

y

11.47
$$(-\tau)^{-k} = f_{k+1} - f_k\tau$$

11.471
$$= f_{k-1} - f_k\tau^{-1}.$$

Al sumar 11.45 (donde k substituye a n) y 11.47, obtenemos

11.48
$$g_k = \tau^k + (-\tau)^{-k}\,.$$

De la misma manera, al substraer 11.471 de 11.45 (donde k substituye a n), obtenemos

$$f_k = \frac{\tau^k - (-\tau)^{-k}}{\tau + \tau^{-1}} = \frac{\tau^k - (-\tau)^{-k}}{\sqrt{5}}, \tag{11.49}$$

que es una fórmula explícita, descubierta por J. P. M. Binet en 1843.

A partir de 11.48 y 11.49 deducimos inmediatamente

$$\tau^k = \frac{g_k + f_k\sqrt{5}}{2}, \quad (-\tau)^{-k} = \frac{g_k - f_k\sqrt{5}}{2};$$

por ejemplo

$$\tau^3 = \sqrt{5} + 2, \qquad \tau^{-3} = \sqrt{5} - 2,$$
$$\tau^6 = 9 + 4\sqrt{5}, \qquad \tau^{-6} = 9 - 4\sqrt{5}.$$

EJERCICIOS

1. Exprésese la suma de la serie finita

$$1 + 1 + 2 + 3 + \ldots + f_n$$

en términos de f_{n+2}.

2. Demuéstrese la identidad de Simson

$$f_{n-1}\, f_{n+1} - f_n^2 = (-1)^n.$$

Esta es la base de un problema desconcertante y entretenido [Ball 1, pág. 85].*

3. Verifíquese la observación de Lagrange acerca de que los dígitos finales de los números de Fibonacci empiezan a recurrir después de un ciclo de sesenta:

$$1, 1, 2, 3, 5, 8, 3, 1, 4, \ldots, 7, 2, 9, 1, 0.$$

4. A partir de la identidad

$$(1 - t - t^2)(1 + t + 2t^2 + 3t^3 + \ldots + f_{n+1}\, t^n + \ldots) = 1,$$

que implica

$$\sum_0^\infty f_{n+1}\, t^n = \frac{1}{1 - t - t^2} = \sum_0^\infty (t + t^2)^k = \sum_0^\infty t^k(1 + t)^k = \sum_{k=0}^\infty \sum_{j=0}^k \binom{k}{j} t^{k+j},$$

dedúzcase la fórmula de Lucas para los números de Fibonacci en términos de coeficientes binomiales:

$$f_{n+1} = \binom{n}{0} + \binom{n-1}{1} + \binom{n-2}{2} + \cdots.$$

5. Dése el valor de 0.01 a t en la identidad $\Sigma f_{n+1}\, t^n = (1,-t-t^2)^{-1}$, y dedúzcase una manera fácil de escribir los 19 primeros dígitos en la forma decimal $\frac{10000}{9899}$.

6. Tabúlese g_{n+1}/g_n y encuéntrese su límite cuando n tiende a infinito.

---

* Véase también Coxeter, The golden section, phyllotaxis, and Wythoff's game, *Scripta Mathematica*, 19 (1953), pág. 139. Desde un punto de vista más general,

$$f_{n+h}\, f_{n+k} - f_n\, f_{n+h+k} = (-1)^n f_h\, f_k;$$

véase A. E. Danese, *American Mathematical Monthly*, 67 (1960), pág. 81.

Preface

by *Egbert Brieskorn*

If you feel attracted by the beautiful figure on the cover of this book, your feeling is something you share with all geometers. "It is the delight in figures in a higher sense which distinguishes the geometer". This is a well known statement of the algebraic geometer Alfred Clebsch. Throughout the history of our science, great men like Plato and Kepler and Poincaré were inspired by the beauty and harmony of such figures. Whether we see them as elements or representations of some universal harmony or simply look at them as a structure accessible to our mind by its very harmony, there is no doubt that the contemplation and the creation of beautiful geometric figures has been and will be an integral part of creative mathematical thought.

Perception of beauty is not the work of the intellect alone – it needs sensitivity. In fact, it does need sensual experience. To seperate the ideas from the appearances, the structure from the surface, analytical thinking from holistic perception and science from art does not correspond to the reality of our mind and is simply wrong if it is meant as an absolute distinction. It would deprive our creative thought of one of its deepest sources of inspiration.

I remember a visit of the blind mathematician B. Morin in Göttingen. He gave us a lecture on the eversion of the sphere, the process which he had discovered for turning the sphere inside out by a continuous family of immersions. At that time, he had no analytic description of this very complicated process, but he had a very precise qualitative picture of its geometry in his mind, and he had pictures of models made according to his instruction. I was deeply impressed by the beauty of these figures, and I was moved by the fact that he had been able to see all this beautiful and complex geometry which we could visualize only with great difficulty even after it was shown to us.

In Göttingen we had a very nice collection of mathematical models dating from the days of Felix Klein and David Hilbert. You can find photographs of some of them in a very nice book of Gerd Fischer entitled "Mathematical models", which was published by Vieweg. Among these models there is one made in 1903 showing the surface of Boy. This is a surface obtained by an immersion of the real projective plane in 3-dimensional space. At the time when it was made it was known that the projective plane cannot be embedded as a smooth surface in 3-space. This is so because any smooth closed surface in 3-space divides the space into an interior part and an exterior. This implies that it is orientable: If you stand in the exterior with your feet on the surface, you know what it means to turn left. But the real projective plane is not orientable. This was a very remarkable discovery of Felix Klein in 1874, and it implies that the projective plane $\mathbb{P}^2$ cannot be embedded in the 3-dimensional space $\mathbb{R}^3$. So if we want to visualize $\mathbb{P}^2$ by means of a surface in $\mathbb{R}^3$, we have to be contented with less than a smooth surface. For instance we should admit that different parts of the surface penetrate each other. If the parts themselves are smooth and penetrate each other transversally, we call the surface transversally immersed. It is by no means obvious that there is a presentation of $\mathbb{P}^2$ as an immersed surface in $\mathbb{R}^3$. If there was none, we would be forced to allow the surface to have some singular points, i. e. points where it is not smooth. Such representations of $\mathbb{P}^2$ by surfaces with selfpenetrations and singular points were known to exist. One of them is a beautiful surface discovered by the German geometer Jacob Steiner. He called it his "Roman surface", because he discovered some of its properties during a stay at Tome in 1844. You can see a picture of this surface on **Plate 57** of this book and you can buy a pretty 3-dimensional model of it from Vieweg. It has tetrahedral symmetry, with six lines of selfpenetration issuing from the center of the tetrahedron in the direction of the midpoints. These singular points are of the simplest possible type. They are so called "Whitney-umbrellas" (**Plate 23**). These singularities are the simplest singularities (apart from selfpenetration) which can occur in this situation, and they are stable: a Whitney umbrella will not go away if the surface is deformed slightly.

Maybe it was the stability of these singularities that made David Hilbert suspicious so that he thought it would be impossible to present the projective plane $\mathbb{P}^2$ by an immersed surface without singular points. But the famous mathematician David Hilbert was mistaken. In 1901 his student W. Boy produced two surfaces which are immersions of $\mathbb{P}^2$ in $\mathbb{R}^3$. One of them is particularly pretty. It has a 3-fold axis of symmetry and this is the Boy surface which is the main theme of this book.

Of course, B. Morin knew Boy's surface when he visited us in Göttingen. He must have had a very clear picture of it in his mind. Nevertheless he asked us to take our model out of the show-case so that he could touch it and feel whether its curvature was beautiful. It is this kind of sensitivity for the genesis and transformation of forms which I think is necessary for the creation of ideas such as those of B. Morin or R. Thom leading to the beautiful constructions of F. Apéry that you find in this book.

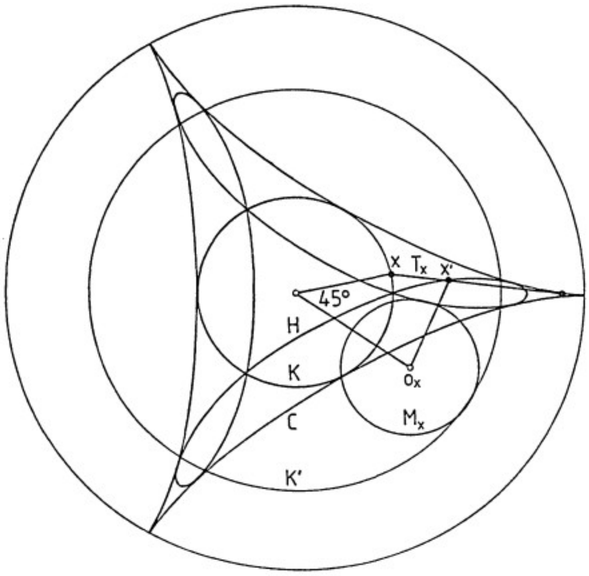
Boy's surface, like Morin's halfway model of the eversion of the sphere at the time of his visit in Göttingen, was only described in terms of a qualitative geometry. Such descriptions are quite satisfactory from the point of view of differential topology. In fact since the days of H. Poincaré we know that in many situations such a qualitative description is all we can hope for. However, there is an older tradition in mathematics which asks for a more definite way of describing solutions of a problem. In algebraic or analytic geometry, a surface imbedded in 3-space is to be described by an equation or a parametrization by nice analytic functions such as polynomials or by some beautiful geometric construction. In a sense, a geometric figure can only be considered as a unique entity worthy of this name "figure" in the ancient tradition if it is well-defined in this way. This is what Kepler meant when he said: "That which is construction in geometry is consonance in music". Thus our desire for harmony in a geometric figure will only be fulfilled if we see it described in such a way. This beautiful book of F. Apéry tells the exciting history of the discovery of such a description for the surface of Boy.

It begins with very qualitative topological and combinatorical descriptions of the projective plane and the surface of Boy, and it shows us nice descriptions in terms of equations and parametrizations obtained by B. Morin 1978 (**Plate 33**), J.-P. Petit and J. Souriau (1981) (**Plates 31, 32**), J. F. Hughes 1985 (**Plate 34**) and J. Bryant (**Plate 35**). He then presents a very nice solution of his own originating from an idea of B. Morin. The idea is to construct the apparent contour of the Boy surface seen from infinity in the direction of its 3-fold axis by interpreting parts of it as a deformation of the "folded handkerchief singularity" mapping (x, y) to (x^2, y^2). This leads to a parametrization of a Boy surface in 3-space by 3 polynomials of degree 4 (proposition 4 on page 60, **Plates 36–38**). However, all these solutions have slight deficiencies. For instance the equation describing the surface may have other real zeros different from the points of the Boy surface.

But finally the author presents a truly perfect solution. It describes the Boy surface by a beautiful geometric construction, which is subtle and elementary, in the best tradition of classical geometry. In order to make it easy for you to understand his analysis, let me explain the construction in purely geometric terms. It generates the surface by a 1-parameter family of ellipses obtained as follows.

Let L be a line and p a point on L. This line will become the 3-fold axis of symmetry, and the pole p will be a point where L intersects the surface. Let P be the plane orthogonal to L passing through p, and let Q be a plane parallel to P at distance 1. In Q draw a circle K of radius $\sqrt{2}/3$ with axis L. Then draw a threecuspidal hypocycloid C such that K is its inscribed circle. C may be obtained as trace of a point of the circumference of a circle of radius $\sqrt{2}/3$ rolling inside a circle of radius $\sqrt{2}$ concentric with K. The curve C will be the apparent contour of the Boy surface that we are going to construct, if we project the surface from the pole p to the plane Q.

Next we draw an elongated hypocycloid H in the plane Q as follows. Let K' be a circle of radius 1 in Q concentric with K. Let M be a moving circle of radius 1/3 which rolls without gliding inside K'. Let t_0 be a point in the moving plane of M at distance $\sqrt{2}/3$ from the centre of M. As M rolls, t_0 will trace out an elongated hypocycloid in the plane Q. This curve will have three ordinary double points, and they lie on K. We choose the initial position of t_0 so that these double points are situated on the tangents of the 3 cusps of the 3-cuspidal hypocycloid C, as indicated by the following figure.



Now we define a map $K \to H$. Let x be a point moving on K in the positive sense. Let o_x be the centre of the moving circle M_x, where o_x is moving on a circle of radius 2/3 with the same angular velocity as x, but trailing behind 45°. The point t_0 for M_x determines a unique point x' on the elongated hypocycloid H, and our map is defined by associating this point x' to x.

It follows from the construction that x and x' lie on a tangent T_x to the hypocycloid C. Let P_x be the plane passing through this tangent T_x and the pole p. We define an ellipse E_x in the plane P_x by the following three conditions:

(a) E_x passes through x and x'.
(b) E_x is tangent to P in p.
(c) The distance d of x and x' and the maximal distance δ of a point on E_x from P are related as follows:

$$\delta = (1 - 9d^2/16)^{-1}.$$

These conditions define E_x uniquely.

And now our construction comes to its end: The surface S to be constructed is simply the union of all ellipses E_x. As x moves on K, the ellipses sweep out the surface. This is the Boy surface constructed by F. Apéry. Apéry proves that it is exactly the set of real zeroes of a polynomial equation of degree 6 which he can write down explicitly. Moreover he gives a nice description of the transversal immersion $\mathbb{P}^2 \to S \subset \mathbb{R}^3$. The ellipses are the images of a pencil of projective lines passing through the point in $\mathbb{P}^2$ which corresponds to the pole p. If we interpret $\mathbb{P}^2$ as quotient of the 2-sphere S^2 identifying antipodal points, the corresponding map $S^2 \to \mathbb{R}^3$ has a nice description in terms of trigonometric functions, and the inverse images of the ellipses are the great circles passing through a pair of antipodal points. **Plates 39–41** show this pretty surface.

Apéry's construction is beautiful, elementary, but subtle and extremely elegant. Moreover there is a similar construction for the Roman surface of Steiner, and one can pass from one surface to the other by a continuous family of surfaces, such that at a certain moment the six Whitney-umbrella-type singularities on the deformations of the Roman surface annihilate each other in pairs by a nice process called hyperbolic confluence. This process is illustrated on **Plates 28–30**, and the family of surfaces is shown on **Plates 51–56.**

Finally Apéry generalizes his approach and gets similar descriptions of other surfaces. Among them is the beautiful halfway model of B. Morin which you see on the cover of this book. All this is sheer beauty, and I hope that you will be delighted.

The compactness of $S^2/\sim$ implies j is a homeomorphism, so $S^2/\sim$ is a representation of the projective plane $\mathbb{P}^2$.

Using representation 4 we see that by j, a line corresponds to the quotient of a great circle of S^2 by the antipodal relation.

Representation 6 (Curt Reinhardt [RE]).

We start with the graph given by the edges and vertices of a regular octahedron, and we construct a 2-complex structure by adding four triangular faces of the octahedron, chosen so that any two have at most one common vertex, and three square faces corresponding to the diagonal of the octahedron (Fig. 7).

It is easy to prove we obtain a closed surface H, and we have

$$\chi(H) = 6 - 12 + 7 = 1$$

The 2-complex H is called the *Rheinhardt heptahedron.* It is homeomorphic to $\mathbb{P}^2$.

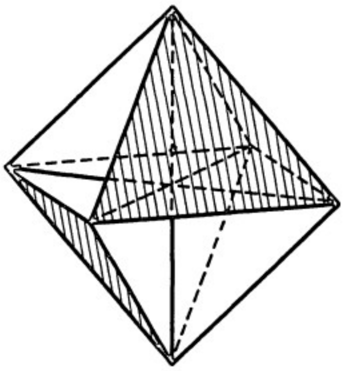


Fig. 7 Rheinhardt heptahedron.

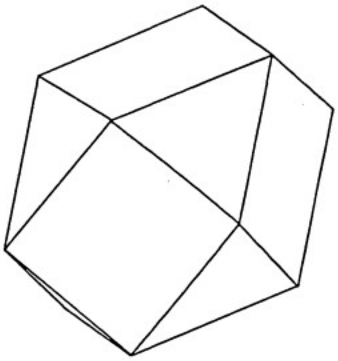

This heptahedron can be described as the quotient of the cuboctahedron by the antipodal map

Representation 7.

As in the preceding representation, we build a 2-complex whose vertices are those of a regular octahedron 0. We specify two antipodal vertices as the north and the south pole, so the four remaining vertices define the equatorial square. To the twelve edges of the octahedron, we add the two diagonals of the equatorial square. To complete the structure we add the four faces of 0 containing the south pole, two faces of 0 with just the north pole as common vertex, two new faces defined by the north pole and the diagonals of the equatorial square, and a quadrilateral face bounded by the two equatorial edges still free and the two previous diagonals (Fig. 8).

As previously, this 2-complex, called the *combinatorial cross-cap* and denoted by C, is a closed surface and its Euler characteristic yields

$$\chi(C) = 6 - 14 + 9 = 1 .$$

Thus C is homeomorphic to $\mathbb{P}^2$.

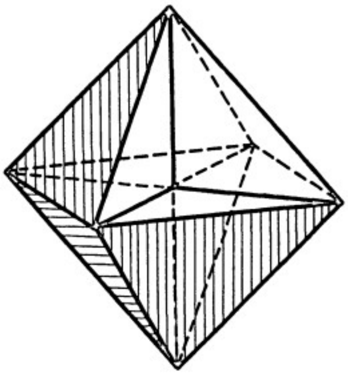

Fig. 8 Combinatorial cross-cap.

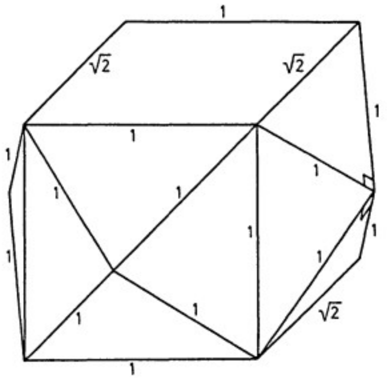

The combinatorial cross-cap can be obtained by making the quotient of this 2-complex by the antipodal map. We have replaced four lateral faces of a rectangular parallelepipet by four pyramids.

Representation 8.

We consider the equivalence relation on the *complex projective line* $\mathbb{C} \cup \{\infty\}$ given by

$$z \sim -1/\bar{z} \quad \text{and} \quad 0 \sim \infty$$

$\mathbb{C} \cup \{\infty\}$ is the Alexandroff compactification of $\mathbb{C}$; so prop. 1 sect. 1.1 implies the compactness of the quotient $\mathbb{C} \cup \{\infty\}/\sim$. This leads back to the spherical model of representation 5 by the stereographic projection from S^2 to $\mathbb{C} \cup \{\infty\}$ (Fig. 9):

$$p(x, y, z) = (x + iy)(1 - z)^{-1} \quad \text{and} \quad p(0, 0, 1) = \infty$$

This homeomorphism induces a homeomorphism between $(\mathbb{C} \cup \{\infty\})/\sim$ and the quotient of S^2 by the antipodal relation.

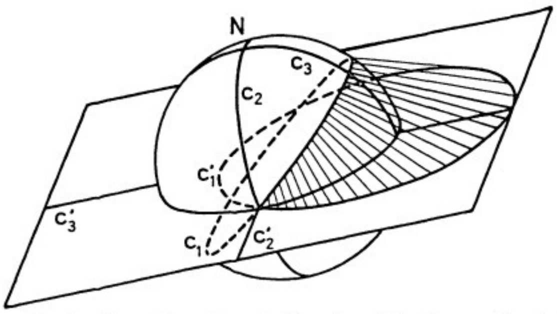

Fig. 9 Stereographic projection from the sphere to the plane. The image of a circle c is denoted by c′.

The image of a great circle on S^2 by p is either an affine line containing the origin 0 and completed by ∞, or a circle with center z and radius $1 + z\bar{z}$, according to the fact that the great circle goes or not through the north pole $(0, 0, 1)$ (Fig. 9). It gives the image of a line in this representation.

Representation 9.

Let K be the 2-complex, in Fig. 10. We consider the equivalence relation $\sim$ on K which identifies the edges according to the numbering and the orientation indicated on the figure. The particularity of this 2-complex is the possibility of realizing the former identifications by folding paper according to instructions given in Fig. 10.

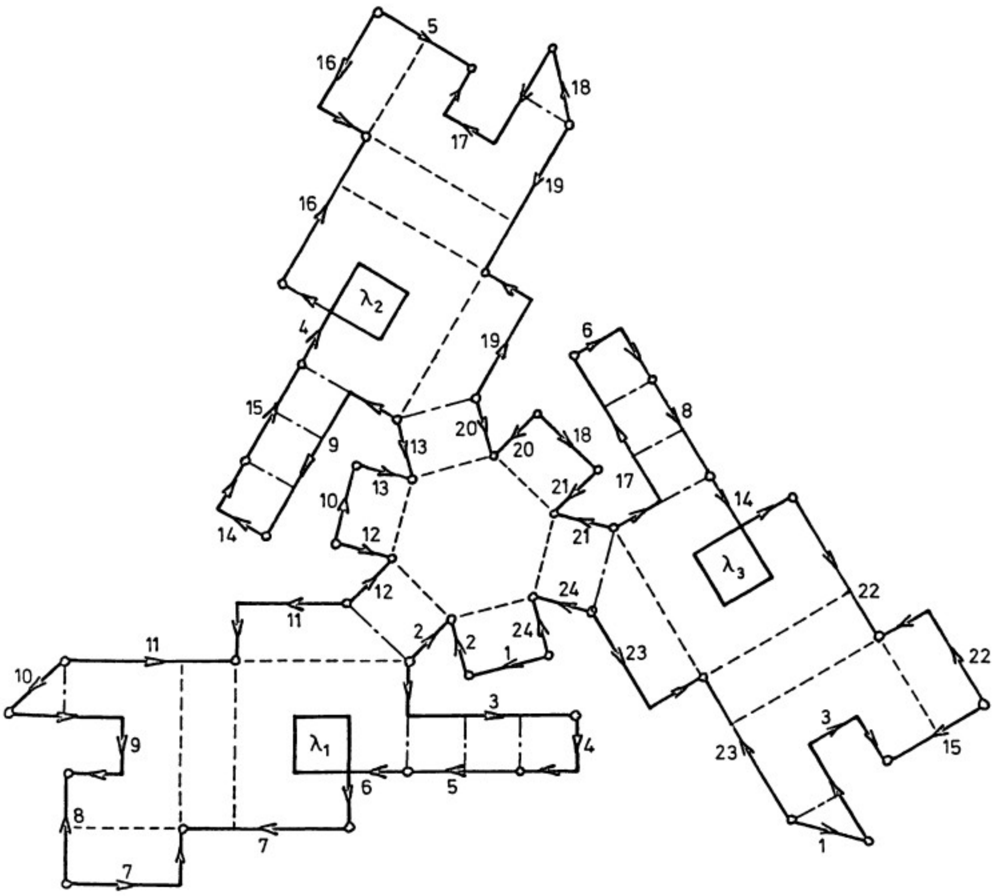

Fig. 10 The numbering of the edges of this 2-complex defines an equivalence relation which can be realized by folding the paper along the dashed lines. The two types of dashed lines indicate the direction of the folding: – – – – for ∨ folding —◦— for ∧ folding. The self-intersection curve in the paper model is the image of the loop defined by the sum $(6-) . \lambda_1 . (6+) . (8) . (14) . (15) . (4-) . \lambda_2 . (4+) . (5) . (6) . (8) . (14-) . \lambda_3 . (14+) . (15) . (4) . (5)$.
where $(6-) . (6+) = (6) \qquad (4-) . (4+) = (4) \qquad (14-) . (14+) = (14)$

It is easy to see that the quotient space $K/\sim$ is homeomorphic to the quotient of the disk $\bar{B}^2$ by the antipodal relation on the boundary (Fig. 11), so $K/\sim$ is homeomorphic to the projective plane $\mathbb{P}^2$ (see representation 3). By prop. 7 sect. 1.1 there are some points of self-intersection in the paper model in $\mathbb{R}^3$. In Fig. 10 these points come from the loop given by the sum

$$\begin{aligned}\lambda = {} & (6-)\,.\,\lambda_1\,.\,(6+)\,.\,(8)\,.\,(14)\,.\,(15)\,.\,(4-).\,\lambda_2\,.\,(4+)\,.\,(5)\,.\,(6)\,.\,(8)\,.\\ & .\,(14-)\,.\,\lambda_3\,.\,(14+)\,.\,(15)\,.\,(4)\,.\,(5)\end{aligned}$$

where

$$\begin{aligned}(6-)\,.\,\ (6+) &= \ (6)\\ (4-)\,.\,\ (4+) &= \ (4)\\ (14-)\,.\,(14+) &= (14)\end{aligned}$$

and (i) denotes the path whose number is i.

Fig. 11 The model of Fig. 10 can be regarded as the quotient of a disk under the identifications shown.

The image of $K/\sim$ in $\mathbb{R}^3$ obtained by folding paper is a polyhedron called the *combinatorial Boy surface* (Fig. 12). The image of λ, that is the self-intersection curve, defines a loop in $\mathbb{R}^3$ which is called a *three-bladed propeller* (Fig. 13). It has only one multiple point, which is a triple point.

Representation 10.

Let K be the 2-complex of Fig. 14. The complex K is isomorphic to the 2-complex K' of Fig. 15 (by an isomorphism of 2-complex we mean a homeomorphism which restricts to a homeomorphism on the underlying graphs and a bijection on the sets of vertices). The isomorphism is fixed by the numbering and the orientation of the edges on each figure.

Chapter 6

Spline Curves

B-spline techniques have become the method of choice for modeling curves. Generalizing the Bézier form, spline representations possess analogous, very intuitive geometric properties. This was realized by Riesenfeld and Gordon, who saw the potential of B-splines for computer aided design. In contrast to polynomials, B-splines allow local shape control. Moreover, they provide approximations of arbitrary accuracy and smoothness.

In Section 6.1, we define polynomial and rational spline curves and, in Section 6.2, discuss basic properties. Then, we describe the fundamental knot insertion and refinement algorithms in Section 6.3. They play a key role for many applications such as conversion to Bézier form and numerical processing of spline curves. Section 6.4 is devoted to evaluation and differentiation. Finally, in Section 6.5, we explain how interpolation schemes for spline functions can be applied to curves.

6.1 ▪ Control Polygon

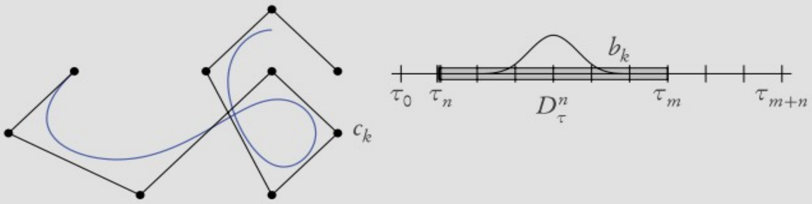
Spline curves are parametrized by linear combinations of B-splines. The coefficients form a control polygon with geometric properties familiar from the Bézier representation.

Spline Curve

A spline curve of degree $\le n$ in $\mathbb{R}^d$ has a parametrization

$$t \mapsto (p_1(t), \ldots, p_d(t)) = \sum_{k=0}^{m-1} c_k b_k(t), \quad t \in D_\tau^n,$$

with components p_ν in a spline space S_τ^n with finite knot sequence $\tau:\ \tau_0, \ldots, \tau_{m+n}$ and parameter interval $D_\tau^n = [\tau_n, \tau_m]$.

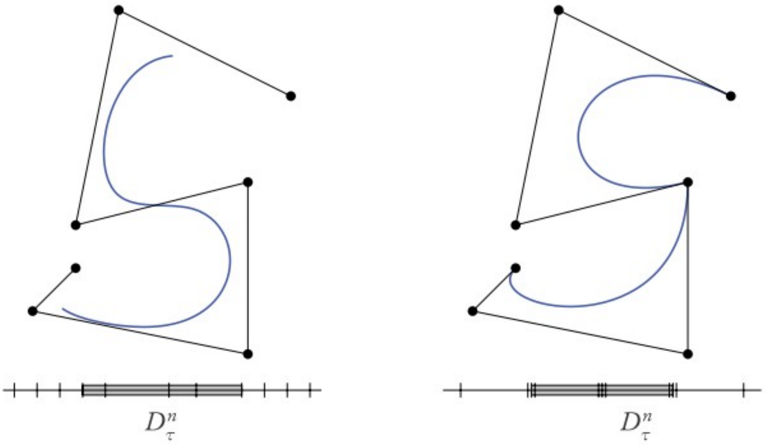


The coefficients $c_k = (c_{k,1}, \ldots, c_{k,d})$ can be combined into an $m \times d$ array C. They are called control points and form the control polygon c for p.

The shape of a spline curve is not only determined by the control points but also influenced by the placement of the knots. This is illustrated in the following example.

□ **Example:**

The figure shows two cubic spline curves together with their control polygons and knot sequences.



The left curve has simple knots; hence, the parametrization is twice continuously differentiable. The example on the right shows how nonsmooth curves can be modeled with the aid of multiple knots. At a knot with multiplicity n, the derivative of the parametrization need not be continuous. Hence, the tangent direction can change abruptly. Moreover, due to the n-fold knots at the endpoints of the parameter interval, the curve interpolates the first and the last control points. □

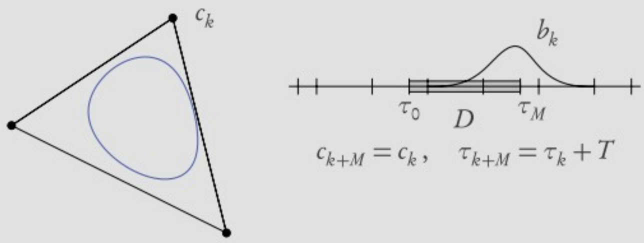
If the spline parametrization is periodic, the corresponding curve is closed. Accordingly, the control polygon is also closed, reflecting the periodicity of the B-spline coefficients. A precise definition, also introducing the proper notation, is given below.

Closed Spline Curve

A closed spline curve of degree $\le n$ in $\mathbb{R}^d$ has a parametrization

$$t \mapsto (p_1(t), \ldots, p_d(t)) = \sum_{k \in \mathbb{Z}} c_k \, b_k(t), \quad t \in \mathbb{R},$$

with components which are continuous T-periodic splines. This means that $p_\nu \in S^n_{\tau,T}$, $\tau = (\tau_0, \ldots, \tau_{M-1})$, and the B-splines b_k correspond to the periodically extended knot sequence $(\ldots, \tau - T, \tau, \tau + T, \ldots)$ and to M-periodic control points.



$$c_{k+M} = c_k\,, \quad \tau_{k+M} = \tau_k + T$$

According to the periodicity conditions, p is determined by M consecutive control points

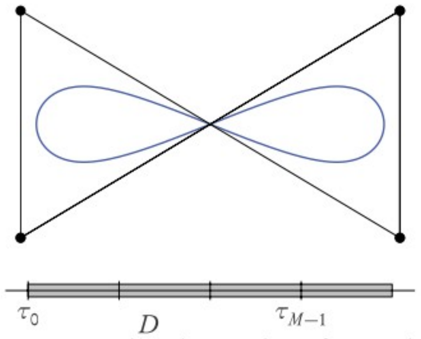
$$C = \begin{pmatrix} c_0 \\ \vdots \\ c_{M-1} \end{pmatrix},$$

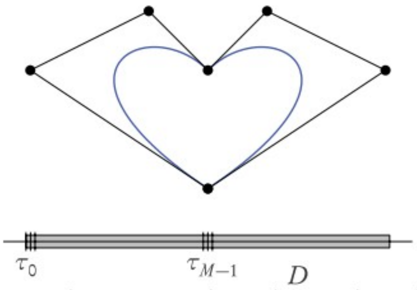
which form a closed control polygon for p.

The following example illustrates the representation of closed spline curves.

□ **Example:**

The figure shows two closed cubic spline curves together with their knots $(\tau_0, \dots, \tau_{M-1})$ in a periodicity interval $D = [\tau_0, \tau_0 + T)$.





We note that the number of control points exactly corresponds to the number of knots in the half-open periodicity interval. For the example on the right, each knot has multiplicity 3. In particular, $\tau_0 = \tau_1 = \tau_2$ and $\tau_M = \tau_{M+1} = \tau_{M+2}$ are the two endpoints of D. □

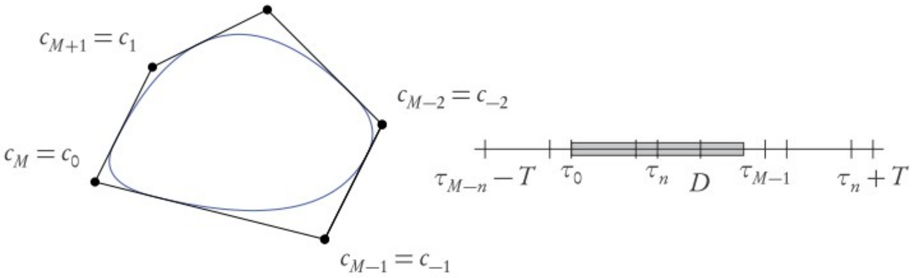
As is illustrated in the figure below, we can describe a closed spline curve $p(t)$, $t \in D = [\tau_0, \tau_0 + T]$, with a nonperiodic parametrization. We adjoin to the knots $\tau_0, \dots, \tau_{M-1}$, $\tau_M = \tau_0 + T$, successively n knots on each side of D according to the periodicity condition:

$$\tau \to \tilde{\tau} : (\tau_{M-n} - T, \dots, \tau_{M-1} - T, \tau_0, \dots, \tau_{M-1}, \tau_0 + T, \dots, \tau_n + T\,.$$

The corresponding control points are

$$c_{M-n}, \dots, c_{M-1}, c_0, \dots, c_{M-1}\,,$$

yielding a parametrization with components in the spline space $S^n_{\tilde{\tau}}$. We note that for $n > M$ the auxiliary control points c_k have to be defined successively, for $k = -1, -2, \dots$.



The alternative representation of a closed spline curve is convenient for numerical methods since algorithms are usually formulated for the nonperiodic case. With the above identification, closed curves can be handled with minor modifications only.

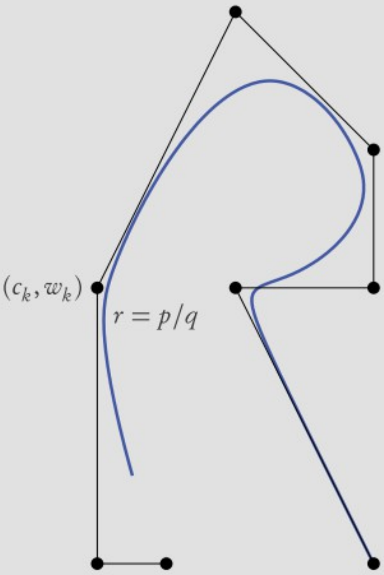
As for Bézier curves, we can use rational parametrizations. While the gain in accuracy and design flexibility is marginal, a number of standard shapes can be represented exactly. Therefore, this most general curve format has become a standard in many modeling systems.

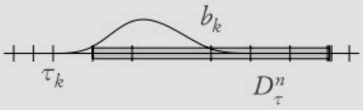
Rational Parametrizations

A nonuniform rational B-spline parametrization (NURBS) $r = p/q$ is the quotient of a spline parametrization $t \mapsto p(t)$ with weighted control points

$$(c_k w_k) \in \mathbb{R}^d, \quad w_k > 0,$$

and a spline function $t \mapsto q(t)$ with coefficients w_k.





The weights w_k provide additional design flexibility. Increasing a weight pulls the curve towards the corresponding control point.

We can identify r with a spline curve in homogeneous coordinates parametrized by

$$t \mapsto (p(t)\,|\,q(t)) = \sum_k (c_k w_k \,|\, w_k)\, b_k(t) \in \mathbb{R}^{d+1}.$$

This interpretation is convenient for implementing algorithms such as knot insertion, evaluation, and differentiation.

As an example, we discuss the relationship to the rational Bézier form which is a special case of the NURBS representation.

□ **Example:**

Conic sections can be represented by rational quadratic Bézier curves. For example, the quarter circle with the standard trigonometric parametrization

$$(\cos\varphi, \sin\varphi), \quad \varphi \in [0, \pi/2],$$

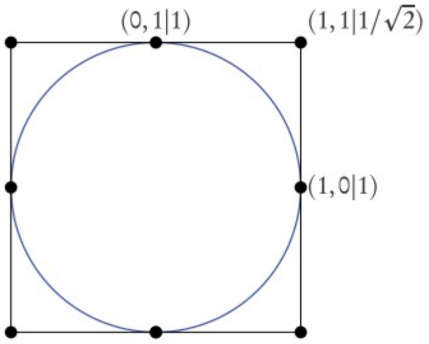
has the Bézier control points and weights

$$(c_k \mid w_k): \quad (1,0 \mid 1), (1,1 \mid 1/\sqrt{2}), (0,1 \mid 1).$$

Accordingly, a full circle can be represented by a closed rational quadratic spline curve r in Bézier form with double knots

$$\tau_0 = 0, 0, 1, 1, 2, 2, 3, 3 = \tau_7, \quad \tau_{k+8} = \tau_k + 4$$

and control points and weights shown in the figure.



It is perhaps a bit surprising that the Bézier form does not correspond to a closed rational quadratic spline curve with simple uniform knots parametrized by

$$t \mapsto r(t) = \frac{\sum_k (c_k w_k)\, b^2(t-k)}{\sum_k w_k\, b^2(t-k)},$$

where

$$c_0 = (1,1),\ c_1 = (-1,1),\ c_2 = (-1,-1),\ c_3 = (1,-1), \quad c_{k+4} = c_k\,.$$

If this were the case, $b^2(1) = b^2(2) = 1/2$ implies

$$1 = |r(k)|^2 = \left| \frac{c_{k-2} w_{k-2}/2 + c_{k-1} w_{k-1}/2}{w_{k-2}/2 + w_{k-1}/2} \right|^2 .$$

In view of the specific form of the control points this yields

$$(w_{k-2} + w_{k-1})^2 + (w_{k-2} - w_{k-1})^2 = (w_{k-2} + w_{k-1})^2\,.$$

We conclude that all weights must be equal. But then the parametrization is polynomial which is not possible. □

6.2 ▪ Basic Properties

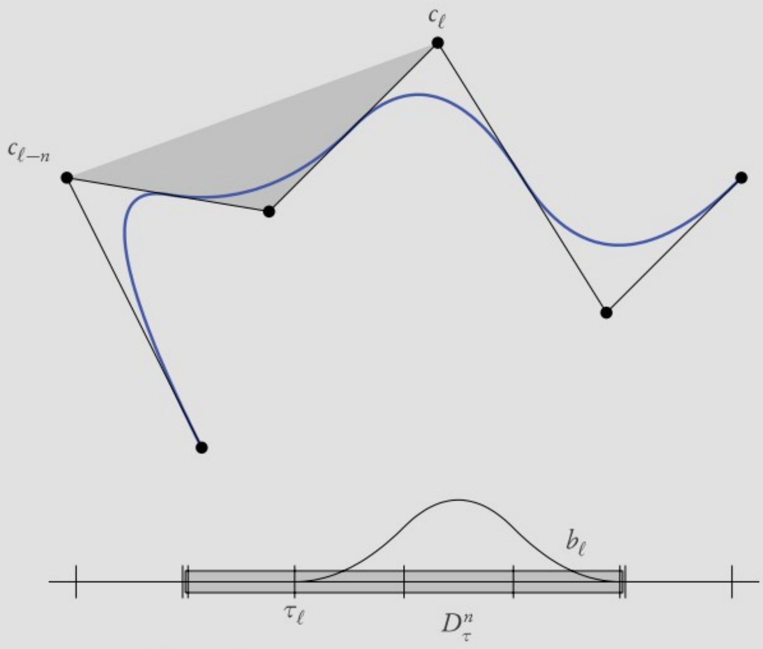
The geometric properties of the Bézier control polygon persist for spline curves. In particular, with appropriate choice of the knots, the endpoint interpolation property can be maintained.

Properties of the Control Polygon

The control polygon c of a spline curve parametrized by

$$p = \sum_{k=0}^{m-1} c_k\, b_k, \quad p_\nu \in S_\tau^n, \quad \tau:\ \tau_0, \ldots, \tau_{m+n},$$

qualitatively models the shape of p.



As is illustrated by the figure,

- for $\tau_\ell \le t \le \tau_{\ell+1}$ the point $p(t)$ lies in the convex hull of $c_{\ell-n}, \ldots, c_\ell$.

Moreover, if both endpoints of the parameter interval $D_\tau^n = [\tau_n, \tau_m]$ are knots with multiplicity n, then

- $p(\tau_n) = c_0$, $p(\tau_m) = c_{m-1}$,
- $p'(\tau_n^+) = \alpha_{1,\tau}^n (c_1 - c_0)$, $p'(\tau_m^-) = \alpha_{m-1,\tau}^n (c_{m-1} - c_{m-2})$

with $\alpha_{k,\tau}^n = n/(\tau_{k+n} - \tau_k)$. The last two properties referred to as endpoint interpolation imply that the control polygon is tangent to the spline curve, which is very useful for design purposes.

While the parametrization of a spline curve is continuous, the derivative can have jumps. This is taken into account in the formula for p', where the superscripts $+/-$ denote limits from the right/left.

The properties are easily verified.

Since only the B-splines b_k, $k = \ell - n, \ldots, \ell$, are relevant for $t \in [\tau_\ell, \tau_{\ell+1}]$, and they are positive and sum to one, the convex hull property is obvious.

To check the endpoint interpolation, we consider, e.g., the left endpoint. Because of the knot multiplicity n, all B-splines except b_0 vanish at τ_n. Moreover, $b_0(\tau_n) = 1$, so that $p(\tau_n)$ coincides with the control point c_0. By the differentiation formula,

$$p' = \sum_{k=1}^{n} \alpha_{k,\tau}^{n} (c_k - c_{k-1}) \, b_{k,\tau}^{n-1}, \quad \alpha_{k,\tau}^{n} = n/(\tau_{k+n} - \tau_k),$$

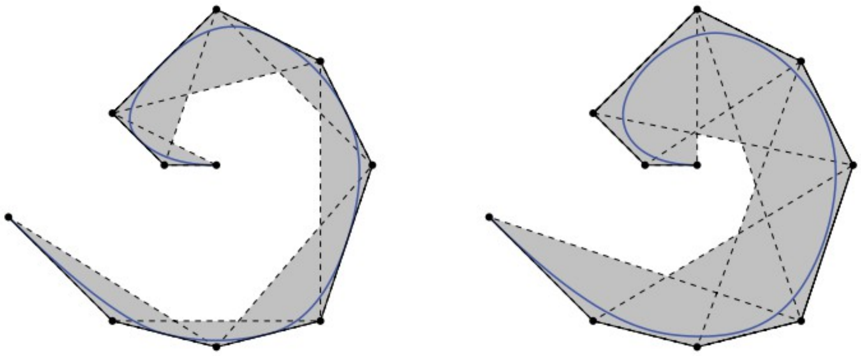
on the interval (τ_n, τ_{n+1}). Since

$$b_{k,\tau}^{n-1}(\tau_n^+) = \delta_{1,k},$$

the formula for $p'(\tau_n^+)$ follows.

□ **Example:**

The figure illustrates the convex hull property and endpoint interpolation for spline curves of degree 2 and 3.



$n = 2$ $n = 3$

Obviously, for small degree, the convex hull provides a more accurate approximation. Moreover, if the control polygon contains nearly flat parts, the bounds are very tight. □

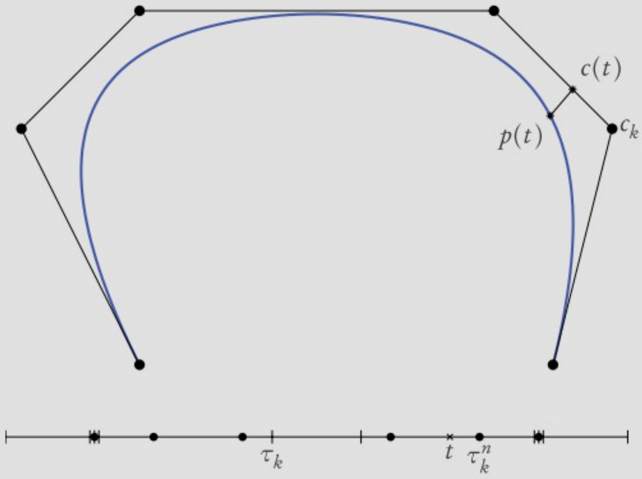
The convex hull property implies that the control polygon c is close to the corresponding curve p. In particular, if c is linear, so is p. Therefore, one expects that the distance to the spline curve is related to the second differences of the control points as a measure for the deviation from linearity. This is indeed the case as implied by the following precise bound due to Reif.

Distance to the Control Polygon

For a spline curve parametrized by

$$p = \sum_{k=0}^{m-1} c_k b_k, \quad p_\nu \in S^n_\tau ,$$

with $n > 1$, let c be a piecewise linear parametrization of the control polygon, which interpolates c_k at the knot averages $\tau_k^n = (\tau_{k+1} + \cdots + \tau_{k+n})/n$.



The distance of p to the control polygon can be bounded in terms of weighted second differences of the control points. For t in a nondegenerate knot interval $[\tau_\ell, \tau_{\ell+1}] \subseteq D_\tau^n$,

$$\|p(t) - c(t)\|_\infty \le \frac{1}{2n} \max_{\ell-n \le k \le \ell} \sigma_k^2 \max_{\ell-n+2 \le k \le \ell} \|\nabla_\tau^2 c_k\|_\infty,$$

where

$$\sigma_k^2 = \frac{1}{n-1} \sum_{i=1}^{n} (\tau_{k+i} - \tau_k^n)^2$$

and $\nabla_\tau^2 c_k$ are the control points of the second derivative p''. Their explicit form is

$$\nabla_\tau^2 c_k = \frac{n-1}{\tau_{k+n-1} - \tau_k} \left(\frac{c_k - c_{k-1}}{\tau_k^n - \tau_{k-1}^n} - \frac{c_{k-1} - c_{k-2}}{\tau_{k-1}^n - \tau_{k-2}^n} \right),$$

where none of the denominators vanishes since the differences are at least as large as $\tau_{\ell+1} - \tau_\ell$.

The local estimate implies a global bound simply by taking the maximum of the right side over all k relevant for the entire parameter interval $D_\tau^n = [\tau_n, \tau_m]$ of the spline curve. In this case, $\nabla_\tau^2 c_k$ is set to 0 if $\tau_k = \tau_{k+n-1}$.

Clearly, it suffices to prove the estimate for each component separately. Therefore, we may consider the univariate case. By scaling the coefficients c_k, which appear linearly on both sides of the estimate, we can further assume that $\max_k |\nabla_\tau^2 c_k| = 1$.

Turning to the main arguments of the proof, we first show that the worst case corresponds to a parabola p^*,

$$p^*(t) = t^2/2 = \sum_k c_k^* b_k, \quad \nabla_\tau^2 c_k^* = 1\,.$$

In terms of the parametrizations $c(t)$ and $c^*(t)$ of the control polygons, this means that

$$-(p^* - c^*) \le p - c \le p^* - c^*$$

for any other spline $p = \sum_k c_k b_k$ with $\max_k |\nabla_\tau^2 c_k| = 1$.

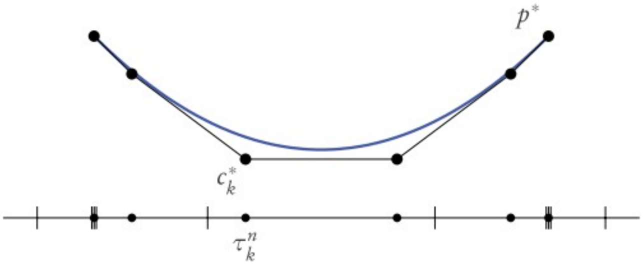
Both inequalities follow from a simple geometric observation. Considering, e.g., an equivalent form of the right estimate

$$p - p^* = \sum_k (c_k - c_k^*)\, b_k \le c - c^*,$$

we observe that $\nabla_\tau^2 (c_k - c_k^*) \le 0$ in view of our assumption about the size of the weighted second differences. By definition, ∇_τ^2 forms differences of consecutive slopes of the polygon, which connects the points $(\tau_k^n,\, c_k - c_k^*)$ weighted by the positive factors $(n-1)/(\tau_{k+n-1} - \tau_k)$. Hence, the polygon is concave. Since, by Marsden's identity,

$$(t,\, p(t) - p^*(t)) = \sum_k (\tau_k^n,\, c_k - c_k^*)\, b_k(t),$$

the convex hull property implies that the graph of the spline $p - p^*$ lies below the polygon $c - c^*$, as claimed.



It remains to bound $p^* - c^*$, which then yields the estimate for $|p - c|$. Since the second derivative of this function, which is the difference between the parabola and the broken line shown in the figure, equals one on each interval (τ_k^n, τ_{k+1}^n), it follows that its maximum must occur at one of the knot averages. With the aid of Marsden's identity we can compute the explicit form of the control points for $p^*(t) = t^2/2$:

$$c_k^* = (\tau_k^n)^2/2 - \sigma_k^2/(2n)$$

(cf. the example in Section 4.3). Substituting this expression into

$$p^*(\tau_k^n) - c^*(\tau_k^n) = (\tau_k^n)^2/2 - c_k^*,$$

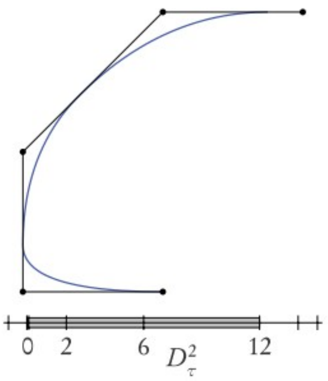
the desired estimate follows; i.e., we can bound $|p - c|$ by the maximum of $\sigma_k^2/(2n)$ for the relevant indices k.

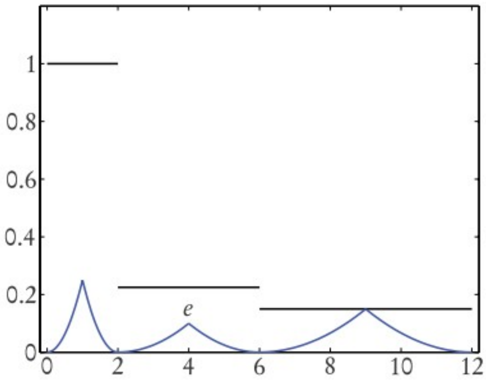
□ **Example:**

As an example, we consider the quadratic spline curve $p = \sum_{k=0}^4 c_k b_k$ shown in the left figure with

$$C = \begin{pmatrix} 1 & 0 & 0 & 1 & 2 \\ 0 & 0 & 1 & 2 & 2 \end{pmatrix}^t, \quad \tau = (-1, 0, 0, 2, 6, 12, 14, 15).$$

The right diagram shows the error $e(t) = \|p(t) - c(t)\|_\infty$ for t in the parameter interval $D_\tau^2 = [0, 12]$ as well as the piecewise constant upper bound provided by the estimate.





Specializing the general formulas for degree $n = 2$, we obtain

$$\tau_k^2 = (\tau_{k+1} + \tau_{k+2})/2, \quad \sigma_k^2 = (\tau_{k+2} - \tau_{k+1})^2/2.$$

The concrete values are

$$(\tau_0^2, \sigma_0^2) = (0,0), (1,2), (4,8), (9,18), (13,2) = (\tau_4^2, \sigma_4^2).$$

Finally, the weighted control point differences equal

$$\nabla_\tau c_k = \frac{c_k - c_{k-1}}{\tau_k^2 - \tau_{k-1}^2}: \quad (-1,0), (0,1/3), (1/5,1/5), (1/4,0),$$

and

$$\nabla_\tau^2 c_k = \frac{\nabla_\tau c_k - \nabla_\tau c_{k-1}}{\tau_{k+1} - \tau_k}: \quad (1/2,1/6), (1/20,-1/30), (1/120,-1/30)$$

with the index k starting from 1 and 2, respectively. This leads to the following estimates. For $t \in [0,2]$,

$$\|p(t) - c(t)\|_\infty \le \frac{1}{4} \cdot \max\{0,2,8\} \cdot \frac{1}{2} = 1.$$

Similarly, for the other two knot intervals $[2,6]$ and $[6,12]$, the bounds are

$$\frac{1}{4}\cdot 18\cdot\frac{1}{20}=\frac{9}{40},\quad \frac{1}{4}\cdot 18\cdot\frac{1}{30}=\frac{3}{20},$$

respectively.

The right figure shows that the estimate for the last knot interval is sharp. □

As a second example, we consider the case of uniform knots which permits slight simplifications.

□ **Example:**

For uniform knots τ_k with grid width h and odd degree $n=2m+1$,

$$\tau_k^n=\tau_k+(m+1)h,\quad \sigma_k^2=\frac{1}{n-1}\sum_{i=-m}^{m}(ih)^2\,.$$

Hence, the product of the first two factors in the error estimate for the control polygon equals

$$\frac{1}{2n}\,\frac{2h^2}{(n-1)}\sum_{i=1}^{m}i^2\,.$$

Substituting $m^3/3+m^2/2+m/6$ for the sum and cancelling common factors, we obtain the simplified expression

$$\frac{n+1}{24}\,h^2\,.$$

Therefore, since

$$\nabla_\tau^2 c_k=h^{-2}\Delta^2 c_{k-2},\quad \Delta^2 c_{k-2}=c_k-2c_{k-1}+c_{k-2}\,,$$

the error estimate for uniform knots has the form

$$||p(t)-c(t)||_\infty\le\frac{n+1}{24}\max_{\ell-n\le k\le\ell-2}||\Delta^2 c_k||_\infty$$

for $\tau_\ell\le t<\tau_{\ell+1}$.

An analogous computation shows that the same formula also holds for even degree $n=2m$. The fact that in this case the knot averages do not coincide with knots but are midpoints of knot intervals does not make any difference. □

6.3 ▪ Refinement

Refinement of the partition of the parameter interval is the standard procedure to increase the local accuracy or design flexibility of spline approximations. For spline curves, the corresponding algorithm for inserting new knots has a simple geometric interpretation in terms of the control polygon, as observed, independently, by Boehm and Cohen, Lyche, and Riesenfeld. It plays a fundamental role also for other applications.

Knot Insertion

Let $p = \sum_0^{m-1} c_k\, b_k \in S^n_\tau$ parametrize a spline curve. If we add a new knot s in the parameter interval D^n_τ and $s \in [\tau_\ell, \tau_{\ell+1})$, then the control points $\tilde{c}_k$ of p with respect to the refined knot vector

$$\tilde{\tau}: \quad \ldots,\, \tilde{\tau}_\ell = \tau_\ell,\, \tilde{\tau}_{\ell+1} = s,\, \tilde{\tau}_{\ell+2} = \tau_{\ell+1}, \ldots$$

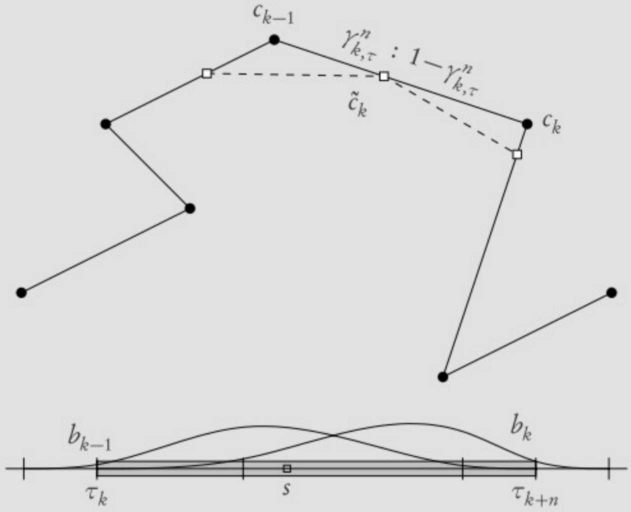
are computed as follows.

On the segments $[c_{k-1}, c_k]$ with $\tau_k < s < \tau_{k+n}$ new control points are generated:

$$\tilde{c}_k = \gamma^n_{k,\tau} c_k + (1 - \gamma^n_{k,\tau}) c_{k-1}, \quad \gamma^n_{k,\tau} = \frac{s - \tau_k}{\tau_{k+n} - \tau_k}\,.$$

The other edges of the control polygon remain unchanged:

$$\tilde{c}_k = c_k \text{ for } \tau_{k+n} \le s, \quad \tilde{c}_k = c_{k-1} \text{ for } s \le \tau_k\,.$$



As illustrated in the figure, the new control point $\tilde{c}_k$ divides the segment $[c_{k-1}, c_k]$ in the same ratio as the parameter s divides the interval $[\tau_k, \tau_{k+n}]$, which is the intersection of the supports of the two associated B-splines. We note that, if s coincides with a knot ($s = \tau_\ell$), fewer control points need to be computed. More precisely, if s has multiplicity j in $\tilde{\tau}$, only $n + 1 - j$ convex combinations need to be formed.

Several new knots can be inserted by repeating the procedure. In particular, by raising the multiplicity of a knot to n, we obtain a point on the curve:

$$\tau_{\ell-n} < \tau_{\ell-n+1} = \cdots = \tau_\ell < \tau_{\ell+1} \implies p(\tau_\ell) = c_{\ell-n}\,.$$

Hence, the evaluation scheme for splines can be viewed as n-fold knot insertion.

To verify the knot insertion formula, we have to show that

$$\sum_k c_k\, b_k(t) = \sum_k \tilde{c}_k\, \tilde{b}_k(t), \quad \tilde{c}_k = \tilde{\gamma}_k c_k + (1 - \tilde{\gamma}_k) c_{k-1}\,,$$

where $\tilde{b}_k$ denote the B-splines of the refined knot sequence $\tilde{\tau}$ and

$$\tilde{\gamma}_k = \begin{cases} 1 & \text{if } \tau_{k+n} \le s, \\ \gamma_k & \text{if } \tau_k < s < \tau_{k+n}, \\ 0 & \text{if } s \le \tau_k. \end{cases}$$

The modified weights $\tilde{\gamma}_k$ incorporate the cases where the control points do not change.

As usual, for a proof, it is convenient to extend τ and $\tilde{\tau}$ to bi-infinite knot sequences and to restrict t to the parameter interval $D_\tau^n = [\tau_n, \tau_m]$ of the curve. Moreover, since the modified weights depend continuously on the knots, it is sufficient to consider simple knots.

With these notations and assumptions, the identity can be derived from general considerations. Since adding a knot enlarges the class of splines, any B-spline b_k can be written as a linear combination of the B-splines corresponding to $\tilde{\tau}$:

$$b_k = \sum_i d_{k,i} \tilde{b}_i .$$

Moreover, since b_k vanishes outside of the interval $[\tilde{\tau}_k, \tilde{\tau}_{k+n+2})$, it follows from the local linear independence of the B-splines that the coefficients can be nonzero only for $i = k$ and $i = k+1$. These observations imply that

$$\sum_k c_k\, b_k = \sum_k c_k\,(p_k \tilde{b}_k + q_k \tilde{b}_{k+1}) = \sum_k (c_k p_k + c_{k-1} q_{k-1})\, \tilde{b}_k .$$

Choosing $c_k = 1$, we obtain in particular

$$q_{k-1} = 1 - p_k$$

since the B-splines form a partition of unity.

It remains to determine the explicit form of the weight p_k. This can be done by analyzing the linear combination representing a single B-spline, which takes on the form

$$b_k = p_k \tilde{b}_k + q_k \tilde{b}_{k+1} .$$

We consider several cases.

(i) If $\tau_{k+n} \le s$, then b_{k-1} and $\tilde{b}_{k-1}$ have the same knots. Consequently, $b_{k-1} = \tilde{b}_{k-1}$, so that

$$1 = p_{k-1}, \quad 0 = q_{k-1} = 1 - p_k .$$

(ii) If $\tau_k < s < \tau_{k+n}$, then b_k has the knots $\tau_k, \ldots, \tau_{k+n+1}$, while $\tilde{b}_k$ has the knots $\tau_k, \ldots, s, \ldots, \tau_{k+n}$. It follows from the recursion for B-splines that

$$b_k(t) = \frac{t-\tau_k}{\tau_{k+1}-\tau_k} \cdots \frac{t-\tau_k}{\tau_{k+n}-\tau_k},$$
$$\tilde{b}_k(t) = \frac{t-\tau_k}{\tau_{k+1}-\tau_k} \cdots \frac{t-\tau_k}{s-\tau_k} \cdots \frac{t-\tau_k}{\tau_{k+n-1}-\tau_k}$$

for $t \in [\tau_k, \min(\tau_{k+1}, s))$. Since the B-spline $\tilde{b}_{k+1}$ vanishes on this interval,

$$p_k = \frac{s-\tau_k}{\tau_{k+n}-\tau_k} = \gamma_{k,\tau}^n .$$

(iii) If $s \le \tau_k$, then b_k and $\tilde{b}_{k+1}$ have the same knots. Hence, $b_k = \tilde{b}_{k+1}$ and

$$1 = q_k = 1 - p_{k+1}, \quad 0 = p_k\,.$$

In all cases,

$$p_k = \tilde{\gamma}_k\,,$$

proving the knot insertion formula.

□ **Example:**

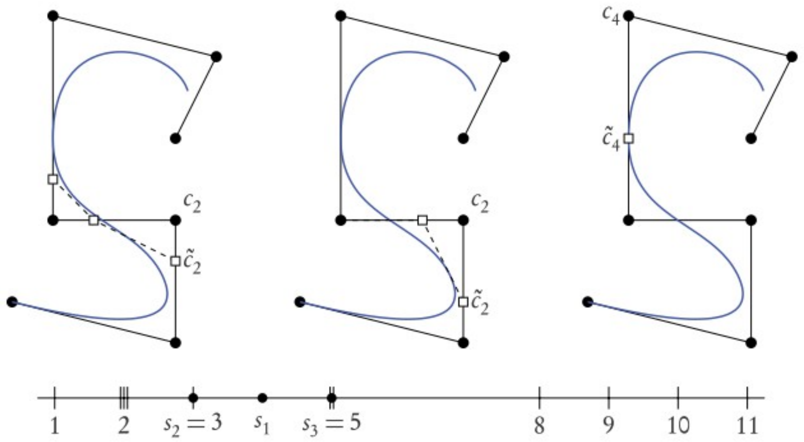
We illustrate the knot insertion algorithm for the cubic spline curve $\sum_{k=0}^{6} c_k\, b_k$ with control points

$$C = \begin{pmatrix} 0 & 4 & 4 & 1 & 1 & 5 & 4 \\ 2 & 1 & 4 & 4 & 9 & 8 & 6 \end{pmatrix}^t$$

and knot sequence

$$\tau_0 = 1,\, 2,\, 2,\, 2,\, 3,\, 5,\, 5,\, 8,\, 9,\, 10,\, 11 = \tau_{10}\,,$$

shown in the figure.



We consider three cases.

(i) $s = 4$ (multiplicity 1): Three segments of the control polygon are subdivided. The ratios

$$2:1,\; 2:1,\; 1:4$$

are determined by the relative position of s in the intervals

$$[\tau_k, \tau_{k+3}]:\; [2,5],\, [2,5],\, [3,8],$$

which are the intersections of the supports of the relevant B-splines. The resulting control points, corresponding to the refined knot sequence

$$\tilde{\tau}_0 = 1,\, 2,\, 2,\, 2,\, 3,\, 4,\, 5,\, 5,\, 8,\, 9,\, 10,\, 11 = \tilde{\tau}_{11}\,,$$

are

$$\tilde{C} = \begin{pmatrix} 0 & 4 & 4 & 2 & 1 & 1 & 5 & 4 \\ 2 & 1 & 3 & 4 & 5 & 9 & 8 & 6 \end{pmatrix}^t .$$

For example,

$$(4,3) = \tilde{c}_2 = \frac{2}{3}\,c_2 + \frac{1}{3}\,c_1$$

(cf. the left figure).

(ii) $s = 3$ (double knot): In this case, only the second and third segments are subdivided according to the ratios

$$1:2,\; 1:2\,,$$

as is shown in the middle figure.

(iii) $s = 5$ (triple knot): As is shown in the right figure, if the multiplicity after knot insertion is maximal, only one new control point is generated, which lies on the curve. In this example,

$$p(s) = \tilde{c}_4 = \frac{2}{5}\,(1,9) + \frac{3}{5}\,(1,4) = (1,6)\,. \qquad \square$$

Instead of inserting one knot at a time, several knots can be inserted simultaneously. For example, all knot intervals can be split in half to gain more approximation power on the entire parameter interval. The corresponding algorithm has a particularly elegant form for spline curves with uniform knots as was described by Lane and Riesenfeld.

Uniform Subdivision

Let

$$p = \sum_k c_k\, b^n_{k,\tau} \in S^n_\tau$$

be a parametrization of a uniform spline curve with grid width h. If new knots are simultaneously inserted at the midpoints of the knot intervals, the control points $\tilde{c}_k$ corresponding to the refined knot sequence $\tilde{\tau}$ with grid width $h/2$ and $\tilde{\tau}_{2k} = \tau_k$ can be computed as follows.

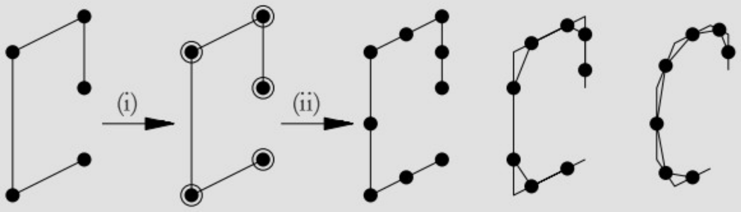
(i) The control points c_k, $k \sim \tau$, are doubled:

$$\tilde{c}_{2k} = \tilde{c}_{2k+1} = c_k\,.$$

(ii) Simultaneous averages of adjacent control points are formed,

$$\tilde{c}_k \leftarrow (\tilde{c}_k + \tilde{c}_{k-1})/2\,,$$

and this process is repeated n-times.



The explicit form of the new control points is

$$\tilde{c}_k = \sum_i s_{k-2i}\, c_i, \quad s_j = 2^{-n}\binom{n+1}{j},$$

where $s_j = 0$ for $j < 0$ or $j > n+1$ in accordance with the convention for binomial coefficients.

We note that for a finite knot sequence $\tau_0, \ldots, \tau_{m+n}$ the indices of the control points $\tilde{c}_k$ are not in the standard range $\{0, 1, \ldots\}$. By definition of $\tilde{\tau}$, the B-splines $b^n_{k,\tilde{\tau}}$, $k = n, \ldots, 2m-1$, are relevant for the parameter interval D^n_τ. We could have changed the definition of $\tilde{\tau}$. This would, however, result in less elegant subdivision formulas.

Turning to the derivation of the subdivision formula, it is sufficient to consider spline functions since the curve components are processed with identical operations. Moreover, in view of linearity, we need to check the identity only for a single B-spline b_ℓ. In this case, the coefficients are $c_k = \delta_{\ell-k}$ and the formula reduces to

$$\tilde{c}_k = s_{k-2\ell} = 2^{-n}\binom{n+1}{k-2\ell},$$

where $\tilde{c}_k$ are the coefficients for representing b_ℓ as a linear combination of the B-splines $\tilde{b}_k$ of the refined knot sequence $\tilde{\tau}$.

Using induction on the degree n, it is convenient to start with $n = 0$, although this case is excluded for splines. Since the B-splines of degree 0 are the characteristic functions of the half-open knot intervals and $\tilde{\tau}_{2\ell} = \tau_\ell$,

$$b^0_{\ell,\tau} = \tilde{b}^0_{2\ell,\tau} + \tilde{b}^0_{2\ell+1,\tau}.$$

This is in agreement with

$$\tilde{c}_{2\ell} = \tilde{c}_{2\ell+1} = 1, \quad \tilde{c}_k = 0,\, k \notin \{2\ell, 2\ell+1\},$$

as asserted by the subdivision formula.

For the induction step $n-1 \to n$, we have to show that

$$b^n_{\ell,\tau} = 2^{-n}\sum_k \binom{n+1}{k-2\ell} b^n_{k,\tilde{\tau}},$$

recalling that we are considering the special case $c_k = \delta_{\ell-k}$; i.e., the spline function $\sum_k c_k b^n_{k,\tau}$ is the single B-spline $b^n_{\ell,\tau}$. We differentiate the formula for subdividing $b^n_{\ell,\tau}$, using the simple recursion for the derivative of uniform B-splines. Since both sides vanish at $\tau_\ell = \tilde{\tau}_{2\ell}$, this yields the equivalent identity

$$B_\ell - B_{\ell+1} = 2^{1-n}\underbrace{\left[\sum_k \binom{n+1}{k-2\ell}(\tilde{B}_k - \tilde{B}_{k+1})\right]}_{S_1},$$

where we have set $B_k = b^{n-1}_{k,\tau}$ and $\tilde{B}_k = b^{n-1}_{k,\tilde{\tau}}$ to simplify notation. The factor 2^{-n} has changed since the differentiation formula involves the different factors h^{-1} and $(h/2)^{-1}$ for the B-splines on the left and right side, respectively. We now use the induction hypothesis and express the B-splines on the left side in terms of the B-splines $\tilde{B}_k$ corresponding to $\tilde{\tau}$. Noting that

$$B_{\ell+1}(x) = B_\ell(x-h), \quad \tilde{B}_k(x-h) = \tilde{B}_{k+2}(x),$$

this yields

$$2^{-(n-1)} \underbrace{\left[\sum_k \binom{n}{k-2\ell} (\tilde{B}_k - \tilde{B}_{k+2}) \right]}_{S_2} .$$

In both expressions $S_\nu = [\dots]$, we sum over $k \in \mathbb{Z}$, using the convention that $\binom{m}{j} = 0$ for $j < 0$ or $j > m$. The equality of these two sums follows by comparing the coefficients of $\tilde{B}_j$, which are

$$\binom{n+1}{j-2\ell} - \binom{n+1}{j-1-2\ell}$$

for S_1 and

$$\binom{n}{j-2\ell} - \binom{n}{j-2-2\ell}$$

for S_2. The expressions agree in view of the recursion for binomial coefficients:

$$\binom{n+1}{j-2\ell} = \binom{n}{j-2\ell} + \binom{n}{j-2\ell-1}, \quad \binom{n+1}{j-1-2\ell} = \binom{n}{j-1-2\ell} + \binom{n}{j-2-2\ell}.$$

It remains to derive the algorithmic definition of the coefficients $\tilde{c}_k$. Again, we can consider spline functions and make use of linearity. Hence, assuming that $c_k = \delta_{k-\ell}$, step (i) of the algorithm yields

$$\dots, \tilde{c}_{2\ell} = 1, 1 = \tilde{c}_{2\ell+1}, \dots,$$

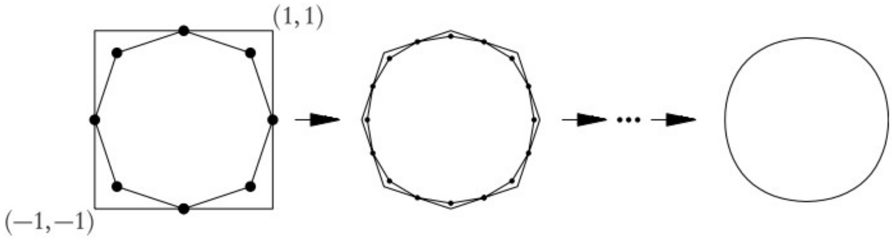
where we list only nonzero coefficients. Applying step (ii) repeatedly, we obtain

$$\begin{array}{llllll} \tilde{c}_{2\ell} = & 1/2, & 2/2, & 1/2 & & \\ & 1/4, & 3/4, & 3/4, & 1/4 & \\ & 1/8, & 4/8, & 6/8, & 4/8, & 1/8 \\ & \dots . & & & & \end{array}$$

We recognize Pascal's triangle, i.e., the algorithm leads to the coefficients $2^{-n}\binom{n+1}{k-2\ell}$, as asserted by the subdivision formula.

☐ **Example:**

We apply the subdivision algorithm to the cubic closed spline curve with control points at the vertices $(\pm 1, \pm 1)$ of a square with side length 2.



In this case, the subdivision rule is

$$\begin{array}{rclcl} \tilde{c}_{2\ell} & = & s_4 c_{\ell-2} + s_2 c_{\ell-1} + s_0 c_\ell & = & \frac{1}{8} c_{\ell-2} + \frac{3}{4} c_{\ell-1} + \frac{1}{8} c_\ell , \\ \tilde{c}_{2\ell+1} & = & s_3 c_{\ell-1} + s_1 c_\ell & = & \frac{1}{2} c_{\ell-1} + \frac{1}{2} c_\ell . \end{array}$$

Two steps of the corresponding refinements as well as the spline curve obtained in the limit are shown in the figure.

To analyze the iteration a little bit further, we derive an explicit formula for a control point sequence, emerging from one of the corners. To this end, we write the modification of three adjacent control points in matrix form:

$$\begin{pmatrix} \tilde{c}_{2\ell-1} \\ \tilde{c}_{2\ell} \\ \tilde{c}_{2\ell+1} \end{pmatrix} = \underbrace{\begin{pmatrix} 1/2 & 1/2 & 0 \\ 1/8 & 3/4 & 1/8 \\ 0 & 1/2 & 1/2 \end{pmatrix}}_{A} \begin{pmatrix} c_{\ell-2} \\ c_{\ell-1} \\ c_\ell \end{pmatrix} .$$

The subdivision matrix has the eigenvalues 1, 1/2, and 1/4, and, by transformation to diagonal form, it can be shown that

$$A_\infty = \lim_{\ell\to\infty} A^\ell = \frac{1}{6} \begin{pmatrix} 1 & 4 & 1 \\ 1 & 4 & 1 \\ 1 & 4 & 1 \end{pmatrix} .$$

This proves, e.g., that the sequence of control points emerging from $(1,1)$ tends to the limit

$$\frac{1}{6} \begin{pmatrix} 1 & 4 & 1 \end{pmatrix} \begin{pmatrix} -1 & 1 \\ 1 & 1 \\ 1 & -1 \end{pmatrix} = \frac{2}{3} \begin{pmatrix} 1 & 1 \end{pmatrix} ,$$

which is a point on the curve. □

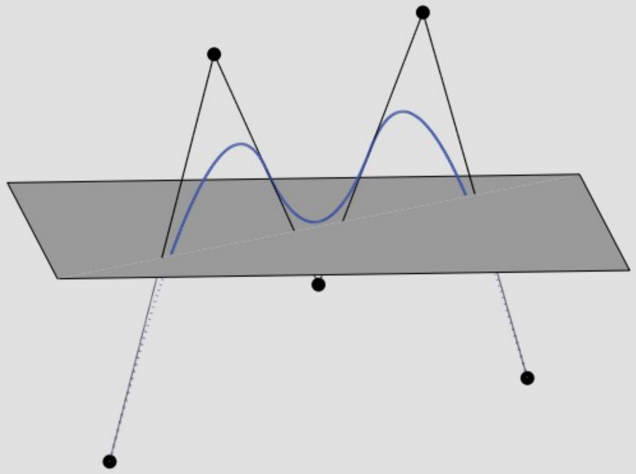
As a more theoretical application of knot insertion, we discuss a measure for the number of oscillations of a spline curve.

Variation Diminution

The variation of a spline curve parametrized by $p = \sum_{k=0}^{m-1} c_k \, b_k$ with respect to a hyperplane H is not larger than the variation of its control polygon c:

$$V(p,H) \le V(c,H),$$

where V denotes the maximal number of pairs of consecutive points on opposite sides of H.



In particular, if the entire control polygon lies on one side of H, so does the spline curve.

This important property of spline curves can be proved by elegant geometric arguments, as was observed by Lane and Riesenfeld.

Since the spline curve consists of finitely many polynomial segments, its variation is finite. Hence, in the nontrivial case, when $V(p,H) > 0$, there exist pairs of points

$$p(t_{k-1}),\ p(t_k), \quad k = 1, \ldots, V(p,H),$$

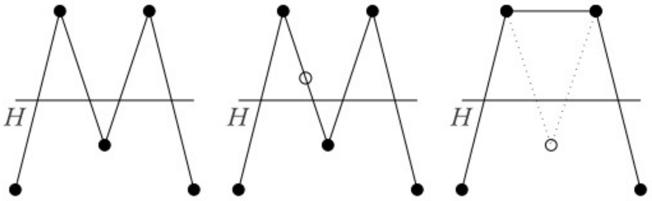
lying on opposite sides of H. These points coincide with control points of a refined control polygon $\tilde{c}$ having the parameters t_k as knots of multiplicity n. Hence, it remains to show that knot insertion does not increase the variation since this implies

$$V(p,H) \le V(\tilde{c},H) \le V(c,H).$$

Without going into details, knot insertion repeats the following two steps (not necessarily in any particular order):

(i) placing an additional control point on an edge of the control polygon (splitting edges);

(ii) deleting a control point (cutting corners).



(i) splitting edges (ii) cutting corners

For example, when inserting an interior knot for a cubic spline curve, we place three points on adjacent edges of the control polygon and then delete two of the intermediate vertices. Obviously, neither of the two steps illustrated in the figure increases the variation.

□ **Example:**

Variation diminution can be used to locate the intersections of a spline curve p with a hyperplane H. To this end, we represent p as a union of Bézier segments, recalling that Bernstein polynomials are particular B-splines (cf. Section 4.1). After this preprocessing step, p is represented by a list of polynomial segments p^i, each described by its Bézier control polygon c^i. We now employ an elementary bisection strategy based on the variations

$$V^i = V(c^i, H),$$

which are upper bounds for variations of the Bézier segments.

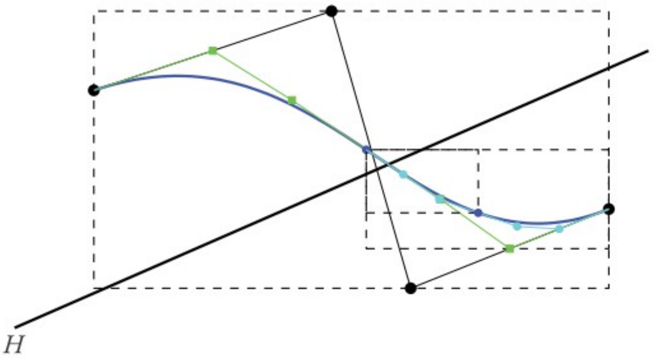
If V^i is zero, we check whether accidentally one or both of the endpoints of p^i are points of intersection. Since $V(p^i, H) = 0$, intersections in the interior of the parameter interval for p^i are not possible, and we delete p^i from the list.

If $V^i \geq 1$ and the diameter of a bounding box for c^i is $>$ tol, we subdivide p^i at the midpoint of its parameter interval and append both parts in place of p^i to the list.

Upon termination of the subdivision procedure, there are two possibilities for the remaining Bézier segments p^i.

(i) If $V^i = 1$, then the endpoints of c^i, which coincide with the endpoints of p^i, must lie on opposite sides of H. Hence, an intersection of p^i with H exists. Since $V(p^i, H) \leq V^i$, this intersection is unique. Its location is determined by the bounding box for c^i with accuracy tol.

(ii) If $V^i > 1$, the existence of an intersection can be neither guaranteed nor excluded. A more subtle test is needed. This is not surprising since the case of more than one alternation includes the possibility of points of tangency, a numerically critical situation. Fortunately, for small tolerances, Bézier segments with $V^i > 1$ and small bounding boxes are relatively rare.



The figure illustrates the subdivision strategy for a planar cubic Bézier segment. Two subdivision steps are performed. We see that the bounding boxes provide an increasingly better approximation to the intersection. When subdivision is terminated, a Newton iteration can be started to determine the exact location. □

6.4 ▪ Algorithms

The algorithms for spline functions easily generalize to curves. We begin by considering the two principal operations.

Evaluation and Differentiation

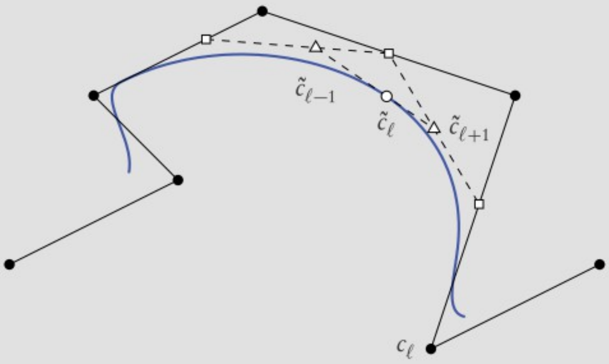
A point

$$p(s) = \sum_{k=0}^{m-1} c_k\, b_k(s)$$

on a spline curve with knot sequence $\tau : \tau_0, \dots, \tau_{m+n}$ can be computed by repeatedly inserting s as a new knot until its multiplicity becomes n:

$$\tilde{\tau}_\ell < \tilde{\tau}_{\ell+1} = \cdots = \tilde{\tau}_{\ell+n} = s < \tilde{\tau}_{\ell+n+1} \implies p(s) = \tilde{c}_\ell\,,$$

where $\tilde{\tau}_\ell$ and $\tilde{c}_k$ denote the modified knots and control points, respectively.



The refined control polygon $\tilde{c}$ is tangent to the curve:

$$p'(s^-) = \frac{n(\tilde{c}_\ell - \tilde{c}_{\ell-1})}{s - \tilde{\tau}_\ell}, \quad p'(s^+) = \frac{n(\tilde{c}_{\ell+1} - \tilde{c}_\ell)}{\tilde{\tau}_{\ell+n+1} - s},$$

where the one-sided derivatives coincide if s is not a knot with multiplicity n of the original knot sequence τ (i.e., if at least one knot is inserted). In this case,

$$p'(s) = \frac{n}{\tilde{\tau}_{\ell+n+1} - \tilde{\tau}_\ell} \left(\tilde{c}_{\ell+1} - \tilde{c}_{\ell-1}\right)$$

is an alternative formula for the tangent vector.

If $s \in (\tilde{\tau}_\ell, \tilde{\tau}_{\ell+n+1})$ is a knot with multiplicity n of $\tilde{\tau}$, the B-splines b_k with $k < \ell$ vanish for parameters $t \geq s$. Hence, $p(s)$ can be regarded as a left endpoint of the spline curve with control points $\tilde{c}_\ell$, $\tilde{c}_{\ell+1}$, ... The formulas for $p(s)$ and $p'(s^+)$ are thus a direct consequence of endpoint interpolation. Similarly, the formula for $p'(s^-)$ follows by regarding $p(s)$ as a right endpoint of the spline curve with control points $\dots, \tilde{c}_{\ell-1}, \tilde{c}_\ell$.

If the parametrization is continuously differentiable, $p'(s^-) = p'(s^+)$. Solving this equation for the control point $\tilde{c}_\ell$ and substituting the resulting expression in either of the formulas for the one-sided derivatives yields the formula for $p'(s)$ in terms of $\tilde{c}_{\ell-1}$ and $\tilde{c}_{\ell+1}$.

□ **Example:**

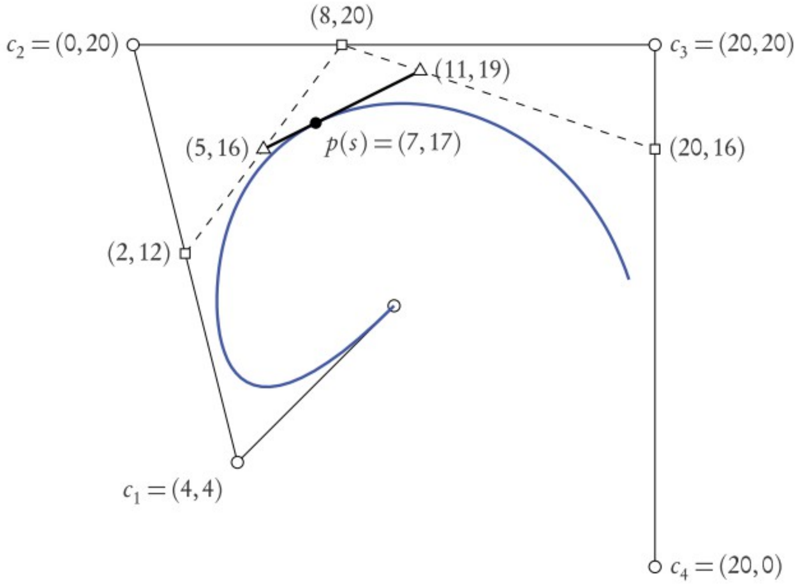
We consider the cubic spline curve p with control points

$$C = \begin{pmatrix} 10 & 4 & 0 & 20 & 20 \\ 10 & 4 & 20 & 20 & 0 \end{pmatrix}^{\mathrm{t}},$$

knots

$$\tau_0 = 0,\ 1,\ 1,\ 1,\ 2,\ 5,\ 6,\ 7,\ 8 = \tau_8,$$

and parameter interval $D^3_\tau = [1,5]$.



As is illustrated in the figure, we determine the point $p(s)$ and the tangent vector $p'(s)$ for $s = 3 \in [2,5)$. To this end, we insert s three times as new knot. Starting with the relevant control points $c_1, \ldots, c_4$ for the knot interval $[2,5)$, the new control points are generated with a triangular scheme. After having inserted s twice, we can compute

$$p'(3) = \frac{3}{5-2}((11,19) - (5,16)) = (6,3).$$

The point on the curve is then obtained by forming one last convex combination:

$$p(3) = \tilde{c}_4 = \frac{3-2}{5-2}(11,19) + \frac{5-3}{5-2}(5,16) = (7,17),$$

where the weights correspond to the relative position of s in the knot interval $[2,5)$. □

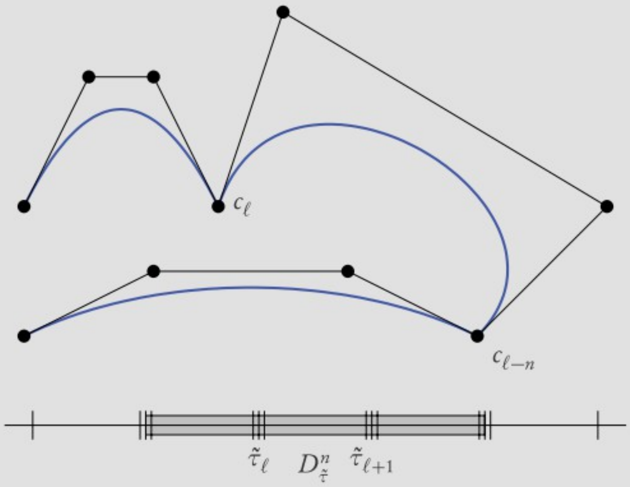
It is often possible to process the polynomial segments of a spline representation simultaneously. This can be done most efficiently by converting to Bézier form, using repeated knot insertion.

Bézier Form

The Bézier form of a spline curve parametrized by $p = \sum_{k=0}^{m-1} c_k\, b_k \in S_\tau^n$ is obtained by raising the multiplicity of each knot τ_k in the parameter interval $D_\tau^n = [\tau_n, \tau_m]$ to n. Then, for t in a nondegenerate parameter interval $[\tilde{\tau}_\ell, \tilde{\tau}_{\ell+1}] \subseteq D_\tau^n$ of the refined knot sequence $\tilde{\tau}$,

$$p(t) = \sum_{k=0}^{n} \tilde{c}_{\ell-n+k}\, b_k^n(s), \quad s = \frac{t - \tilde{\tau}_\ell}{\tilde{\tau}_{\ell+1} - \tilde{\tau}_\ell} \in [0,1],$$

where b_k^n are the Bernstein polynomials and $\tilde{c}_k$ the control points with respect to $\tilde{\tau}$. Hence, up to linear reparametrization (which is immaterial for the shape of the curve), the spline segments have Bézier form.



As shown in the figure, every nth control point lies on the curve separating the Bézier segments. Thus, by converting to Bézier form, we can apply polynomial algorithms simultaneously on the different knot intervals.

We already remarked in Section 4.1 that Bernstein polynomials are particular B-splines. If $\tilde{\tau}$ has n-fold knots at both endpoints of a knot interval $D_\ell = [\tilde{\tau}_\ell, \tilde{\tau}_{\ell+1}]$, i.e., if

$$\tilde{\tau}_{\ell-n} < \tilde{\tau}_{\ell-n+1} = \cdots = \tilde{\tau}_\ell < \tilde{\tau}_{\ell+1} = \cdots = \tilde{\tau}_{\ell+n} < \tilde{\tau}_{\ell+n+1},$$

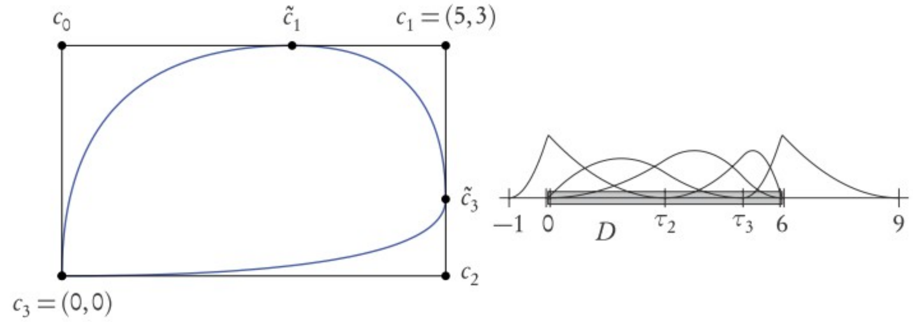
then the relevant B-splines $\tilde{b}_k$ for D_ℓ ($k = \ell - n, \ldots, n$) coincide with the transformed Bernstein polynomials on D_ℓ. As a consequence of the B-spline recursion,

$$\tilde{b}_{\ell-n}(t) = \left(\frac{\tilde{\tau}_{\ell+1} - t}{\tilde{\tau}_{\ell+1} - \tilde{\tau}_\ell} \right)^n = b_0^n(s), \quad \tilde{b}_\ell(t) = \left(\frac{t - \tilde{\tau}_\ell}{\tilde{\tau}_{\ell+1} - \tilde{\tau}_\ell} \right)^n = b_n^n(s)$$

for $t \in D_\ell \Leftrightarrow s \in [0,1]$. We note that these two B-splines have support also on the neighboring intervals, thus ensuring continuity of the curve at the junction points. For $0 < i < n$, the B-spline $\tilde{b}_{\ell-n+i}$ has an $(n+1-i)$-fold knot at τ_ℓ and an $(i+1)$-fold knot at $\tau_{\ell+1}$ and, thus, $\tilde{b}_{\ell-n+i}(t) = b_i^n(s)$; those B-splines are supported entirely on D_ℓ.

□ **Example:**

As an example, we consider the closed quadratic spline curve with control points and extended knot sequence shown in the figure.



To convert to Bézier form, we double the knots $\tau_2 = 3$ and $\tau_3 = 5$, taking into account the periodicity of the extended partition and the control points:

$$\tau_{k+4} = \tau_k + 6, \quad c_{k+4} = c_k\,.$$

Applying the knot insertion algorithm first for $s = \tau_2$, only the index $k = 1$ satisfies

$$\tau_k < s = 3 < \tau_{k+2}\,.$$

Hence, inserting $s = 3$ yields only one new control point, namely,

$$\tilde{c}_1 = \frac{3}{5}(5,3) + \frac{2}{5}(0,3) = (3,3)\,.$$

Similarly, inserting $s = 5$, we compute the control point

$$\tilde{c}_3 = \frac{2}{3}(5,0) + \frac{1}{3}(5,3) = (5,1)$$

and obtain the Bézier control polygon

$$\tilde{c}_0 = c_0,\ \tilde{c}_1,\ \tilde{c}_2 = c_1,\ \tilde{c}_3,\ \tilde{c}_4 = c_2,\ \tilde{c}_5 = c_3\,.$$

We notice that the control points on the curve, which separate the spline segments, lie on the initial control polygon which touches the curve at these points. This is a particular feature of quadratic spline curves. The conversion is very simple in this case. The Bézier control points separating the curve segments at a simple knot τ_ℓ are computed by dividing the segment $[c_{\ell-2}, c_{\ell-1}]$ in the ratio

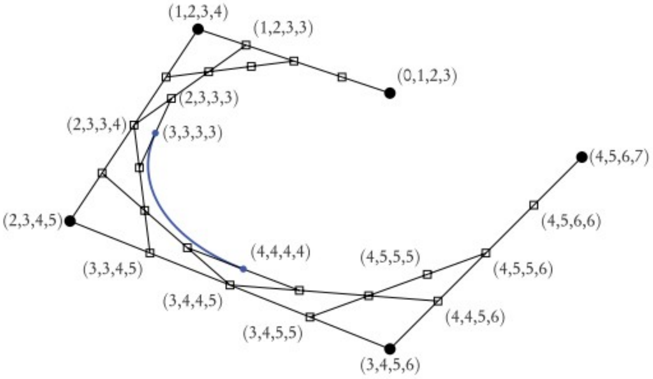
$$(\tau_\ell - \tau_{\ell-1}) : (\tau_{\ell+1} - \tau_\ell).$$

At a double knot $\tau_\ell = \tau_{\ell+1}$, no computations are necessary; $c_{\ell-1}$ is already a separating Bézier control point. □

As a further illustration, we consider the conversion for uniform knots. In this special case, the knot insertion procedure has an intriguing description via a combinatoric labeling scheme.

□ **Example:**

For spline curves parametrized by $p = \sum_k c_k b_k \in S^n_\tau$ with uniform knots τ_k the conversion to Bézier form has a beautiful geometric interpretation due to Ramshaw and is referred to as blossoming. It is illustrated in the figure below for a parametrization of degree $n = 4$.



We label the control points by the indices of the inner knots of the corresponding B-splines. For example, c_3 has the label $(4,5,6,7)$ since b_3 has support $[\xi_3, \xi_8]$. Then, we connect pairs of points with labels

$$(a,b,c,d), \quad (b,c,d,e)$$

which have $n-1 = 3$ indices in common. On the resulting line segment, we place $e-a-1$ equally spaced new points and label them with

$$(a+1,b,c,d), \dots, (e-1,b,c,d),$$

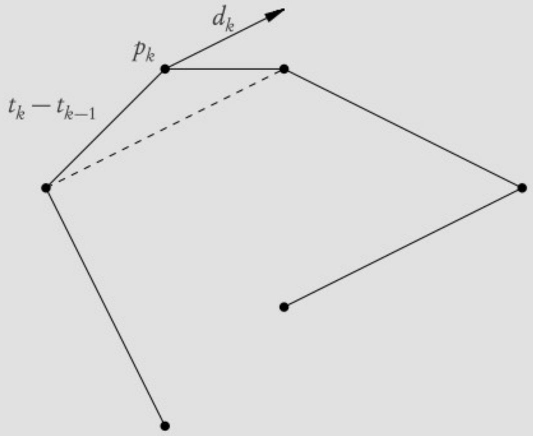
reordering the indices if necessary. The process is repeated, at each stage utilizing the newly generated points, until all possible connections have been formed. In the final configuration, the Bézier segments consist of all points with labels, which have at most two different indices. In particular, the Bézier endpoints have labels with just one index of multiplicity $n = 4$. □

6.5 ▪ Interpolation

Interpolation methods for functions can be applied to curves in an obvious way. Each component is processed separately. Below, we list the most commonly used schemes.

Interpolation

Points p_k and tangent vectors d_k (if provided) can be interpolated with a spline curve at parameter values t_k, using any of the interpolation methods for spline functions. The univariate schemes are applied separately in each component to determine the components of the parametrization $p = \sum_k c_k b_k$. Standard choices are cubic Hermite interpolation and cubic spline interpolation with not-a-knot, natural, or clamped boundary conditions.



If only points are given, knots τ_j, parameter values t_k, and tangent vectors d_k (if required) have to be determined based on the available information. Basic choices are

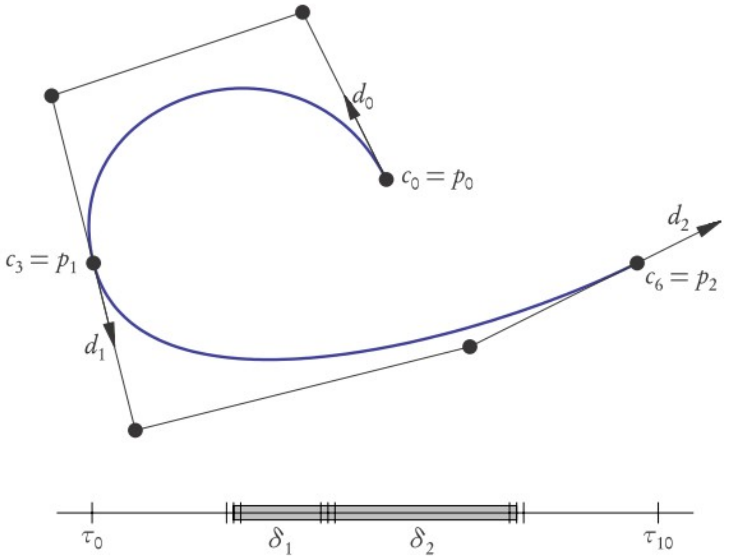
- $t_k - t_{k-1} = |p_k - p_{k-1}|$;
- $t_k = \tau_{k+\ell}$ with the shift ℓ depending on the labeling of the knots;
- $d_k = (p_{k+1} - p_{k-1})/(t_{k+1} - t_{k-1})$.

More accurate derivative approximations employ local polynomial interpolation. The resulting formulas are used in particular at the endpoints of the parameter interval, where one-sided approximations are needed.

As a first example we consider cubic Hermite interpolation. While the interpolant is not curvature continuous, it can be constructed with a few simple operations without having to solve a linear system.

☐ **Example:**

If tangent vectors d_j are given at all points p_j, we can interpolate each pair of consecutive data with a cubic Bézier segment. By construction, these segments form a spline curve in Bézier form. In particular, two adjacent segments share a common control point lying on the curve.



Considering, e.g., the interpolation by the segment interpolating p_0 and p_1, we choose the length of the parameter interval as $\tau_4 - \tau_3 = |p_1 - p_0| = \delta_1$. This means that the parametrization has the form

$$p(t) = \sum_{k=0}^{3} c_k\, b_k^3(s), \quad s = \frac{t - \tau_3}{\tau_4 - \tau_3},$$

where b_k^3 are the cubic Bernstein polynomials. Accordingly, the interpolation conditions imply

$$p_0 = c_0, \quad p_1 = c_3,$$

and

$$d_0 = \frac{3}{\delta_1}(c_1 - c_0), \quad d_1 = \frac{3}{\delta_1}(c_3 - c_2).$$

Solving the last equations for the two middle control points finally yields

$$c_1 = p_0 + \frac{\delta_1}{3} d_0, \quad c_2 = p_1 - \frac{\delta_1}{3} d_1. \qquad \square$$

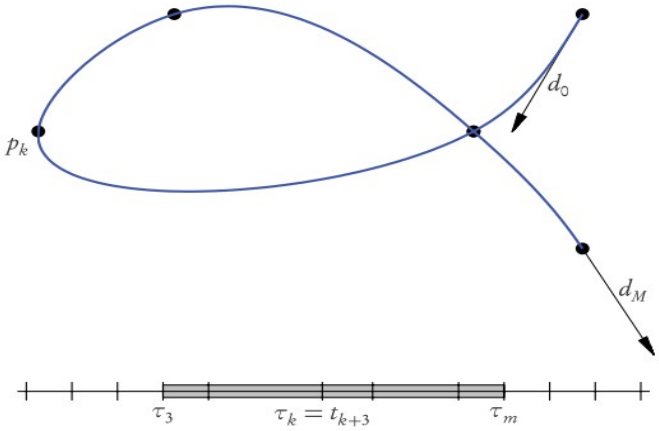
Very popular interpolation schemes, also for curves, are natural spline interpolation and its variants. The implementation of these methods is discussed in the following example.

□ **Example:**

To interpolate points $p_0, \ldots, p_M$ by a natural cubic spline curve, we first make a standard selection of the parameter values. We choose t_k so that

$$t_{k+1} - t_k = |p_{k+1} - p_k|, \quad k = 0, \ldots, M-1.$$

In $D = [t_0, t_M]$, the knots $\tau_k = t_{k-3}$, $k = 3, \ldots, m$, $m = M + 3$, are used. Outside of D, we choose three equally spaced knots on each side, keeping the distance of the first and last knot interval. We can now apply the univariate scheme with the boundary conditions $p''(t_0) = p''(t_M) = 0$.



A more accurate approximation is obtained by using either clamped or not-a-knot boundary conditions. In the first case, derivatives are prescribed at the endpoints:

$$p'(t_0) = d_0, \quad p'(t_M) = d_M .$$

The not-a-knot conditions mean that the knots $\tau_4 = t_1$ and $\tau_{m-1} = t_{M-1}$ are removed. As a result, we interpolate using the B-splines $\tilde{b}_0, \ldots, \tilde{b}_M$ corresponding to the reduced knot sequence

$$\tilde{\tau}: \ \tau_0 < \cdots < \tau_3 = t_0 < \tau_5 < \tau_6 < \cdots < \tau_{m-3} < \tau_{m-2} < t_M = \tau_m < \cdots < \tau_{m+3}$$

Hence, the dimension $\tilde{m} = M + 1$ of the spline space $S^3_{\tilde{\tau}}$ matches the number of interpolation conditions and, as implied by the Schoenberg–Whitney condition, the interpolation problem is well posed. □

A Cornucopia of Quadrilaterals - MAA Press - Vol 45

The midpoints of the sides of any quadrilateral are the vertices of a parallelogram, or that in a convex quadrilateral (not a parallelogram) the line through the midpoints of the diagonals (the Newton line) is equidistant from opposite vertices, or that, if your quadrilateral has an inscribed circle, its center lies (conversely) on the Newton line.

There are results dating back to Euclid: the side-lengths of a pentagon, a hexagon, and a decagon inscribed in a circle can be assembled into a right triangle (the proof uses a quadrilateral and circumscribing circle); and results dating to Erdős: from any point in a triangle the sum of the distances to the vertices is at least twice as large as the sum of the distances to the sides.

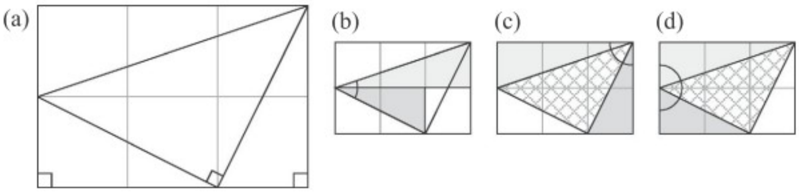

Figure 3.2.

The solution follows immediately from the Garfield trapezoid in Figure 3.1. The upper edge of the trapezoid has length $c\sqrt{2}$ (from the Pythagorean theorem just proven), and is at least as long as the base $a+b$. The two are equal if and only if the upper and lower edges are parallel, which occurs if and only if $a=b$.

If we divide both sides of (3.1) by 2 and recall that $c=\sqrt{a^2+b^2}$ we have

$$\frac{a+b}{2} \le \sqrt{\frac{a^2+b^2}{2}} \tag{3.2}$$

with equality if and only if $a=b$. The term on the right side in (3.2) is the root mean square, which we encountered in Challenge 2.5, and (3.2) is the arithmetic mean-root mean square inequality.

3.3 Trigonometric formulas and identities

Since the Garfield trapezoid is constructed from three triangles that share sides, it is remarkably well suited for illustrating a variety of trigonometric formulas and identities. In this section we often adjoin a fourth triangle to the trapezoid, and use the resulting rectangle to explore relationships among the sides and angles of the triangles in the configuration.

We begin by setting $a=1$ and $b=2$ in Figure 3.1 and embedding the icon in a 2-by-3 rectangle, as illustrated in Figure 3.2a. This enables us to evaluate certain angles marked $\measuredangle$ in the shaded triangles as arctangents and sums of arctangents.

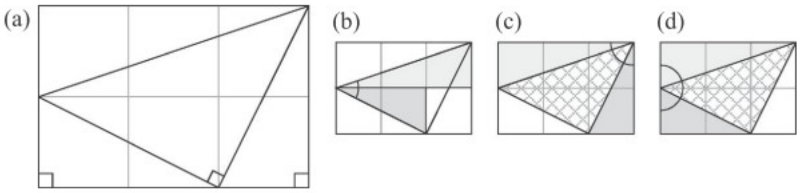

Figure 3.2.

From the marked angles in Figures 3.2b, 3.2c, and 3.2d we obtain

$$\begin{aligned} &\arctan(1/2)+\arctan(1/3)=\pi/4, \\ &\arctan(1)+\arctan(1/2)+\arctan(1/3)=\pi/2, \text{ and} \\ &\arctan(1)+\arctan(2)+\arctan(3)=\pi\,\text{[Wu, 2003]}. \end{aligned} \tag{3.3}$$

The argument can be easily modified to derive *Euler's arctangent identity*: For positive numbers p and q,

$$\arctan(1/p) = \arctan(1/(p+q)) + \arctan(q/(p^2+pq+1)). \quad (3.4)$$

See Figure 3.3 [Wu, 2004], and observe that $\alpha = \beta + \gamma$ where $\alpha = \arctan(1/p)$, $\beta = \arctan(1/(p+q))$, and $\gamma = \arctan(q/(p^2+pq+1))$.

Figure 3.3.

When $p = q = 1$, we obtain (3.3) as a special case of (3.4). See Challenges 3.3 and 3.4 for further arctangent identities.

The usual way to evaluate the trigonometric functions of 15° and 75° is with addition and subtraction formulas, e.g., $\sin(15°) = \sin(45° - 30°)$ or $\sin(60° - 45°)$, $\tan(75°) = \tan(30° + 45°)$, etc. However, they are readily evaluated geometrically using a modified Garfield trapezoid and a procedure adapted from [Hoehn, 2004]. In Figure 3.4a we construct the trapezoid from two isosceles right triangles, one with sides 1, 1, and $\sqrt{2}$ and the other with sides $\sqrt{3}$, $\sqrt{3}$, and $\sqrt{6}$. Since the sides containing the right angle in the gray triangle in Figure 3.4a are $\sqrt{2}$ and $\sqrt{6}$, the gray triangle has acute angles measuring 30° and 60°.

Figure 3.4.

Adjoin a right triangle to the top of the trapezoid to form the rectangle in Figure 3.4b. The acute angles of the adjoined triangle (shaded gray) are 15° and 75°; the sides are $\sqrt{3}-1$, $\sqrt{3}+1$, and $2\sqrt{2}$; and hence

$$\sin 15^\circ = \frac{\sqrt{3}-1}{2\sqrt{2}}, \tan 75^\circ = \frac{\sqrt{3}+1}{\sqrt{3}-1}, \text{etc.}$$

The procedure can be modified to illustrate the addition and subtraction formulas for the sine, cosine, and tangent, at least for small positive angles. Let α and β be acute angles whose sum is less than $\pi/2$, and arrange two triangles with acute angle α and one with acute angle β as shown in Figure 3.5.

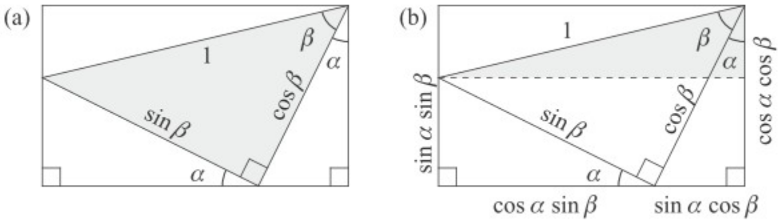

Figure 3.5.

If we let the sides of the gray triangle in Figure 3.5a be $\sin\beta$, $\cos\beta$, and 1, then it is easy to compute the lengths of the sides of the triangles with acute angle α, as shown in Figure 3.5b. Evaluating the lengths of the sides of the gray triangle in Figure 3.5b yields

$$\sin(\alpha+\beta) = \sin\alpha\cos\beta + \cos\alpha\sin\beta,$$
$$\cos(\alpha+\beta) = \cos\alpha\cos\beta - \sin\alpha\sin\beta.$$

The other formulas can be similarly illustrated, see Challenges 3.5 and 3.6.

We conclude this section with two little known identities for sums and products of tangents, again illustrated with modified Garfield trapezoids. In Figure 3.6 we show that for positive angles α, β, and γ such that $\alpha+\beta+\gamma=\pi$ (for instance, the angles in a triangle), we have

$$\tan\alpha + \tan\beta + \tan\gamma = \tan\alpha\tan\beta\tan\gamma.$$

The identity results from equating the two expressions for the vertical height of the rectangle.

$\tan\alpha\tan\gamma$
$\tan\beta\tan\gamma$

Figure 3.6.

In Figure 3.7 we see a complementary result: for positive angles α, β, and γ such that $\alpha + \beta + \gamma = \pi/2$, we have

$$\tan\alpha\tan\beta + \tan\beta\tan\gamma + \tan\gamma\tan\alpha = 1.$$

3.4 Challenges

3.1. Use Garfield's trapezoid to show that for any θ, $|\sin\theta + \cos\theta| \leq \sqrt{2}$.

3.2. Use Garfield's trapezoid to illustrate the AM-GM inequality.

3.3. Let $0 < a < b$. Use a diagram similar to Figure 3.2a to show

$$\arctan(a/b) + \arctan((b-a)/(b+a)) = \pi/4.$$

3.4. Let $\{F_n\}_{n=1}^{\infty}$ denote the sequence of Fibonacci numbers, defined by $F_1 = F_2 = 1$ and $F_n = F_{n-1} + F_{n-2}$ for $n \geq 3$. Prove

$$\arctan\frac{1}{F_{2n}} = \arctan\frac{1}{F_{2n+1}} + \arctan\frac{1}{F_{2n+2}}$$

for $n \geq 1$. [Hint: Use Euler's arctangent identity and *Cassini's identity* for the Fibonacci numbers: $F_{k-1}F_{k+1} - F_k^2 = (-1)^k$ for $k \geq 2$. See Challenge 18.2 for a proof of Cassini's identity.]

3.5. Use a diagram similar to Figure 3.4 to illustrate the subtraction formulas for the sine and cosine:

$$\sin(\alpha - \beta) = \sin\alpha\cos\beta - \cos\alpha\sin\beta,$$
$$\cos(\alpha - \beta) = \cos\alpha\cos\beta + \sin\alpha\sin\beta.$$

3.6. Use diagrams similar to Figure 3.4 to illustrate the addition and subtraction formulas for the tangent:

$$\tan(\alpha + \beta) = \frac{\tan\alpha + \tan\beta}{1 - \tan\alpha\tan\beta} \quad \text{and} \quad \tan(\alpha - \beta) = \frac{\tan\alpha - \tan\beta}{1 + \tan\alpha\tan\beta}.$$

3.7. Let a, b, c be the sides of a right triangle, with c the hypotenuse. Show that three right triangles (each similar to the given triangle) with sides a^2, ab, ac; ab, b^2, bc; and ac, bc, c^2; can be arranged to form a Garfield trapezoid that is actually a rectangle, yielding another proof of the Pythagorean theorem.

3.8. An integration technique often presented in calculus is the *Weierstrass substitution*, useful for integrals of rational functions of the sine and cosine. The change of variables $z = \tan(\theta/2)$ yields rational functions of z for $\sin\theta$ and $\cos\theta$. Use the Garfield trapezoid in Figure 3.8 to evaluate $\sin\theta$ and $\cos\theta$ as functions of z.

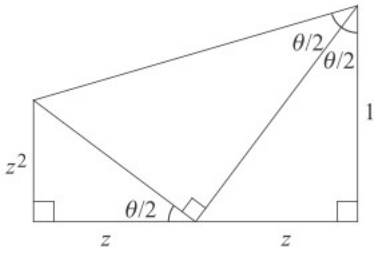

Figure 3.8.

3.9. Given $a, b > 0$ consider for any $k > 0$ the trapezoid in Figure 3.9, where P_k is the midpoint of the slanted edge. Describe the position of P_k as a function of k.

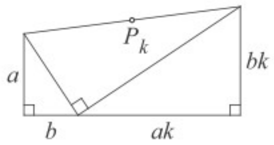

Figure 3.9.

3.10. It is an immediate consequence of the AM-GM inequality (see Section 2.2 or Challenge 3.2) that for x positive, $x + (1/x) \geq 2$. Show that this inequality can be improved to

$$x + \frac{1}{x} \geq \frac{1}{2}\left(\sqrt{x} + \frac{1}{\sqrt{x}}\right)^2 \geq 2. \tag{3.5}$$

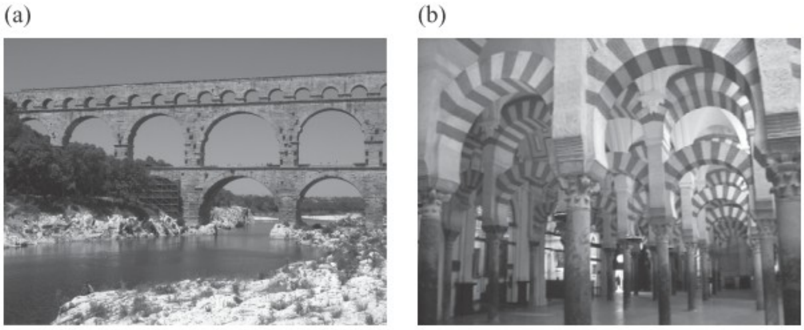
CHAPTER 4

The Semicircle

The eye is the first circle; the horizon which it forms is the second; and throughout nature this primary figure is repeated without end. It is the highest emblem in the cipher of the world.

Ralph Waldo Emerson, *Essays*

The semicircle has long played an important role in architecture and art. The Romans employed semicircular arches in their constructions such as the Pont du Gard aqueduct near Nîmes, France (see Figure 4.1a). Similar arches can be found in Romanesque architecture throughout Europe. The Moors also used semicircular arches in their most impressive buildings, such as in the interior of the Mezquita mosque in Córdoba, Spain (see Figure 4.1b). Semicircles also appear in paintings of modern artists such as Wassily Kandinsky (*Semicircle*, 1927) and Robert Mangold (*Semi-Circle I–IV*, 1995).



(a) (b)

Figure 4.1.

The icon for this chapter is a semicircle, simple and easily constructed with straightedge and compass but nonetheless remarkably useful in geometry and trigonometry. It figures prominently in the work of Greek geometers such as Thales, Euclid, Archimedes, Hippocrates, and Pappus. The semicircle also appears in the solution of the first optimization problem in literature, Dido's problem. We also encounter it in visual demonstrations of a variety of trigonometric identities, and in an exploration of the five Platonic solids inscribed in a sphere.

4.1 Thales' triangle theorem

Perhaps the first occurrence of the semicircular icon in geometry is in a theorem named after Thales of Miletus (circa 624–546 BCE), one of the earliest of the great Greek mathematicians. The theorem also appears as Proposition 31 in Book III of Euclid's *Elements*. There are two theorems commonly called "Thales' theorem"—one about a right angle inscribed in a semicircle, which we call *Thales' triangle theorem*, and another about similar triangles, which we call *Thales' proportionality theorem* and present in Chapter 5.

Thales' triangle theorem. *A triangle inscribed in a semicircle is a right triangle.* See Figure 4.2a.

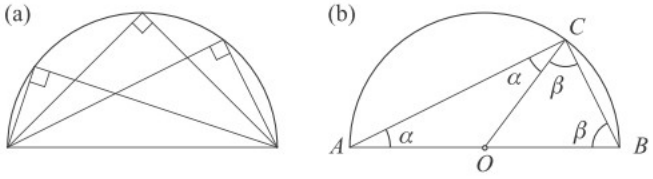


Figure 4.2.

Label the vertices of the triangle as shown in Figure 4.2b, and let O denote the center of the semicircle. Then $|AO| = |BO| = |CO|$ since each is the length of a radius, and thus triangles AOC and BOC are isosceles. Hence $\angle OAC = \angle OCA = \alpha$ and $\angle OBC = \angle OCB = \beta$. The angles of triangle ABC sum to 180°, so $2\alpha + 2\beta = 180°$, or $\alpha + \beta = 90°$. Thus C is a right angle as claimed.

Also, $2\alpha + 2\beta = 180°$ implies that $\angle BOC = 2\alpha$.

Thales' triangle theorem is used repeatedly throughout this chapter. The converse of the theorem also holds, see Challenge 4.1.

4.2 The right triangle altitude theorem and the geometric mean

In Section 2.2 we encountered the *geometric mean* $\sqrt{ab}$ of two positive numbers a and b (and we will meet it again in Sections 13.4 and 18.4). Why is it called geometric? The three numbers a, $\sqrt{ab}$, b are in geometric progression, just as the three numbers a, $(a+b)/2$, b (where $(a+b)/2$ is the arithmetic mean of a and b) are in arithmetic progression, but it is more likely that the answer lies in the purely geometric construction found in Proposition 13 in Book VI of the *Elements* of Euclid, and illustrated in Figure 4.3a.

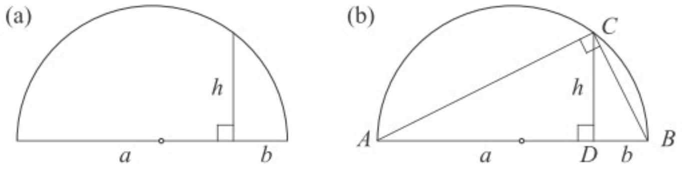

Figure 4.3.

The construction in Figure 4.3a is based on the corollary to Proposition 8 in that Book, which is also known as the

Right triangle altitude theorem: *The length of the altitude to the hypotenuse of a right triangle is the geometric mean of the lengths of the resulting two segments of the hypotenuse.*

Thus in Figure 4.3a we have $h = \sqrt{ab}$.

From Thales' triangle theorem, ABC is a right triangle and the half-chord CD partitions ABC into two triangles ACD and BCD, each similar to ABC. Ratios of corresponding sides in ACD and BCD yields $a/h = h/b$ so that $h = \sqrt{ab}$ is the geometric mean of a and b.

Since $h^2 = ab$, h is the side of a square equal in area to a rectangle with sides a and b, yielding a geometric average of a and b. The arithmetic mean $(a+b)/2$ of a and b appears in Figure 4.3b as the radius of the semicircle. Since the radius to C (not drawn) is at least as long as h, we have another proof of the arithmetic mean-geometric mean inequality $(a+b)/2 \geq \sqrt{ab}$.

When we construct a square equal in area to a given figure, we say we have *squared* the figure. Figure 4.3a shows how to square rectangles. To square a triangle, first construct a rectangle equal in area to the triangle. To square a convex n-gon, first partition it into triangles and square them. By virtue of the Pythagorean theorem, we can construct a square equal in area to two squares, and repeating this procedure yields a square equal in area to any number of squares, which completes the squaring of the n-gon.

4.3 Queen Dido's semicircle

The legend of Dido comes to us from the epic poem *Aeneid*, written by the Roman poet Virgil (70–19 BCE). Dido was a princess from the Phoenician city of Tyre (in present-day Lebanon). Dido fled the city after her brother murdered her husband and arrived in Africa in about 900 BCE, near the bay of Tunis. Dido decided to purchase land from the local leader, King Jarbas of Numidia, so she and her people could settle there. She paid Jarbas a sum of money for as much land as she could enclose with the hide of an ox. Virgil (as translated by Sarah Ruden) describes the scene as follows:

> They came here, where you now see giant walls
> And the rising citadel of newborn Carthage.
> They purchased land, 'as much as one bull's hide
> Could reach around,' and called the place 'the Bull's Hide.'

To obtain as much land as possible, Dido cut the ox skin into thin strips and tied them together, as illustrated in the 17th century woodcut in Figure 4.4. This plot of land would later become the site of the city of Carthage.

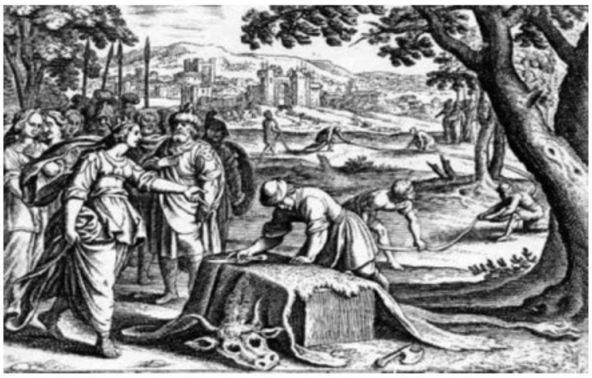

Figure 4.4.

This brings us to *Dido's problem*: How should she lay the strips on the ground to enclose as much land as possible? If we assume that the ground is flat and the Mediterranean shore is a straight line, then the optimal solution is to lay the strips in the shape of a semicircle, which legend tells us is what Dido did. Our proof is from [Niven, 1981], who attributes it to Jakob Steiner (1796–1863).

To prove that the semicircle is the optimal solution we first need the elementary result: *Of all triangles with two sides of fixed length and a third side of arbitrary length, the triangle with the largest area is the right triangle with the arbitrary side as hypotenuse*. If the fixed sides have lengths a and b and if θ denotes the angle between them, then the area T of the triangle equals $(ab\sin\theta)/2$. To maximize T we need only maximize $\sin\theta$, which occurs if and only if $\theta = 90°$.

Dido's problem is closely related to the *isoperimetric problem* ("isoperimetric" means "having the same perimeter"): Among all closed curves of a given length, which encloses the greatest area? The difference is that in Dido's case only the length of the strips of oxhide was fixed, so she was free to use as much of the straight shoreline as she wished. We call the solution

Dido's theorem. *Suppose a curve C of fixed length and a straight line L enclose a region. If C is not a semicircle, then it can be replaced by another curve C' of the same length so that C' and L enclose a region with greater area. Hence if there is a curve enclosing (with L) a region with maximal area, it must be a semicircle.*

Let A and B be the points of L which are the endpoints of the curve C, as illustrated in Figure 4.5a. From Thales' triangle theorem we know that if C is not a semicircle, then we can find a point P on C where $\angle APB \neq 90°$. Then the region enclosed by C and L consists of three parts: the region R enclosed by the line segment AP and C, the region S enclosed by the line segment BP and C, and the triangle APB denoted by T.

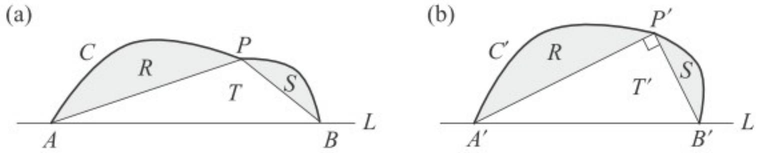

Figure 4.5.

With AP and BP fixed at the point P, slide A and B along L to A' and B' with $|A'P'| = |AP|$ and $|B'P'| = |BP|$ so that $\angle A'P'B' = 90°$, as shown in Figure 4.5b. By construction, the shaded areas R and S remain the same, but the area of T' is greater that the area of T, so that the curve C has been transformed into a curve C' with the same length as C but enclosing a greater area with L.

As noted in the statement of Dido's theorem, we must assume that a curve enclosing the maximum area exists. The existence of such a curve was proven formally by Karl Theodor Wilhelm Weierstrass (1815–1897).

4.4 The semicircles of Archimedes

The *Book of Lemmas* (or *Liber Asumptorum*) is a collection of fifteen propositions and their proofs attributed to Archimedes (287–212 BCE). It survives today from an Arabic translation by Thabit ibn Qurra (836–901). Several of the propositions in the *Book of Lemmas* concern semicircles and we present four of them, Propositions 3, 4, 8, and 14. Proposition 3 presents a bisection of the vertical line segment in our icon, proposition 8 uses the semicircle to trisect an angle, and propositions 4 and 14 concern area of figures known as an *arbelos* (shoemaker's knife) and a *salinon* (a salt-cellar). See [Heath, 1897] for all the propositions and their proofs.

Archimedes' Proposition 3. *Let AB be the diameter of a semicircle, and let the tangents to it at B and at any other point D on it meet at T. If now DE is drawn perpendicular to AB, and if AT, DE meet at F,* then $|DF| = |FE|$. See Figure 4.6a.

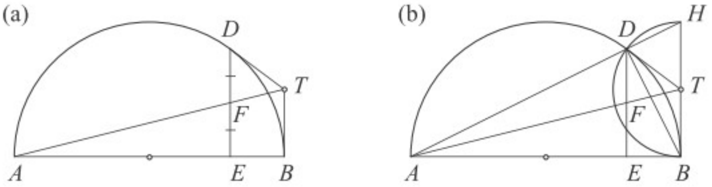

Figure 4.6.

Draw AD, and extend it and BT to meet at H, as shown in Figure 4.6b. Since $\angle ADB$ is a right angle, so is $\angle BDH$. In addition we have $|BT| = |TD|$. Hence T is the center of a semicircle with diameter BH, and $|BT| = |TH|$. Since DE and BH are parallel, it follows that $|DF| = |FE|$.

Archimedes' Proposition 4. *Let P, Q, and R be three points on a line, with Q lying between P and R. Semicircles are drawn on the same side of the line with diameters PQ, QR, and PR. An arbelos is the figure bounded by the three semicircles. Draw the perpendicular to PR at Q, meeting the* *largest semicircle at S. Then the area A of the arbelos equals the area C of the circle with diameter QS.* See Figure 4.7.

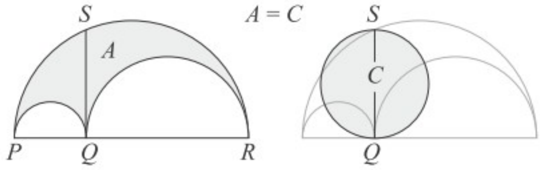

Figure 4.7.

There is a direct algebraic proof of Proposition 4 using the geometric mean, which we present as Challenge 4.2. Here we present a geometric proof [Nelsen, 2002b] based on the Pythagorean theorem. In Proposition 31 of Book VI of the *Elements*, Euclid writes: *In right-angled triangles the figure on the side opposite the right angle equals the sum of the similar and similarly described figures on the sides containing the right angle*. For similar figures on the sides, we now use semicircles. See Figure 4.8.

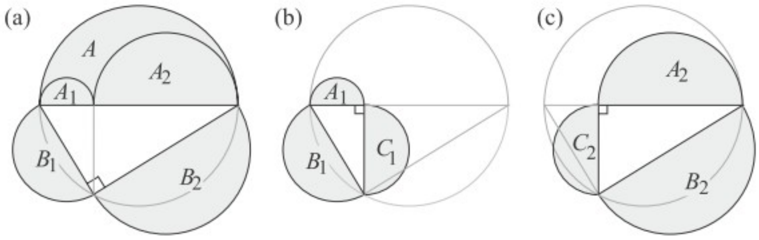

Figure 4.8.

In Figure 4.8a we have $A + A_1 + A_2 = B_1 + B_2$, in Figure 4.8b, $B_1 = A_1 + C_1$, and in Figure 4.8c, $B_2 = A_2 + C_2$. Together the equations yield $A + A_1 + A_2 = A_1 + C_1 + A_2 + C_2$, which simplifies to $A = C_1 + C_2 = C$.

In Proposition 8 Archimedes uses a circle to trisect an angle. We present a slight variation with a semicircle [Aaboe, 1964].

Archimedes' Proposition 8. *In a semicircle with center O and diameter AB, let $\angle AOE$ be the angle to be trisected. Let C be the point on the extension of AB so that the line CE intersects the circle at D with $|CD|$ equal to the radius of the circle. Then $\angle ACE = (1/3)\angle AOE$.* See Figure 4.9.

Let $\alpha = \angle AOE$. Since $|CD| = |OD| = |OE|$, triangles DOE and ODC are isosceles, and hence have equal base angles β and γ, respectively,

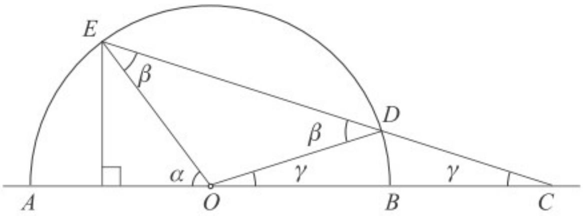

Figure 4.9.

as indicated in Figure 4.9. Hence by the exterior angle theorem (Proposition 32 in Book I of Euclid's *Elements*) $\beta = 2\gamma$ and $\alpha = \beta + \gamma = 3\gamma$.

Figure 4.9 can also be used to derive the triple angle formulas for the sine and cosine. See Section 7.5.

Archimedes' Proposition 14. *Let P, Q, R, S be four points on a line (in that order) such that $PQ = RS$. Semicircles are drawn above the line with diameters PQ, RS, and PS, and another semicircle with diameter QR is drawn below the line.* A salinon *is the figure bounded by the four semicircles. Let the axis of symmetry of the salinon intersect its boundary at M and N. Then the area A of the salinon equals the area C of the circle with diameter MN.* See Figure 4.10.

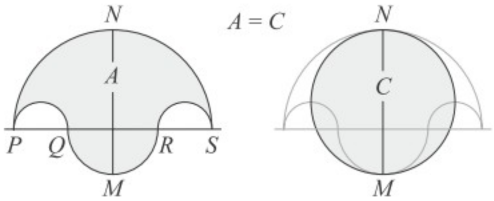

Figure 4.10.

In our proof [Nelsen, 2002a], we use the fact that the area of a semicircle is $\pi/2$ times the area of the inscribed isosceles right triangle (see Figure 4.11).

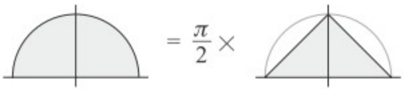

Figure 4.11.

Consequently, the area of the salinon is $\pi/2$ times the area of a square (see Figure 4.12), which equals the area of a circle and proves the proposition.

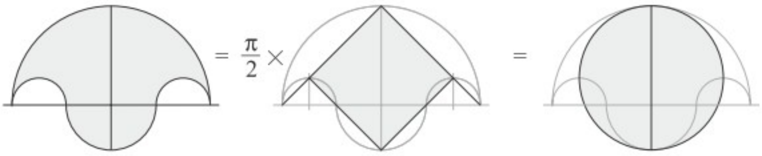

Figure 4.12.

4.5 Pappus and the harmonic mean

The *harmonic mean* of two positive numbers a and b is often defined as the reciprocal of the arithmetic mean of the reciprocals of a and b, i.e., $([(1/a)+(1/b)]/2)^{-1}$, which simplifies to $2ab/(a+b)$. The name harmonic derives from its connection with the harmonic sequence $1, 1/2, 1/3, 1/4, \ldots$, which is important in music. In the harmonic sequence, each term is the harmonic mean of its predecessor and its successor, e.g., $1/3$ is the harmonic mean of $1/2$ and $1/4$.

We have seen how the arithmetic and geometric means of a and b appear as line segments in a semicircle with diameter $a+b$ in Figure 4.3a: the radius is the arithmetic mean $(a+b)/2$ and the half-chord perpendicular to the diameter is the geometric mean $\sqrt{ab}$. Pappus of Alexandria (circa 290–350), in Book III of his *Collection*, added one more line segment to illustrate the harmonic mean as well, as shown in Figure 4.13.

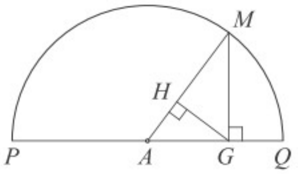

Figure 4.13.

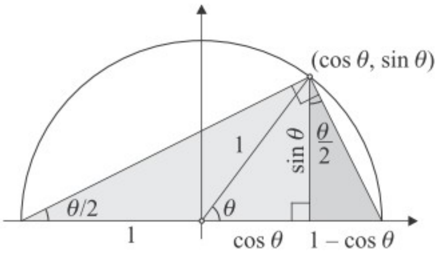
When $|PG| = a$ and $|GQ| = b$, the arithmetic and geometric means are $|AM| = (a+b)/2$ and $|GM| = \sqrt{ab}$ respectively. Since GH is perpendicular to AM, triangles AGM and GHM are similar, so that $|HM|/|GM| = |GM|/|AM|$. Thus the harmonic mean is $|HM| = 2ab/(a+b)$, with $|HM| \leq |GM| \leq |AM|$. Also, the geometric mean of a and b equals the geometric mean of $(a+b)/2$ and $2ab/(a+b)$.

4.6 More trigonometric identities

The trigonometric functions can be expressed both in terms of the coordinates of points on the unit circle and as ratios of sides of right triangles. The two approaches combine with our semicircle icon to produce illustrations of a variety of trigonometric identities.

In Figure 4.2b, $\angle BOC = 2\alpha$ as a consequence of the exterior angle theorem, which immediately yields the two half-angle formulas for the tangent function.

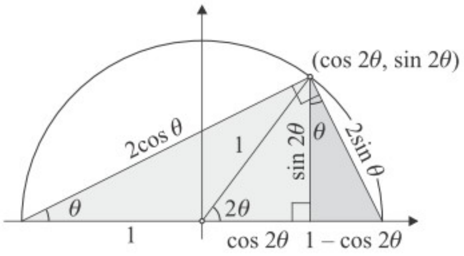


$(\cos\theta, \sin\theta)$
1
$\sin\theta$
$\frac{\theta}{2}$
$\theta/2$
θ
1
$\cos\theta$
$1-\cos\theta$

Figure 4.14.

In the light gray triangle in Figure 4.14 we have $\tan(\theta/2) = \sin\theta/(1 + \cos\theta)$, and in the dark gray one we have $\tan(\theta/2) = (1 - \cos\theta)/\sin\theta$ [Walker, 1942]. Figure 4.14 can also be used to establish certain inverse trigonometric identities: see Challenge 4.3.

If we replace θ by 2θ in Figure 4.14, we can obtain the double-angle formulas for the sine and cosine. See Figure 4.15.



$(\cos 2\theta, \sin 2\theta)$
$2\cos\theta$
1
$\sin 2\theta$
θ
$2\sin\theta$
θ
2θ
1
$\cos 2\theta$
$1-\cos 2\theta$

Figure 4.15.

In the light gray triangle, we have $\sin\theta = \sin 2\theta/2\cos\theta$, hence $\sin 2\theta = 2\sin\theta\cos\theta$, $\cos\theta = (1+\cos 2\theta)/2\cos\theta$ or $\cos 2\theta = 2\cos^2\theta - 1$. In the dark gray triangle, we have $\sin\theta = (1-\cos 2\theta)/2\sin\theta$, so that $\cos 2\theta =$

$1 - 2\sin^2\theta$ [Woods, 1936]. See Challenge 4.4 for another derivation of the formulas.

In Challenge 3.8 we encountered the Weierstrass substitution, useful for integrals of rational functions of the sine and cosine. The change of variables $z = \tan(\theta/2)$ yields rational functions of z for $\sin\theta$ and $\cos\theta$, as illustrated in Figure 4.16.

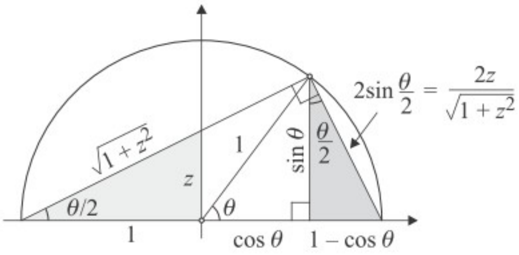


Figure 4.16.

Since $z = \tan(\theta/2)$, the sides of the light gray triangle are 1, z, and $\sqrt{1+z^2}$, and consequently the hypotenuse of the dark gray triangle is $2\sin(\theta/2) = 2z/\sqrt{1+z^2}$. Since the shaded triangles are similar, we have

$$\frac{\sin\theta}{2z/\sqrt{1+z^2}} = \frac{1}{\sqrt{1+z^2}} \text{ and } \frac{1-\cos\theta}{2z/\sqrt{1+z^2}} = \frac{z}{\sqrt{1+z^2}},$$

and hence $\sin\theta = 2z/(1+z^2)$ and $\cos\theta = (1-z^2)/(1+z^2)$ [Deiermann, 1998].

4.7 Areas and perimeters of regular polygons

There is a nice relationship between the perimeter of a regular polygon with n sides (an *n-gon*) and the area of a regular polygon with $2n$ sides when both are inscribed in a circle of radius r. If we let s_n denote the side length, $P_n = ns_n$ the perimeter, and A_n the area of a regular n-gon, then the area $A_{2n}/2n$ of the shaded triangle in Figure 4.17 is equal to one-half its base r times its altitude $s_n/2$, i.e., $A_{2n}/2n = rs_n/4$.

Hence the area of the $2n$-gon is $A_{2n} = rns_n/2 = rP_n/2$, i.e., half the product of the circumradius and perimeter of the n-gon. For example, the perimeter of a regular hexagon inscribed in a circle of radius r is $P_6 = 6r$, and hence the area of a regular dodecagon inscribed in the same circle is $A_{12} = rP_6/2 = 3r^2$.

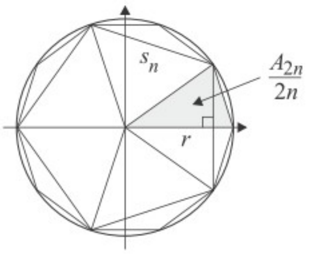

Figure 4.17.

As a consequence we can conclude that the area of a circle is equal to one-half the product of its radius and its circumference, a fact known to the Indian mathematician Bhāskara (circa 1114–1185).

4.8 Euclid's construction of the five Platonic solids

The last of the thirteen Books of the *Elements* of Euclid concerns the five Platonic solids—the tetrahedron, cube, octahedron, dodecahedron, and icosahedron. After numerous Propositions about the individual solids Proposition 18, the final Proposition of the final Book, provides a construction for the edge length of each of the five solids when inscribed in the same sphere. The construction is remarkably simple, based on a semicircle and several segments perpendicular to its diameter. Figure 4.18 is a simplified version of a diagram that appears in many translations of the *Elements*.

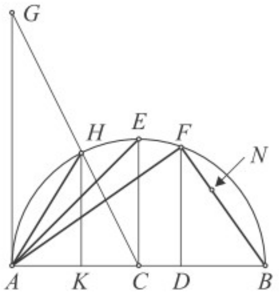

Figure 4.18.

Draw a semicircle with AB as diameter, and locate points C and D on AB so that $|AC| = |CB|$ and $|AD| = 2|DB|$. Draw AG perpendicular to

AB with $|AG| = |AB|$, let GC intersect the semicircle at H, and draw HK perpendicular to AB. Draw CE and DF perpendicular to AB, draw AH, AE, AF, and BF, and locate N on BF so that $|BF| = \phi|BN|$ where $\phi = (1 + \sqrt{5})/2$ is the golden ratio, the positive root of the quadratic equation $\phi^2 = \phi + 1$. (Euclid describes how to do this in Proposition II.11.) Then

AF is the edge of the tetrahedron,
BF is the edge of the cube,
AE is the edge of the octahedron,
BN is the edge of the dodecahedron, and
AH is the edge of the icosahedron.

We justify the last claim and leave the others to Challenge 4.8. The twelve vertices of an icosahedron with edge s are determined by three s-by-$s\phi$ *golden rectangles*. See Figure 4.19.

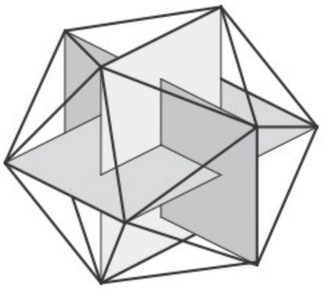

Figure 4.19.

If $|AB| = d$ in Figure 4.18, then triangle geometry yields $|AH| = d/\sqrt{2+\phi}$. The diagonal of the golden rectangle is also the diameter d of the sphere, and hence $d = \sqrt{s^2 + s^2\phi^2} = s\sqrt{2+\phi}$. It now follows that $s = d/\sqrt{2+\phi} = |AH|$, as required.

4.9 Challenges

4.1. Prove the converse of Thales' triangle theorem: the hypotenuse of a right triangle is a diameter of its circumcircle.

4.2. Prove Proposition 4 from the *Book of Lemmas* using the fact that, in Figure 4.7, $|QS|$ is the geometric mean of $|PQ|$ and $|QR|$.

4.3. Many identities for inverse trigonometric functions are equivalent to identities for trigonometric functions. Establish the following identities by relabeling sides and angles in Figure 4.14:

(a) $\dfrac{\arcsin x}{2} = \arctan\dfrac{x}{1+\sqrt{1-x^2}} = \arctan\dfrac{1-\sqrt{1-x^2}}{x}$;

(b) $\dfrac{\arccos x}{2} = \arctan\dfrac{1-x}{\sqrt{1-x^2}} = \arctan\dfrac{\sqrt{1-x^2}}{1+x} = \arctan\sqrt{\dfrac{1-x}{1+x}}$;

(c) $\dfrac{\arctan x}{2} = \arctan\dfrac{x}{1+\sqrt{1+x^2}} = \arctan\dfrac{\sqrt{1+x^2}-1}{x}$.

4.4. Use Figure 4.20 to derive the double angle formulas for the sine and cosine. (Hints: Compute the area of the shaded triangle in two ways, and express the length of the chord in two ways.)

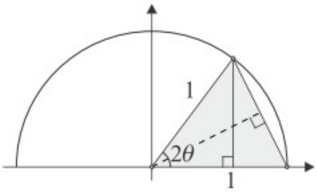

Figure 4.20.

4.5. Using the semicircle icon show that $\arctan x \le \arcsin x$ for x in [0,1].

4.6. Show that the area of the shaded region in Figure 4.21 depends only on a.

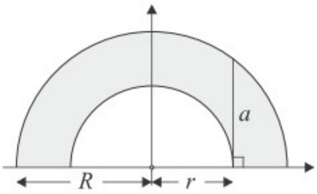

Figure 4.21.

4.7. If we draw semicircles on the legs of a right triangle inscribed in a semicircle, we create a *lune* on each leg, the region inside the small semicircle and outside the large one, as illustrated in light gray in Figure 4.22. Show that the combined area of the two lunes equals the area of the right triangle, a fact known to Hippocrates of Chios (circa 470–410 BCE).

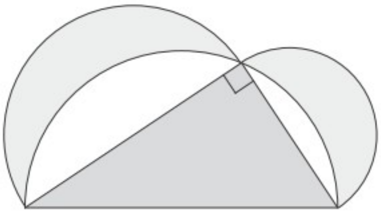

Figure 4.22.

4.8. In Figure 4.18, show that AF, BF, AE, and BN are, respectively, the edges of the tetrahedron, cube, octahedron, and dodecahedron inscribed in a sphere of diameter AB.

4.9. Another curve bounded by three semicircular arcs, like the arbelos, is the heart-shaped curve called the *cardioid of Boscovich* (Roger Boscovich, 1711–1787) illustrated in Figure 4.23. Show that any line through the cusp bisects its perimeter.

Sur les engrenages*).

§ 1. Dans les recherches théoriques sur le tracé des engrenages on suppose ordinairement donnée la forme du profil de la dent de l'une des roues et on en déduit celle du profil de la dent de l'autre. On peut trouver ainsi une infinité de différentes formes des engrenages, mais il n'y en a que très peu, qui sont employées dans la pratique. Pour que la pratique puisse, sans se borner à ces formes particulières, se servir de telle forme qui est la plus avantageuse dans le cas donné, il faut avoir une méthode générale pouvant donner un moyen facile pour tracer les profils des dents d'un couple des roues qui satisfont le mieux aux exigences de la pratique. Si l'on veut tracer les profils des dents mathématiquement exacts, on rencontre des obstacles insurmontables, mais la pratique n'exige pas cette rigueur; pour lui suffisent les procédés approximatifs, qui consistent en ce, qu'on donne aux faces et aux flancs des dents la forme des arcs de cercle convenablement choisis. Quand on n'a en vue que les profils des dents en arcs de cercle (ces profils peuvent en général remplacer tous les autres avec une approximation suffisante pour la pratique), la question de la détermination de la forme des dents le mieux satisfaisant aux exigences de la pratique devient considérablement simplifiée, parce qu'il ne s'agit alors que de déterminer les centres et les rayons des quelques cercles. En étudiant le mouvement des engrenages profilés en arcs de cercle, on voit qu'ils ne peuvent jamais donner lieu à l'invariabilité du rapport des vitesses angulaires, qui présente une condition nécessaire pour que le mouvement de l'engrenage soit regulier; par suite en déterminant le profil de ces engrenages il faut se proposer pour but de diminuer autant qu'il est possible les irrégularités du mouvement de l'engrenage, qui proviennent de la variabilité plus ou moins considérable du rapport des vitesses angulaires.

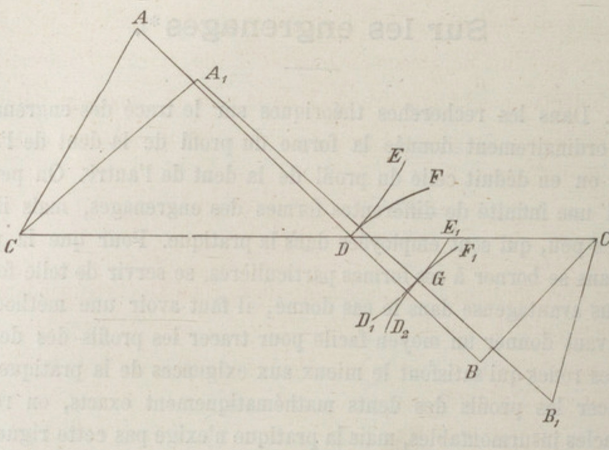
---

*) Ce mémoire a paru en français sous le titre: «Mémoire sur les engrenages par M. Tchebycheff. Traduction de MM. Dwelshauvers-Dery et Couharevitch.» dans la «Revue universelle des mines» 1875, pp. 523—546; la traduction de M. Mescherskiy se distingue de la précédente en ce qu'elle reproduit de plus près le texte original.

Tel est notre objet; nous allons montrer, comment on trouve, en satisfaisant aux exigences de la pratique, la forme des faces et des flancs des dents de l'engrenage profilé en arcs de cercle, pour laquelle les irrégularités du mouvement de l'engrenage sont les moindres possibles.

§ 2. Soient: C, C_1 (fig. 1) les centres des roues dentées (que nous appellerons en abrégé: la roue C et la roue C_1), et de leurs circonférences primitives; $R = CD$, $R_1 = C_1D$ les rayons de ces dernières; $\rho = AD$, $\rho_1 = BD$ les rayons des arcs de cercle DE et DF, dont le premier est le profil de la face de la dent de la roue C et le second celui du flanc de la dent de la roue C_1; A et B les positions respectives des centres de ces arcs au moment, où leur point de contact est sur la ligne des centres CC_1 au point D; A_1 et B_1 les positions de ces centres à un autre moment, lorsque les arcs sont en contact au point quelconque G. Les angles $ACA_1 = \lambda$ et $BC_1B_1 = \mu$ sont ceux, dont les roues C et C_1 tournent en même temps que le point de contact des dents se déplace de D en G. L'angle μ est une fonction de λ que nous désignerons par $F(\lambda)$; la dérivée de cette fonction $F'(\lambda)$ représentera alors le rapport des vitesses angulaires des roues C et C_1 correspondant aux différentes valeurs de $\lambda = ACA_1$.

Fig. 1.



Pour $\lambda = 0$ on a $\mu = 0$, donc la fonction $F(\lambda)$ devient nulle quand $\lambda = 0$; d'autre part il est facile de voir que pour cette valeur $\lambda = 0$ la dérivée $F'(\lambda)$ doit être égale à $\frac{R}{R_1}$. En effet, quand $\lambda = 0$, le point de contact des dents est sur la ligne des centres au point D; donc le rapport des vitesses angulaires des roues C et C_1 pour cette valeur de λ, comme il suit d'une propriété générale des engrenages, est égal à $\frac{CD}{C_1D}=\frac{R}{R_1}$; mais nous avons vu que ce rapport est égal à la dérivée $F'(\lambda)$, par conséquent $F'(\lambda)=\frac{R}{R_1}$ pour $\lambda=0$.

Avant d'examiner les irrégularités du mouvement des roues C et C_1, — inévitables, quand les dents sont profilées en arcs de cercle, — remarquons que dans le cas considéré, où les rayons des circonférences primitives sont R et R_1, le rapport des vitesses angulaires devrait être constant et égal à $\frac{R}{R_1}$, de manière qu'à un déplacement $\lambda=ACA_1$ de la roue C devrait correspondre un déplacement angulaire $\frac{R}{R_1}\lambda$ de la roue C_1, mais le déplacement réel de cette roue, comme nous avons posé plus haut, est égal à $\mu=F(\lambda)$; par suite la différence

$$F(\lambda)-\frac{R}{R_1}\lambda$$

représente l'erreur dans le déplacement de la roue C_1 correspondant au déplacement angulaire λ de la roue C_1.

Or, nous venons de voir que $F(\lambda)$ s'annule pour $\lambda=0$, donc pour cette valeur de λ la différence

$$F(\lambda)-\frac{R}{R_1}\lambda$$

devient nulle également. Pour les autres valeurs de λ cette différence n'est pas nulle en général, mais elle s'écarte plus ou moins de zéro pendant que λ croît de zéro jusqu'à sa limite l qu'elle atteint, lorsque les extrémités E et F des arcs DE et DF, profils des dents, sont en contact.

Donc pour diminuer autant que possible les irrégularités du mouvement de l'engrenage considéré il faut choisir les arcs de cercle DE et DF de manière que la différence

$$F(\lambda)-\frac{R}{R_1}\lambda$$

s'écarte le moins possible de zéro, tandis que λ varie entre les limites $\lambda=0$ et $\lambda=l$.

La détermination exacte des arcs de cercle DE et DF, qui rempliraient cette condition est excessivement difficile à cause de la complication de la forme de la fonction $F(\lambda)$; mais, si l'on se borne à une approximation des dents est sur la ligne des centres au point D; donc le rapport des vitesses angulaires des roues C et C_1 pour cette valeur de λ, comme il suit d'une propriété générale des engrenages, est égal à $\frac{CD}{C_1D} = \frac{R}{R_1}$; mais nous avons vu que ce rapport est égal à la dérivée $F'(\lambda)$, par conséquent $F'(\lambda) = \frac{R}{R_1}$ pour $\lambda = 0$.

Avant d'examiner les irrégularités du mouvement des roues C et C_1,— inévitables, quand les dents sont profilées en arcs de cercle, — remarquons que dans le cas considéré, où les rayons des circonférences primitives sont R et R_1, le rapport des vitesses angulaires devrait être constant et égal à $\frac{R}{R_1}$, de manière qu'à un déplacement $\lambda = ACA_1$ de la roue C devrait correspondre un déplacement angulaire $\frac{R}{R_1}\lambda$ de la roue C_1, mais le déplacement réel de cette roue, comme nous avons posé plus haut, est égal à $\mu = F(\lambda)$; par suite la différence

$$F(\lambda) - \frac{R}{R_1}\lambda$$

représente l'erreur dans le déplacement de la roue C_1 correspondant au déplacement angulaire λ de la roue C_1.

Or, nous venons de voir que $F(\lambda)$ s'annule pour $\lambda = 0$, donc pour cette valeur de λ la différence

$$F(\lambda) - \frac{R}{R_1}\lambda$$

devient nulle également. Pour les autres valeurs de λ cette différence n'est pas nulle en général, mais elle s'écarte plus ou moins de zéro pendant que λ croît de zéro jusqu'à sa limite l qu'elle atteint, lorsque les extrémités E et F des arcs DE et DF, profils des dents, sont en contact.

Donc pour diminuer autant que possible les irrégularités du mouvement de l'engrenage considéré il faut choisir les arcs de cercle DE et DF de manière que la différence

$$F(\lambda) - \frac{R}{R_1}\lambda$$

s'écarte le moins possible de zéro, tandis que λ varie entre les limites $\lambda = 0$ et $\lambda = l$.

La détermination exacte des arcs de cercle DE et DF, qui rempliraient cette condition est excessivement difficile à cause de la complication de la forme de la fonction $F(\lambda)$; mais, si l'on se borne à une approximation suffisante pour la pratique, on pourra bien se débarrasser des difficultés, provenant de la complication de la fonction $F(\lambda)$, en substituant à l'expression

$$F(\lambda)-\frac{R}{R_1}\lambda$$

son développement suivant les puissances ascendantes de λ; puisque entre les limites 0 et l l'angle λ est toujours fort petit, on n'a pas besoin de prendre un nombre considérable de termes de ce développement; pour la résolution des questions, qui se présentent dans la pratique, il suffit, comme on verra, s'arrêter à la troisième ou à la quatrième puissance de λ, de manière que l'expression de la différence

$$F(\lambda)-\frac{R}{R_1}\lambda$$

prendra la forme de l'un des deux polynomes suivants:

$$K_3\lambda^3+K_2\lambda^2+K_1\lambda+K_0,$$

ou

$$K_4\lambda^4+K_3\lambda^3+K_2\lambda^2+K_1\lambda+K_0.$$

§ 3. D'après ce qui précède, la détermination des arcs DE et DF, qui forment le profil de l'engrenage le plus régulier, se réduit à la recherche des coefficients des polynomes

$$K_3\lambda^3+K_2\lambda^2+K_1\lambda+K_0,$$
$$K_4\lambda^4+K_3\lambda^3+K_2\lambda^2+K_1\lambda+K_0,$$

pour qu'ils se rapprochent le plus possible de zéro entre des limites données de λ. Ces polynomes ressemblent à ceux qui se présentent, quand on cherche la meilleure forme du parallélogramme de Watt: ceux-là ne diffèrent de ceux-ci que par quelques particularités, résultant de ce que nous avons remarqué plus haut par rapport aux valeurs de la fonction $F(\lambda)$ et de sa dérivée $F'(\lambda)$ pour $\lambda=0$. La fonction $F(\lambda)$ s'annule pour $\lambda=0$, donc dans le développement de la différence

$$F(\lambda)-\frac{R}{R_1}\lambda$$

n'existe pas le terme, qui ne contient pas λ; la dérivée $F'(\lambda)$ pour $\lambda=0$ devient égale à $\frac{R}{R_1}$, par conséquent le coefficient de λ dans ce développement est égal à zéro. Il s'en suit que nos polynomes prennent l'une des deux formes:

$$K_3\lambda^3 + K_2\lambda^2,$$

$$K_4\lambda^4 + K_3\lambda^3 + K_2\lambda^2.$$

Dans ces derniers polynomes comme dans ceux qui se rapportent à la théorie du parallélogramme de Watt, le premier coefficient étant supposé connu, les autres doivent être choisis de manière que les valeurs des polynomes s'écartent le moins possible de zéro entre les limites $\lambda = 0$ et $\lambda = l$. D'après ce qui a été démontré dans notre mémoire intitulé: *Théorie des mécanismes connus sous le nom de parallélogrammes* *), la détermination de tels polynomes dans le cas général n'est possible qu'à l'aide des fonctions elliptiques, mais dans le cas des polynomes du troisième et du quatrième degré elle est très facile. En s'arrêtant aux millièmes dans les valeurs des coefficients, on trouve que les polynomes prennent les formes suivantes:

$$K_2(\lambda^3 - 0{,}894\,l\lambda^2),$$

$$K_4(\lambda^4 - 1{,}559\,l\lambda^3 + 0{,}578\,l^2\lambda^2)\ ^{**)}$$

Ces polynomes entre les limites $\lambda = 0$ et $\lambda = l$ s'écartent de zéro moins que tous les autres de la même espèce, cependant il n'est pas difficile de voir que leur écart de zéro devient le plus grand, lorsque λ atteint sa valeur limite l, par conséquent dans les engrenages, où les variations du rapport des vitesses angulaires s'expriment par les polynomes ci-dessus, la poussée est la plus defectueuse au moment, où une dent échappe et où la suivante va se remettre en prise à la ligne des centres. Cette circonstance est très desavantageuse dans la pratique, qui exige, qu'à la fin comme au commencement de la prise le rapport des vitesses soit le même; c'est pourquoi il faut remplacer les polynomes, trouvés plus haut, par les autres, qui,

---

*) T. I, pag. 111—143.

**) Les expressions exactes de ces polynomes sont:

$$K_3(\lambda^3 - al\lambda^2),$$

$$K_4\left(\lambda^4 - \frac{4pl}{q}\lambda^3 + \frac{(13p^2-4)\,l^2}{2q^2}\lambda^2\right),$$

où a est déterminée par l'équation: $a^3 + \frac{27}{4}(a-1) = 0$,

$$p = \sqrt{\frac{20 + 24\sqrt{3}}{83}},$$

$$q = \frac{p}{2} + \sqrt{1-p^2} + \sqrt{p^2 + 2p\sqrt{1-p^2}}.$$

s'écartant le moins de zéro entre les limites $\lambda = 0$ et $\lambda = l$, s'annuleraient non seulement pour $\lambda = 0$, mais aussi pour $\lambda = l$. D'après le § 9 du mémoire précité on trouvera les polynomes cherchés, si l'on remplace l par $\frac{l}{0,894}$ dans l'expression écrite plus haut du polynome du troisième degré et par $\frac{l}{0,952}$ dans celle du polynome du quatrième degré. On obtient ainsi

$$K_3(\lambda^3 - l\lambda^2),$$
$$K_4(\lambda^4 - 1,638 l\lambda^3 + 0,638 l^2\lambda^2),$$

polynomes, qui serviront à déterminer les profils des dents remplissant la condition que le rapport des vitesses angulaires aie la même valeur normale à la fin ainsi qu'au commencement de la prise et qui pendant la durée de la prise s'écarte les moins possible de cette valeur.

4. Nous commencerons par le cas, où dans le choix des profils des dents, les exigences de la pratique étant satisfaites, il ne reste qu'une quantité disponible, qu'on peut déterminer de manière, que les irrégularités du mouvement de l'engrenage soient les moindres possibles. Dans ce cas, en nous arrêtant à la troisième puissance dans le développement de la différence

$$F(\lambda) - \frac{R}{R_1}\lambda$$

nous devons poser

$$F(\lambda) - \frac{R}{R_1}\lambda = K_3(\lambda^3 - l\lambda^2). \tag{1}$$

Or, en vertu de la nature de la fonction $F(\lambda)$, le premier membre de l'équation (1) peut être réduit toujours à la forme suivante exacte jusqu'à λ^3

$$K_3\lambda^3 + K_2\lambda^2,$$

comme nous l'avons vu au § 3; donc l'équation (1) nous donne une relation entre les coefficients K_2 et K_3 et, par conséquent, aussi entre les quantités, qui déterminent le profil cherché.

Pour obtenir cette relation nous pourrions trouver l'expression de la fonction $F(\lambda)$ et puis comparer les coefficients de λ^2 et de λ^3 dans les deux membres de l'équation (1), mais on peut procéder plus simplement, en remarquant, que l'équation (1) différenciée donne

$$F'(\lambda) - \frac{R}{R_1} = K_3(3\lambda^2 - 2l\lambda)$$

ce qui suppose avec une approximation jusqu'à λ^2, que la différence

$$F'(\lambda) - \frac{R}{R_1}$$

devient nulle pour $\lambda = 0$ et $\lambda = \frac{2}{3} l$.

La première valeur $\lambda = 0$, annule toujours la différence

$$F'(\lambda) - \frac{R}{R_1},$$

comme nous l'avons vu au § 2; l'annulation de cette différence pour $\lambda = \frac{2}{3} l$ nous servira à trouver la relation entre les quantités, lesquelles contient la fonction $F(\lambda)$.

Dans ce but rappelons que, d'après le § 2, la dérivée $F'(\lambda)$ représente le rapport réel des vitesses angulaires des roues considérées et la fraction $\frac{R}{R_1}$ — la valeur normale de ce rapport; si donc la différence

$$F'(\lambda) - \frac{R}{R_1}$$

s'annule pour $\lambda = \frac{2}{3} l$, c'est qu'à ce moment le rapport des vitesses angulaires a sa valeur normale et par conséquent la normale commune aux deux profils en prise passe par le point de contact D des circonférences primitives sur la ligne des centres CC_1. Or, il est facile de trouver l'inclinaison de la normale commune sur la ligne des centres dans la position, où $\lambda = \frac{2}{3} l$, ce qui servira à établir la relation entre les quantités qui déterminent le profil cherché.

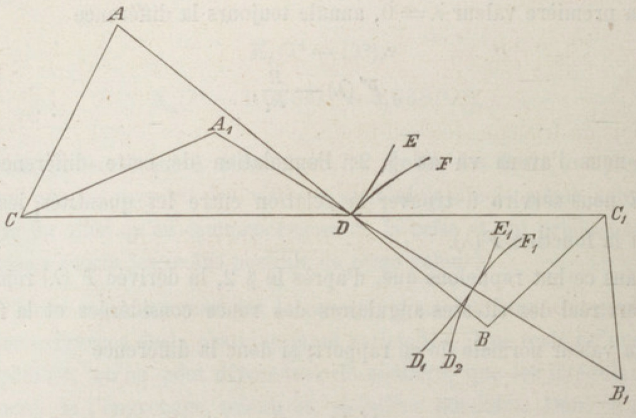
§ 5. Conservant les mêmes notations que dans la figure 1, nous aurons (fig. 2): $CD = R$, $C_1D = R_1$ les rayons des circonférences primitives, $AD = \rho$, $BD = \rho_1$, les rayons des arcs de cercle DE et DF; A et B les positions des centres des arcs DE et DF au moment, où leur point de contact est sur la ligne des centres CC_1 au point D; A_1 et B_1 les positions respectives de ces centres après une rotation de l'angle $\lambda = ACA_1 = \frac{2}{3} l$ de la roue C, quand la normale commune A_1B_1 aux profils D_1E_1 et D_2F_1, comme il est dit au paragraphe précédent, passera par la point de contact primitif D; soient: $r = AC = A_1C$ et les angles

$$L = ACD, \quad N = ADC, \quad v = ADA_1.$$

Le triangle A_1DC donne la relation

$$\operatorname{tang}(ADC - ADA_1) = \frac{A_1C \, . \, \sin A_1CD}{CD - A_1C \, . \, \cos A_1CD};$$

Fig. 2.



en employant les notations adoptées on a donc

$$\operatorname{tang}(N - v) = \frac{r \sin\left(L - \frac{2}{3}l\right)}{R - r\cos\left(L - \frac{2}{3}l\right)}$$

ou

$$\frac{\operatorname{tang} N - \operatorname{tang} v}{1 + \operatorname{tang} N . \operatorname{tang} v} = \frac{r \sin\left(L - \frac{2}{3}l\right)}{R - r\cos\left(L - \frac{2}{3}l\right)}$$

En résolvant cette équation par rapport à tang v, on trouve

$$\operatorname{tang} v = \frac{\left[R - r\cos\left(L - \frac{2}{3}l\right)\right] \operatorname{tang} N - r \sin\left(L - \frac{2}{3}l\right)}{R - r\cos\left(L - \frac{2}{3}l\right) + r \sin\left(L - \frac{2}{3}l\right) \operatorname{tang} N},$$

ou

$$(2) \qquad \operatorname{tang} v = \frac{R \sin N - r \sin\left(L + N - \frac{2}{3}l\right)}{R \cos N - r \cos\left(L + N - \frac{2}{3}l\right)}.$$

Développant ici

$$\sin\left(N + L - \frac{2}{3}l\right), \ \cos\left(N + L - \frac{2}{3}l\right)$$

suivant les puissances ascendantes de l, on exprime par les séries suivantes: le numérateur

$$R \sin N - r \sin(L+N) + \frac{2}{3} r \cos(L+N) . l + \frac{2}{9} r \sin(L+N) . l^2 + \ldots ,$$

et le dénominateur

$$R \cos N - r \cos(L+N) - \frac{2}{3} r \sin(L+N) . l + \frac{2}{9} r \cos(L+N) . l^2 + \ldots .$$

Mais du triangle ACD on tire

$$CD . \sin ADC = AC . \sin CAD.$$

$$CD . \cos ADC + AC . \cos CAD = AD,$$

d'où, en remplaçant l'angle CAD par

$$\pi - (ADC + ACD),$$

avec les notations adoptées on reçoit

$$R \sin N = r \sin(L+N),$$

$$R \cos N - r \cos(L+N) = \rho,$$

ce qui réduit les expressions trouvées du numérateur et du dénominateur dans la formule (2) aux formes suivantes plus simples:

$$\frac{2}{3}(R \cos N - \rho)\, l + \frac{2}{9} R \sin N . l^2 + \ldots .$$

$$\rho - \frac{2}{3} R \sin N . l + \frac{2}{9}(R \cos N - \rho) l^2 + \ldots .$$

En divisant la première de ces séries par la seconde on trouve

$$\frac{2}{3}\left(\frac{R}{\rho} \cos N - 1\right) l + \frac{4}{9} \frac{R}{\rho}\left(\frac{R}{\rho} \cos N - \frac{1}{2}\right) \sin N . l^2 + \ldots ,$$

et par suite, d'après l'équation (2), la valeur de tang v exacte jusqu'à la deuxième puissance inclusivement sera

$$\operatorname{tang} v = \frac{2}{3}\left(\frac{R}{\rho} \cos N - 1\right) l + \frac{4}{9} \frac{R}{\rho}\left(\frac{R}{\rho} \cos N - \frac{1}{2}\right) \sin N . l^2 .$$

Mais l'approximation admise permet de remplacer la tangente par son arc, ce qui donne

$$(3)\qquad v=\frac{2}{3}\left(\frac{R}{\rho}\cos N-1\right)l+\frac{4}{9}\,\frac{R}{\rho}\left(\frac{R}{\rho}\cos N-\frac{1}{2}\right)\sin N.l^2.$$

Telle doit être la variation de l'inclinaison de la normale commune aux profils en prise après une rotation de l'angle $ACA_1=\frac{2}{3}l$ de la roue C, pour que cette normale passe par le point de contact des circonférences primitives lorsque $ACA_1=\frac{2}{3}l$, ce qui doit avoir lieu pour l'engrenage considéré.

Cela posé, il est facile de trouver une relation entre les quantités

$$\rho,\ \rho_1,\ N,$$

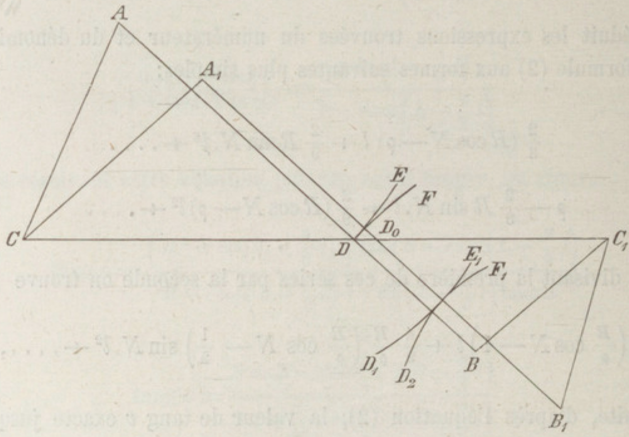
qui déterminent les arcs DE et DF; à cet effet il faut connaître la valeur de v pour des valeurs quelconques de

$$\rho,\ \rho_1,\ N.$$

C'est ce que nous allons chercher.

§ 6. Soient (fig. 3) A et B les positions des centres des arcs consi-

Fig. 3.



dérés, quand leur point de contact est sur la ligne des centres;

$$ACD=L,\ ADC=N,\ CD=R,\ C_1D=R_1,$$

A_1 et B_1 les positions des centres des arcs après que la roue C a tourné de l'angle quelconque $ACA_1 = \lambda$,

$$A_1CD = L - \lambda, \quad A_1D_0C = N - v;$$

soient aussi $BC_1D = M$ et μ l'accroissement de cet angle correspondant à l'angle de la rotation $ACA_1 = \lambda$ de la roue C; alors

$$B_1C_1D = M + \mu.$$

Pour obtenir l'équation qui détermine la valeur de v pour une valeur quelconque de λ, projetons le polygone $CA_1B_1C_1$ sur la direction de la ligne des centres et sur une perpendiculaire à cette direction; nous aurons

$$A_1C.\cos A_1CD + A_1B_1 \cos A_1D_0C + B_1C_1 \cos B_1C_1D = CC_1$$
$$A_1C \sin A_1CD - A_1B_1 \sin A_1D_0C + B_1C_1 \sin B_1C_1D = 0,$$

d'où, en remarquant que

$$A_1C = r, \quad B_1C_1 = r_1, \quad A_1B_1 = \rho + \rho_1, \quad CC_1 = R + R_1$$
$$A_1CD = L - \lambda, \quad A_1D_0C = N - v, \quad DC_1B_1 = M + \mu,$$

on trouve

$$r\cos(L-\lambda) + (\rho+\rho_1)\cos(N-v) + r_1\cos(M+\mu) = R + R_1,$$
$$r\sin(L-\lambda) - (\rho+\rho_1)\sin(N-v) + r_1\sin(M+\mu) = 0.$$

Éliminant $(M + \mu)$ entre ces équations, on a:

$$r_1^2 = [R + R_1 - r\cos(L-\lambda) - (\rho+\rho_1)\cos(N-v)]^2$$
$$+ [-r\sin(L-\lambda) + (\rho+\rho_1)\sin(N-v)]^2,$$

ou en supprimant les parenthèses

$$r_1^2 = (R+R_1)^2 + (\rho+\rho_1)^2 + r^2 + 2r(\rho+\rho_1)\cos(L+N-\lambda-v)$$
$$-2(R+R_1)\left[r\cos(L-\lambda) + (\rho+\rho_1)\cos(N-v)\right].$$

Pour les valeurs particulières $\lambda = 0$, $v = 0$, cette égalité devient:

$$r_1^2 = (R + R_1)^2 + (\rho + \rho_1)^2 + r^2 + 2r(\rho + \rho_1)\cos(L + N)$$
$$- 2(R + R_1)\left[r \cos L + (\rho + \rho_1)\cos N\right].$$

Soustrayant cette équation de la précédente, on obtient

$$\frac{\cos(L + N - \lambda - v) - \cos(L + N)}{R + R_1} - \frac{\cos(N - v) - \cos N}{r} - \frac{\cos(L - \lambda) - \cos L}{\rho + \rho_1} = 0.$$

Pour en déduire la valeur de l'angle v développée suivant les puissances ascendantes de l'angle λ posons

$$v = K_1\lambda + K_2\lambda^2 + \ldots.$$

et déterminons les coefficients K_1, K_2, ...

En portant cette expression de v dans l'équation précédente et développant suivant les puissances de λ, nous aurons

$$\left.\begin{array}{l} \left\{\dfrac{\sin(L + N)}{R + R_1}(K_1 + 1) - \dfrac{\sin N}{r}K_1 - \dfrac{\sin L}{\rho + \rho_1}\right\}\lambda \\ + \left\{\begin{array}{c} \dfrac{2\sin(L + N)K_2 - \cos(L + N)(K_1 + 1)^2}{R + R_1} \\ - \dfrac{2\sin N.K_2 - \cos N.K_1^2}{r} + \dfrac{\cos L}{\rho + \rho_1} \end{array}\right\}\dfrac{\lambda^2}{2} + \ldots \end{array}\right\} = 0,$$

d'où pour la détermination des coefficients K_1, K_2 on tire les équations suivantes:

$$\frac{\sin(L + N)}{R + R_1}(K_1 + 1) - \frac{\sin N}{r}K_1 - \frac{\sin L}{\rho + \rho_1} = 0,$$

$$\frac{2\sin(L + N)K_2 - \cos(L + N)(K_1 + 1)^2}{R + R_1} - \frac{2\sin N.K_2 - \cos N.K_1^2}{r} + \frac{\cos L}{\rho + \rho_1} = 0,$$

. . . .

qui donnent

$$K_1 = \frac{\dfrac{\sin L}{\rho + \rho_1} - \dfrac{\sin(L + N)}{R + R_1}}{\dfrac{\sin(L + N)}{R + R_1} - \dfrac{\sin N}{r}};$$

$$K_2 = \frac{\dfrac{\cos(L + N)}{R + R_1}(K_1 + 1)^2 - \dfrac{\cos N}{r}K_1^2 - \dfrac{\cos L}{\rho + \rho_1}}{2\left(\dfrac{\sin(L + N)}{R + R_1} - \dfrac{\sin N}{r}\right)}.$$

Afin de chasser de ces expressions les angles

$$L = ACD \text{ et } L + N = ADC + ACD$$

remarquons, que le triangle ACD donne

$$\sin ACD = \frac{AD}{AC} \sin ADC,$$

$$\sin (ADC + ACD) = \sin CAD = \frac{CD}{AC} \sin ADC;$$

$$\cos ACD = \frac{CD - AD . \cos ADC}{AC},$$

$$\cos (ADC + ACD) = - \cos CAD = - \frac{AD - CD . \cos ADC}{AC},$$

ou, d'après la notation adoptée,

$$\sin L = \frac{\rho}{r} \sin N; \ \sin (L + N) = \frac{R}{r} \sin N;$$

$$\cos L = \frac{R - \rho \cos N}{r}; \ \cos (L + N) = - \frac{\rho - R \cos N}{r}.$$

En portant ces valeurs de

$$\sin L, \ \sin (L + N), \ \cos L, \ \cos (L + N)$$

dans les expressions précédentes des coefficients K_1, K_2, on trouve, toutes les réductions faites,

$$K_1 = \frac{R \rho_1 - R_1 \rho}{R_1 (\rho + \rho_1)};$$

$$K_2 = \frac{(\rho - R \cos N)(K_1 + 1)^2 + (R + R_1) \left[\cos N . K_1{}^2 + \frac{R - \rho \cos N}{\rho + \rho_1} \right]}{2 R_1 \sin N}.$$

Telles sont les valeurs des coefficients K_1 et K_2 de la série

$$v = K_1 \lambda + K_2 \lambda^2 + \ldots, \tag{4}$$

qui donne la valeur de l'angle v correspondant à une valeur quelconque de l'angle λ pour toutes les valeurs de

$$\rho, \ \rho_1, \ N.$$

§ 7. En posant dans la formule trouvée

$$\lambda = \frac{2}{3} l,$$

nous aurons la valeur correspondante de l'angle v

$$v = \frac{2}{3} K_1 l + \frac{4}{9} K_2 l^2 + \ldots .$$

Or dans le cas de l'engrenage considéré d'après la formule (3) (§ 5) cette valeur particulière de v est

$$\frac{2}{3}\left(\frac{R}{\rho}\cos N - 1\right) l + \frac{4}{9}\,\frac{R}{\rho}\left(\frac{R}{\rho}\cos N - \frac{1}{2}\right)\sin N \,.\, l^2.$$

Comparant ces deux valeurs du même angle on obtient une équation, qui, étant divisée par $\frac{2}{3} l$, prend la forme

$$(5)\qquad K_1 - \frac{R}{\rho}\cos N + 1 + \frac{2}{3}\left[K_2 - \frac{R}{\rho}\left(\frac{R}{\rho}\cos N - \frac{1}{2}\right)\sin N\right] l = 0,$$

où K_1 et K_2 ont les valeurs indiquées au § 6.

La valeur de K_1, comme nous avons vu, est très simple:

$$(6)\qquad K_1 = \frac{R\rho_1 - R_1\rho}{R_1(\rho + \rho_1)}.$$

Quant à l'expression de la valeur de K_2 elle peut être considérablement simplifiée en vertu de l'approximation, à laquelle on se borne.

Remarquons que dans le calcul de cette valeur on peut négliger même les premières puissances de l, puisque cette quantité n'entre comme facteur que dans le dernier des termes retenus. En outre, d'après l'équation (5), si l'on néglige le second terme, on a

$$(7)\qquad K_1 - \frac{R}{\rho}\cos N + 1 = 0,$$

équation, à l'aide de laquelle on simplifie facilement l'expression de la valeur K_2.

En effet le numérateur de cette expression, K_1 étant remplacé par la différence

$$\frac{R}{\rho}\cos N - 1,$$

devient

$$(\rho + R_1 \cos N)\frac{R^2}{\rho^2}\cos^2 N - 2\,(R + R_1)\frac{R}{\rho}\cos^2 N + \frac{R + R_1}{\rho + \rho_1}(R + \rho_1 \cos N).$$

Mais la formule (7), d'après (6), donne

$$\frac{R\rho_1 - R_1\rho}{R_1(\rho + \rho_1)} - \frac{R}{\rho}\cos N + 1 = 0,$$

formule, qui se réduit à

$$\frac{R + R_1}{\rho + \rho_1} = \frac{RR_1}{\rho\rho_1}\cos N. \tag{8}$$

En remplaçant le facteur

$$\frac{R + R_1}{\rho + \rho_1}$$

dans le dernier terme de l'expression précédente par

$$\frac{RR_1}{\rho\rho_1}\cos N,$$

on la réduit à la suivante:

$$\left[\frac{R^2R_1}{\rho^2}\cos^2 N - \frac{(R + R_1)R}{\rho}\cos N + \frac{R^2R_1}{\rho\rho_1}\right]\cos N,$$

qui après la substitution

$$\frac{RR_1(\rho + \rho_1)}{\rho\rho_1}\cos N$$

au lieu de

$$R + R_1$$

devient

$$\frac{R^2R_1}{\rho\rho_1}(1 - \cos^2 N)\cos N$$

ou

$$\frac{R^2R_1}{\rho\rho_1}\sin^2 N . \cos N.$$

Remplaçons ici

$$\frac{\cos N}{\rho\rho_1}$$

d'après la formule (8) par

$$\frac{R + R_1}{\rho + \rho_1}\,\frac{1}{RR_1}.$$

et nous aurons

$$\frac{R(R + R_1)}{\rho + \rho_1}\sin^2 N,$$

expression réduite du numérateur de K_2, donné à la fin du § 6.

Par suite on obtient pour la détermination du coefficient K_2 la formule suivante très simple:

$$K_2 = \frac{R}{2R_1} \frac{R+R_1}{\rho+\rho_1} \sin N. \tag{9}$$

Portant les valeurs trouvées de K_1 et K_2 dans l'équation (5) et remplaçant dans son dernier terme, d'après (8),

$$\frac{R.\cos N}{\rho}$$

par

$$\frac{R+R_1}{R_1} \frac{\rho_1}{\rho+\rho_1},$$

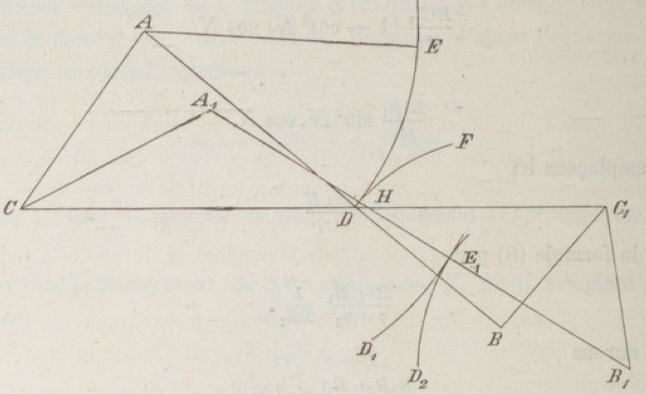
on obtient, la réduction faite,

$$\cos N - \frac{R+R_1}{RR_1} \frac{\rho\rho_1}{\rho+\rho_1} + \frac{1}{3R_1} \frac{(R_1+2R)\,\rho_1 - (R+2R_1)\,\rho}{\rho+\rho_1} \sin N.l = 0. \tag{10}$$

§ 8. Cette équation exprime une propriété géometrique très-simple des arcs de cercle qui forment les profils de la face et du flanc de la dent de l'engrenage considéré. Mais avant de la faire ressortir cherchons la formule qui sert à déterminer les longueurs de ces arcs.

Conservant les notations précédentes des arcs DE, DF et de leurs centres A et B au moment, où le point de contact des dents est sur la ligne des centres, soient (fig. 4) D_1E_1, D_2E_1, A_1, B_1, les positions extrêmes des

Fig. 4.



arcs et de leurs centres au moment, où les dents vont se quitter, ce qui correspond, comme on l'a vu, à la rotation de l'angle $ACA_1 = l$ de la roue C.

Traçons la droite AE; l'angle CAE est égal à CA_1E_1, parceque A et A_1 de même que E et E_1 représentent les mêmes points de la roue C dans ses deux positions; donc l'angle DAE qui est égal à $CAE - CAD$ sera égal aussi à $CA_1H - CAD$; or

$$\begin{aligned} CA_1H &= \pi - A_1CH - A_1HC, \\ CAD &= \pi - ACD - ADC, \end{aligned}$$

donc

$$DAE = ACD - A_1CH + ADC - A_1HC.$$

D'après nos notations:

$$ACD - A_1CH = ACA_1 = l,$$

$$ADC - A_1HC = N - (N - v) = v,$$

où la valeur de v s'obtient de la formule (4) pour $\lambda = l$; il s'ensuit, que si nous appellons ω l'angle DAE, qui détermine la longueur de l'arc DE, profil de la face de la dent de l'engrenage considéré, on a pour la valeur de cet angle

$$\omega = l + v = (K_1 + 1)\, l + K_2 l^2,$$

ce qui, après la substitution des valeurs de K_1 et K_2 trouvées au § 7, se réduit à la forme suivante:

$$\omega = \frac{R + R_1}{R_1} \frac{\rho_1}{\rho + \rho_1}\, l + \frac{R}{2R_1} \frac{R + R_1}{\rho + \rho_1} \sin N . l^2. \tag{11}$$

A l'aide de cette expression de l'angle $\omega = DAE$ il est facile à faire voir, que l'équation (10) représente une simple propriété géométrique de l'arc DE, à savoir:

«Au moment où le point de contact des deux dents est sur la ligne des centres, le point extrême E de l'arc DE (fig. 5) se trouve sur la circonférence, qui passe par le point D de contact primitif et par les extrémités P et P_1 des deux arcs DP et DP_1 des circonférences primitives, qui correspondent à l'angle de rotation de la roue C pendant la durée de la prise des arcs DE et DF».

Pour le démontrer traçons la circonférence, passant par les points D, P et P_1, et la corde DE; soit E_1 le point de leur intersection; cherchons la longueur DE_1.

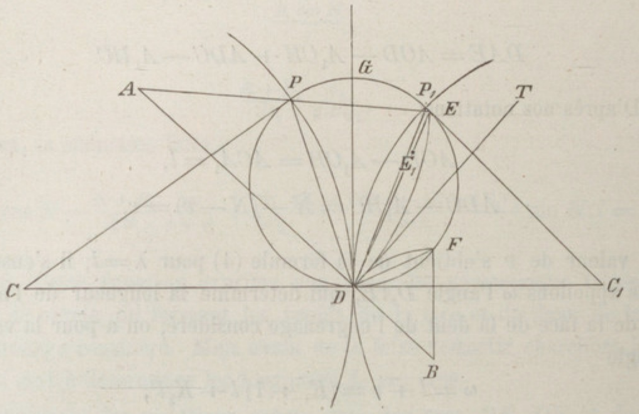
D'après nos notations

$$ADC = N; \quad DAE = \omega, \quad DCP = l, \quad CD = R, \quad C_1D = R_1,$$

et l'angle DC_1P_1 est celui dont a tourné la roue C_1 pendant toute la durée de la prise des arcs DE et DF, de sorte que

$$DC_1P_1 = \frac{R}{R_1}\,DCP = \frac{R}{R_1}\,l.$$

Fig. 5.



Menons par le point D la droite DG perpendiculaire à CC_1 et DT perpendiculaire à AD; ces droites étant tangentes aux arcs DP, DP_1 et DE respectivement font avec les cordes de ces arcs les angles

$$PDG = \tfrac{1}{2}\,DCP,\ P_1DG = \tfrac{1}{2}\,DC_1P_1,\ EDT = \tfrac{1}{2}\,DAE,$$

ou d'après les notations adoptées

$$PDG = \frac{l}{2};\ P_1DG = \frac{Rl}{2R_1};\ EDT = \frac{\omega}{2}.$$

Quant à l'angle GDT, ses côtés étant perpendiculaires à ceux de l'angle ADC, on a $GDT = ADC$ et par suite $GDT = N$.

On en déduit:

$$PDP_1 = PDG + P_1DG = \frac{l}{2} + \frac{R}{2R_1}\,l,$$

$$P_1DE_1 = GDT - GDP_1 - EDT = N - \frac{R}{2R_1}\,l - \frac{\omega}{2},$$

$$PDE_1 = GDT + PDG - EDT = N + \frac{l}{2} - \frac{\omega}{2}.$$

D'autre part ayant

$$DCP = l,\ DC_1P_1 = \frac{R}{R_1}\, l$$
$$DC = R,\ DC_1 = R_1,$$

on trouve les longueurs des cordes DP et DP_1:

$$DP = 2\,.\,CD\,.\sin\frac{PCD}{2} = 2R\sin\frac{l}{2},$$
$$DP_1 = 2C_1D\,.\sin\frac{DC_1P_1}{2} = 2R_1\sin\frac{Rl}{2R_1}.$$

Connaissant les longueurs de ces cordes ainsi que les angles qu'elles forment avec la corde DE_1, on trouve facilement la longueur de cette dernière à l'aide de l'équation:

$$DP\,.\sin(P_1DE_1) - DP_1\sin(PDE_1) + DE_1\sin(PDP_1) = 0,$$

qui a lieu pour trois cordes quelconques passant par un même point de la circonférence.

En y portant les valeurs trouvées des longueurs de DP et DP_1 et des angles P_1DE_1, PDE_1, PDP_1, on obtient pour la détermination de la longueur de DE_1 l'équation suivante:

$$(12)\quad 2R\sin\frac{l}{2}\sin\left(N - \frac{Rl}{2R_1} - \frac{\omega}{2}\right) - 2R_1\sin\frac{Rl}{2R_1}\sin\left(N + \frac{l}{2} - \frac{\omega}{2}\right) + DE_1\sin\left(\frac{l}{2} + \frac{Rl}{2R_1}\right) = 0.$$

Pour en déduire la longueur de DE_1 avec une approximation du deuxième ordre, développons les deux premiers termes jusqu'au troisième ordre et le facteur de DE_1 jusqu'au deuxième; nous aurons:

$$\frac{R+R_1}{2R_1}DE_1\,.\,l - \frac{(R+R_1)R}{2R_1}\cos N\,.\,l^2 + \left[\frac{R_1{}^2 - R^2}{12R_1{}^2}Rl - \frac{(R+R_1)R}{4R_1}\,\omega\right]\sin N\,.\,l^2 = 0,$$

d'où

$$DE_1 = R\cos N\,.\,l + R\left\{\frac{\omega}{2} + \frac{R-R_1}{6R_1}\,l\right\}\sin N\,.\,l,$$

Remplaçant ω par sa valeur (11) on trouve

$$DE_1 = R\cos N\,.\,l + R\,\frac{(4R+2R_1)\,\rho_1 + (R-R_1)\,\rho}{6R_1(\rho+\rho_1)}\sin N\,.\,l^2.$$

expression exacte jusqu'à la deuxième puissance de l inclusivement de la longueur de DE_1, qui détermine la position du point E_1, où la circonférence passant par les trois points D, P, P_1 est coupée par la corde DE.

En déterminant d'après les formules trouvées plus haut la longueur de la corde DE, on voit qu'avec une approximation du deuxième ordre on peut remplacer cette corde par l'arc DE et par suite exprimer sa longueur par le produit

$$\rho \, . \, \omega.$$

A l'aide de la formule (11) on trouve

$$DE = \frac{R+R_1}{R_1} \frac{\rho\rho_1}{\rho+\rho_1} l + \frac{R\rho}{2R_1} \frac{R+R_1}{\rho+\rho_1} \sin N . l^2.$$

Nous aurons donc pour la différence des longueurs des cordes DE et DE_1 l'expression suivante exacte jusqu'à la deuxième puissance de l:

$$DE - DE_1 =$$

$$\left(\frac{R+R_1}{R_1} \frac{\rho\rho_1}{\rho+\rho_1} - R \cos N\right) l - \frac{R}{3R_1} \frac{(2R+R_1)\rho_1 - (2R_1+R)\rho}{\rho+\rho_1} \sin N . l^2.$$

Comparant cette expression avec le premier membre de l'équation (10) on voit, qu'elle ne diffère de celui-ci que par un facteur $-lR$; par suite en vertu de l'équation (10) on a

$$DE - DE_1 = 0,$$

donc le point E_1 coïncide avec le point E, qui est par conséquent sur la circonférence considérée, ce qu'il fallait démontrer.

§ 9. Répétant relativement à l'arc DF, profil du flanc de la dent de la roue C_1, tout ce qui vient d'être dit relativement à l'arc DE, profil de la face de la dent de la roue C, on arrive aux formules, qui se déduisent des formules précédentes en remplaçant des lettres relatives à la roue C par celles relatives à la roue C_1 et réciproquement.

Quant à la quantité l, qui représente l'angle de la rotation de la roue C pendant la prise des arcs DE et DF, il faut la remplacer par

$$-\frac{R}{R_1} l,$$

parce que la roue C_1 en même temps tourne de l'angle $\frac{R}{R_1} l$ dans le sens opposé.

Au lieu de l'angle $\omega = DAE$, qui mesure l'inclinaison réciproque des rayons AD et AE passant par les extrémités de l'arc DE, nous aurons

$$\omega_1 = DBF$$

avec le signe — à cause de la position inverse des rayons BD et BF, passant par les extrémités de l'arc DF.

L'équation (11) deviendra par ces changements

$$\omega_1 = \frac{R+R_1}{R} \frac{\rho}{\rho+\rho_1} l - \frac{R}{2R_1} \frac{R+R_1}{\rho+\rho_1} \sin N . l^2; \tag{13}$$

l'équation (10) reste la même, quand on passe de l'arc DE à l'arc DF; ces deux équations nous conduisent au même résultat relativement à l'arc DF, que nous avons obtenu dans le paragraphe précédent relativement à l'arc DE, c'est à dire, l'extrémité F est située sur la circonférence passant par les points D, P et P_1.

On arrive ainsi à la conclusion suivante, concernant l'engrenage conconsidéré:

«Au moment, où le point de contact des dents est sur la ligne des centres, les cinq points suivants sont sur une même circonférence: les extrémités des profils de la face de l'une et de la partie vive du flanc de l'autre des deux dents qui sont en contact sur la ligne des centres, les points des circonférences primitives qui viennent à la ligne des centres à la fin de la prise de ces dents, et le point de contact des circonférences primitives».

Cette propriété n'est exacte que jusqu'à la troisième puissance de l, puisque en déterminant les positions des différents points nous avons négligé dans nos formules les puissances de l supérieures à la seconde. Mais cette approximation est suffisante dans la pratique en vertu de la petitesse de la quantité l, qui représente l'angle de la rotation de la roue pendant la prise d'un couple des dents de l'un ou de l'autre côté de la ligne des centres.

En se basant sur les formules (11) et (13), on peut trouver une autre propriété de l'engrenage considéré. Ces formules étant ajoutées donnent

$$\omega + \omega_1 = \frac{R+R_1}{R_1} l,$$

mais d'après nos notations

$$\omega = DAE, \quad \omega_1 = DBF, \quad l = DCP,$$

et comme nous avons remarqué plus haut

$$\frac{Rl}{R_1} = DC_1P_1;$$

donc l'équation trouvée se réduit à la suivante:

$$DAE + DBF = DCP + DC_1P_1.$$

Considérant les angles que forment les cordes des arcs DP, DP_1, DE et DF avec leurs tangentes DG et DT, on voit que

$$PDG = \frac{1}{2}\, DCP,\ \ P_1DG = \frac{1}{2}\, DC_1P_1,$$

$$EDT = \frac{1}{2}\, DAE,\ \ FDT = \frac{1}{2}\, DBF,$$

par suite l'égalité précédente donne

$$EDT + FDT = PDG + P_1DG,$$

d'où

$$EDF = PDP_1,$$

c'est-à-dire que les cordes des arcs DE et DF font entre elles le même angle que les cordes des arcs de retraite DP et DP_1; les points P, P_1, F, E étant situés sur la même circonférence passant par le point D, il en résulte, que les droites PP_1 et EF sont égales entre elles.

On peut énoncer cette propriété de l'engrenage considéré comme il suit:

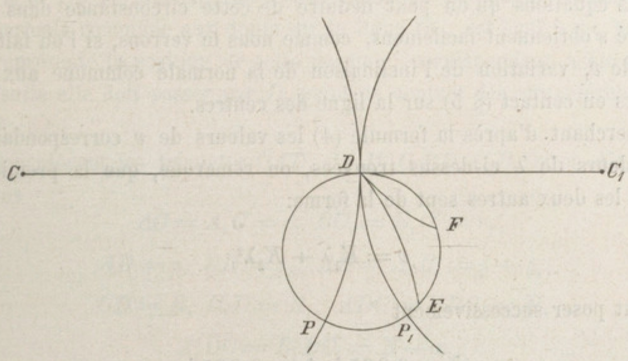
«La distance entre les extrémités des profils de la face de l'une et de la partie vive du flanc de l'autre des deux dents, dont le point de contact est sur la ligne des centres, est égale à la distance des points des circonférences primitives, qui viennent à la ligne des centres à la fin de la prise de ces dents».

Puisque dans le tracé des engrenages, on donne les circonférences primitives et les arcs de retraite et d'approche, on pourra toujours, d'après ce que nous avons montré plus haut, tracer la circonférence, où doivent être situées les extrémités des profils de la face et de la partie vive du flanc des deux dents et on connaîtra la distance de ces extrémités au moment, où les dents sont en contact sur la ligne des centres.

Soient (fig. 6) C et C_1 les centres des circonférence primitives, D le point de leur contact. Ayant en vue de déterminer le tracé des profils des dents des roues C et C_1 portons les longueurs DP et DP_1 des arcs d'approche sur les circonférences primitives; puis traçons la circonférence passant par les points D, P, P_1, sur laquelle doivent se trouver les extrémités E et F des profils de la face et de la partie vive du flanc des dents au moment, où le point de leur contact et sur la ligne des centres; la distance de ces extrémités doit être égale à PP_1. Quant au choix de la position des points E et F sur la circonférence, il dépend des exigences de la pratique: plus ces points seront éloignés du point D, plus longue sera la dent de la roue C et plus profond sera le creux de la roue C_1; en même temps sera plus mince le bout de la dent de la roue C et plus étroit près du fond le creux de la roue C_1.

Après avoir choisi les positions des points E et F sur la circonférence et la direction de la normale commune aux profils des dents en contact au point D, nous aurons les profils cherchés, en traçant par le points D et E, D et F les arcs de cercle, ayant au point D la normale choisie.

Fig. 6.



§ 10. Passons maintenant au cas, où l'on dispose de deux quantités dans le choix des arcs de cercle formant les profils des dents, en vue de diminuer autant qu'il est possible les irrégularités, qui sont inévitables une fois que l'engrenage est profilé en arcs de cercle.

Développant la différence:

$$F(\lambda) - \frac{R}{R_1}\lambda$$

suivant les puissances ascendantes de λ jusqu'à la quatrième puissance, on trouve, que d'après le § 3 cette différence se réduit au polynome:

$$K_4(\lambda^4 - 1,638\,l\lambda^3 + 0,638\,l^2\lambda^2).$$

D'où il suit que pour déterminer les valeurs de λ, qui annulent la dérivée

$$F'(\lambda) - \frac{R}{R_1}$$

on à l'équation:

$$4\lambda^3 - 1,638.3.l\lambda^2 + 0,638.2.l^2\lambda = 0.$$

dont les racines sont:

$$\lambda = 0,\ \lambda = 0,365\,l,\ \lambda = 0,865\,l.$$

On conclut de là, d'après le § 4, que la normale commune aux profils des dents en contact passe par le point de contact des circonférences primitives pour les valeurs suivantes de l'angle λ:

$$\lambda = 0,\quad \lambda = 0{,}365\,l,\quad \lambda = 0{,}865\,l.$$

Les équations qu'on peut déduire de cette circonstance dans le cas considéré s'obtiennent facilement, comme nous le verrons, si l'on fait usage de l'angle v, variation de l'inclinaison de la normale commune aux profils des dents en contact (§ 5) sur la ligne des centres.

Cherchant d'après la formule (4) les valeurs de v correspondant aux trois valeurs de λ ci-dessus trouvées, on remarque, que la première est nulle et les deux autres sont de la forme:

$$v = K_1\lambda + K_2\lambda^2,$$

où il faut poser successivement

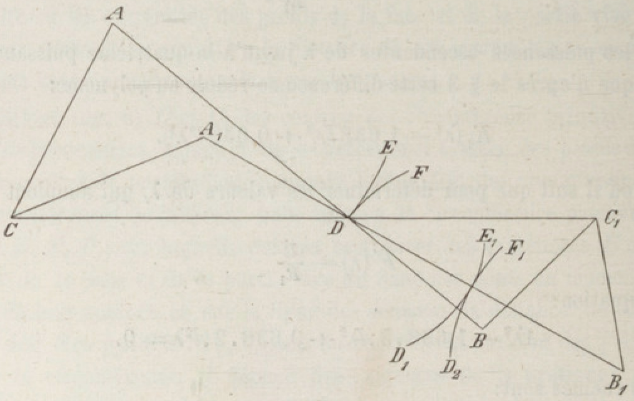
$$\lambda = 0{,}365\,l,\quad \lambda = 0{,}865\,l.$$

En désignant ces deux valeurs de v par v_1 et v_2 nous aurons

$$v_1 = 0{,}365\,K_1 l + 0{,}365^2 K_2 l^2,$$
$$v_2 = 0{,}865\,K_1 l + 0{,}865^2 K_2 l^2.$$

Soient, conformément aux notations précédentes, C et C_1 (fig. 7) les

Fig. 7.



centres des circonférences primitives, $CD = R$, $C_1D = R_1$ leurs rayons; A

et B les centres des arcs de cercle DE et DF, lorsque leur point de contact est sur la ligne des centres; $AD=\rho$, $BD=\rho_1$ les rayons de ces arcs; $AC=r$, $BC_1=r_1$ les distances des points A, B aux centres C, C_1; $ADC=N$ l'angle, qui mesure l'inclinaison de la normale commune aux arcs DE et DF sur la ligne des centres. Si A_1 et B_1 sont les positions des centres des arcs DE et DF au moment, où le décroissement de l'angle de l'inclinaison de la normale commune aux dents sur la ligne CC_1 est égal à v_1, la droite A_1B_1 représente la position de cette normale, correspondant à $\lambda=0{,}365\,l$; et par suite elle doit passer par D, point de contact des circonférences primitives.

Considérant les triangles CAD, CA_1D, C_1BD, C_1B_1D, où d'après nos notations

$$AC=A_1C=r,\ BC_1=B_1C_1=r_1,$$
$$AD=\rho,\ BD=\rho_1,\ AB=A_1B_1=\rho+\rho_1,$$
$$CD=R,\ C_1D=R_1,\ ADC=BDC_1=N,$$
$$A_1DC=B_1DC_1=N-v_1,$$

et posant

$$AD-A_1D=B_1D-BD=h,$$

nous aurons les égalités suivantes:

$$r^2=\rho^2+R^2-2\rho R\cos N,$$
$$r^2=(\rho-h)^2+R^2-2(\rho-h)R\cos(N-v_1),$$
$$r_1{}^2=\rho_1{}^2+R_1{}^2-2\rho_1R_1\cos N,$$
$$r_1{}^2=(\rho_1+h)^2+R_1{}^2-2(\rho_1+h)R_1\cos(N-v_1),$$

qui, après l'élimination de r et r_1, nous donnent:

$$\rho^2+R^2-2\rho R\cos N=(\rho-h)^2+R^2-2(\rho-h)R\cos(N-v_1),$$
$$\rho_1{}^2+R_1{}^2-2\rho_1R_1\cos N=(\rho_1+h)^2+R_1{}^2-2(\rho_1+h)R_1\cos(N-v_1).$$

Pour éliminer de ces équations la quantité h on peut les résoudre par rapport à

$$\rho-h \text{ et } \rho_1+h$$

et ajouter les résultats.

On arrive ainsi à l'équation:

$$\rho+\rho_1-(R+R_1)\cos(N-v_1)=$$
$$\sqrt{\rho^2-2R\rho\cos N+R^2\cos^2(N-v_1)}+\sqrt{\rho_1{}^2-2R_1\rho_1\cos N+R_1{}^2\cos^2(N-v_1)},$$

qui peut être réduite à la forme:

$$\begin{aligned}\rho+\rho_1-(R+R_1)\cos(N-v_1)= \\ \sqrt{(\rho-R\cos N)^2+R^2\left[\cos^2(N-v_1)-\cos^2 N\right]} \\ +\sqrt{(\rho_1-R_1\cos N)^2+R_1^2\left[\cos^2(N-v_1)-\cos^2 N\right]}.\end{aligned}$$

Posons pour abréger

$$\frac{\cos^2(N-v_1)-\cos^2 N}{\cos^2 N}=t_1, \tag{14}$$

ce qui donne

$$\cos(N-v_1)=\cos N\sqrt{1+t_1},$$

et nous pourrons écrire l'équation précédente comme il suit:

$$\begin{gathered}\rho+\rho_1-(R+R_1)\cos N\sqrt{1+t_1}= \\ \sqrt{(\rho-R\cos N)^2+R^2\cos^2 N.t_1}+\sqrt{(\rho_1-R_1\cos N)^2+R_1^2\cos^2 N.t_1}.\end{gathered}$$

Développant les radicaux suivant les puissances de t_1, on ramène tous les termes dans le premier membre; divisant par t_1, on trouve:

$$\left.\begin{aligned}&\frac{R^2\cos N}{\rho-R\cos N}+\frac{R_1^2\cos N}{\rho_1-R_1\cos N}+R+R_1 \\ -\frac{1}{4}&\left[\frac{R^4\cos^3 N}{(\rho-R\cos N)^3}+\frac{R_1^4\cos^3 N}{(\rho_1-R_1\cos N)^3}+R+R_1\right]t_1 \\ +\frac{1}{8}&\left[\frac{R^6\cos^5 N}{(\rho-R\cos N)^5}+\frac{R_1^6\cos^5 N}{(\rho_1-R_1\cos N)^5}+R+R_1\right]t_1^2 \\ +&\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\end{aligned}\right\}=0.$$

Faisons pour abréger

$$\frac{R\cos N}{\rho-R\cos N}=X, \quad \frac{R_1\cos N}{\rho_1-R_1\cos N}=Y, \tag{15}$$

et l'équation ci-dessus prendra la forme suivante:

$$\left.\begin{aligned}RX+R_1Y+R+R_1-\tfrac{1}{4}(RX^3+R_1Y^3+R+R_1)\,t_1 \\ +\tfrac{1}{8}(RX^5+R_1Y^5+R+R_1)\,t_1^2+\ldots\end{aligned}\right\}=0. \tag{16}$$

En répétant les mêmes opérations pour l'angle v_2, qui correspond à l'angle de la rotation $\lambda = 0{,}865\, l$, pour lequel la normale commune doit passer aussi par le point D et posant:

$$\frac{\cos^2 (N - v_2) - \cos^2 N}{\cos^2 N} = t_2, \tag{17}$$

nous obtenons l'équation

$$\left. \begin{array}{l} RX + R_1 Y + R + R_1 - \frac{1}{4} (RX^3 + R_1 Y^3 + R + R_1)\, t_2 \\ \quad + \frac{1}{8} (RX^5 + R_1 Y^5 + R + R_1)\, t_2^2 + \ldots \end{array} \right\} = 0, \tag{18}$$

analogue à l'équation (16).

Des équations (16) et (18) on déduit les valeurs de X et Y; en suite à l'aide des formules (15) on trouve les valeurs de ρ et ρ_1, rayons des arcs de cercle formant les profils des dents.

§ 11. Pour faciliter la résolution des équations (16) et (18) nous négligerons d'abord les termes contenant les puissances de t_1 et t_2 supérieures à la première. Nous aurons pour les valeurs approchées de X et Y les équations:

$$RX + R_1 Y + R + R_1 - \frac{1}{4} (RX^3 + R_1 Y^3 + R + R_1)\, t_1 = 0,$$

$$RX + R_1 Y + R + R_1 - \frac{1}{4} (RX^3 + R_1 Y^3 + R + R_1)\, t_2 = 0$$

qui se réduisent aux équations suivantes:

$$RX + R_1 Y + R + R_1 = 0,$$

$$RX^3 + R_1 Y^3 + R + R_1 = 0.$$

On déduit de la première

$$Y = -\frac{R}{R_1} X - \frac{R}{R_1} - 1. \tag{19}$$

Substituant cette valeur de Y dans la seconde on arrive à l'équation:

$$RX^3 + R_1 \left(-\frac{R}{R_1} X - \frac{R}{R_1} - 1 \right)^3 + R + R_1 = 0,$$

qui, les réductions faites, aura la forme:

$$(R_1 - R)\, X^3 - 3RX^2 - 3\, (R + R_1)\, X - R - 2R_1 = 0.$$

Cette équation a deux racines égales à -1 et la troisième, qui est égale à

$$\frac{R+2R_1}{R_1-R}.$$

Or, remarquant que d'après la première des formules (15) X ne peut devenir égal à -1 que si le rayon ρ devient nul, on conclut que les racines égales à -1 ne sont pas admissibles dans notre problème; donc il faut prendre pour la valeur cherchée de X la racine

$$\frac{R+2R_1}{R_1-R}.$$

Substituant cette valeur de X dans l'équation (19) on trouve

$$Y=\frac{R_1+2R}{R-R_1}.$$

Telles sont les premières valeurs approchées de X et de Y. Pour les déterminer avec plus d'exactitude, posons:

$$(20)\qquad \left\{\begin{aligned} X&=\frac{R+2R_1}{R_1-R}+\alpha,\\ Y&=\frac{R_1+2R}{R-R_1}+\beta,\end{aligned}\right.$$

où α et β sont les quantités négligées dans la première approximation.

Introduisant ces nouvelles valeurs de X et de Y dans les équations (16) et (18) et supprimant les termes, qui contiennent les puissances des quantités α, β, t_1, t_2 supérieures à la première, on obtient:

$$\left.\begin{aligned} &R\alpha+R_1\beta-\frac{3}{4}\left[R\left(\frac{R+2R_1}{R_1-R}\right)^2\alpha+R_1\left(\frac{R_1+2R}{R-R_1}\right)^2\beta\right]t_1\\ &\quad+\frac{1}{8}\left[R\left(\frac{R+2R_1}{R_1-R}\right)^5+R_1\left(\frac{R_1+2R}{R-R_1}\right)^5+R+R_1\right]t_1^2\end{aligned}\right\}=0,$$

$$\left.\begin{aligned} &R\alpha+R_1\beta-\frac{3}{4}\left[R\left(\frac{R+2R_1}{R_1-R}\right)^2\alpha+R_1\left(\frac{R_1+2R}{R-R_1}\right)^2\beta\right]t_2\\ &\quad+\frac{1}{8}\left[R\left(\frac{R+2R_1}{R_1-R}\right)^5+R_1\left(\frac{R_1+2R}{R_1-R}\right)^5+R+R_1\right]t_2^2\end{aligned}\right\}=0.$$

Si l'on se borne à la première puissance de t_1 et t_2 dans la détermination des valeurs de α et β, les deux équations précédentes donnent immédiatement l'équation

$$R\alpha+R_1\beta=0.$$

Pour obtenir une seconde équation simple entre α et β soustrayons l'une de l'autre les mêmes équations et, supprimant le facteur commun $\frac{3}{4}(t_2 - t_1)$, nous aurons:

$$R\left(\frac{R+2R_1}{R_1-R}\right)^2\alpha + R_1\left(\frac{R_1+2R}{R-R_1}\right)^2\beta =$$

$$\frac{1}{6}\left[R\left(\frac{R+2R_1}{R_1-R}\right)^5 + R_1\left(\frac{R_1+2R}{R-R_1}\right)^5 + R + R_1\right](t_1+t_2).$$

Remplaçant dans cette équation

$$\beta = -\frac{R}{R_1}\alpha,$$

on a

$$R\left[\left(\frac{R+2R_1}{R_1-R}\right)^2 - \left(\frac{R_1+2R}{R_1-R}\right)^2\right]\alpha =$$

$$\frac{1}{6}\left[R\left(\frac{R+2R_1}{R_1-R}\right)^5 + R_1\left(\frac{R_1+2R}{R-R_1}\right)^5 + R + R_1\right](t_1+t_2),$$

d'où l'on tire

$$\alpha = \frac{R_1(R+2R_1)(R_1+2R)}{2(R_1-R)^3}(t_1+t_2),$$

et par suite

$$\beta = \frac{R(R+2R_1)(R_1+2R)}{2(R_1-R)^3}(t_1+t_2).$$

En portant ces valeurs de α et β, exactes jusqu'à la première puissance de t_1 et t_2 dans les formules (20), on obtient avec le même degré d'approximation:

$$X = \frac{R+2R_1}{R_1-R}\left[1 + \frac{R_1(R_1+2R)}{2(R_1-R)^2}(t_1+t_2)\right],$$

$$Y = \frac{R_1+2R}{R-R_1}\left[1 + \frac{R(R+2R_1)}{2(R_1-R)^2}(t_1+t_2)\right].$$

§ 12. Substituant les valeurs trouvées de X et Y dans les formules (15), on aura pour la détermination des valeurs ρ et ρ_1 les équations suivantes:

$$\frac{R\cos N}{\rho - R\cos N} = \frac{R+2R_1}{R_1-R}\left[1 + \frac{R_1(R_1+2R)}{2(R_1-R)^2}(t_1+t_2)\right],$$

$$\frac{R_1\cos N}{\rho_1 - R_1\cos N} = \frac{R_1+2R}{R-R_1}\left[1 + \frac{R(R+2R_1)}{2(R-R_1)^2}(t_1+t_2)\right].$$

Si l'on se borne aux termes du premier ordre relativement à t_1 et t_2, on en tire:

$$\rho = \frac{3RR_1\cos N}{R+2R_1}\left[1 - \frac{(R_1+2R)(t_1+t_2)}{6(R_1-R)}\right],$$

$$\rho_1 = \frac{3RR_1\cos N}{R_1+2R}\left[1 - \frac{(R+2R_1)(t_1+t_2)}{6(R-R_1)}\right].$$

Quant à la valeur de la somme $t_1 + t_2$, qui entre dans ces formules, on remarque que les expressions (14) et (17), étant développées suivant les puissances de v, donnent avec approximation jusqu'à la deuxième puissance

$$t_1 = \frac{2 \cos N . \sin N}{\cos^2 N} v_1 = 2 \operatorname{tang} N . v_1 ; \quad t_2 = \frac{2 \cos N . \sin N}{\cos^2 N} v_2 = 2 \operatorname{tang} N . v_2 .$$

Mais d'après le § 10 on a avec approximation jusqu'à la deuxième puissance de l

$$v_1 = 0{,}365\, K_1 l, \quad v_2 = 0{,}865\, K_1 l,$$

donc avec la même approximation

$$t_1 + t_2 = 2\,(0{,}365 + 0{,}865)\, K_1 \operatorname{tang} N . l = 2{,}460\, K_1 \operatorname{tang} N . l,$$

où d'après (6)

$$K_1 = \frac{R\rho_1 - R_1 \rho}{R_1 (\rho + \rho_1)}$$

Si dans cette expression de K_1 on remplace ρ et ρ_1 par leurs valeurs trouvées ci-dessus, on a avec approximation jusqu'à la première puissance de t_1 et t_2 exclusivement

$$K_1 = \frac{R - R_1}{3R_1} .$$

et par suite

$$t_1 + t_2 = \frac{2{,}460}{3} \frac{R - R_1}{R_1} \operatorname{tang} N . l$$

$$= 0{,}820 . \frac{R - R_1}{R_1} \operatorname{tang} N . l .$$

Substituant cette valeur de $t_1 + t_2$ dans les expressions des valeurs de ρ et ρ_1 trouvées plus haut, nous obtenons

$$\rho = \frac{3RR_1 \cos N}{R + 2R_1} \left[1 + 0{,}137 \frac{R_1 + 2R}{R_1} \operatorname{tang} N . l \right],$$

$$\rho_1 = \frac{3RR_1 \cos N}{R_1 + 2R} \left[1 - 0{,}137 \frac{R + 2R_1}{R_1} \operatorname{tang} N . l \right].$$

Tels sont donc les rayons des arcs de cercle, dont l'un forme le profil de la face de la dent de la roue C et l'autre celui du flanc de la dent de roue C_1.

§ 13. Pour déterminer les longueurs de ces arcs, on a d'après le § 8 avec approximation jusqu'à l^3

$$\omega = (K_1 + 1)\, l + K_2 l^2,$$

où ω est la longueur de l'arc de cercle, profil de la face de la dent de la roue C_1, supposant que le rayon de cet arc est pris pour l'unité, et les coefficients K_1 et K_2 d'après le § 6 ont les valeurs suivantes:

$$K_1 = \frac{R\rho_1 - R_1\rho}{R_1(\rho + \rho_1)};$$

$$K_2 = \frac{(\rho - R\cos N)(K_1 + 1)^2 + (R + R_1)\left[\cos N . K_1^2 + \frac{R - \rho\cos N}{\rho + \rho_1}\right]}{2R_1 \sin N}.$$

Remplaçant ρ et ρ_1 par leurs valeurs trouvées dans le § 12, nous supprimons les termes contenant, comme facteurs, l^2 dans l'expression de K_1 et l dans celle de K_2; nous aurons ainsi:

$$K_1 + 1 = \frac{R + 2R_1}{3R_1}\left(1 - 0{,}137\,\frac{R_1 + 2R}{R_1}\,\operatorname{tang} N . l\right),$$

$$K_2 = \frac{(R + 2R_1)(R_1 + 2R)}{18R_1^2}\operatorname{tang} N.$$

Après la substitution de ces valeurs dans l'expression ci-dessus de ω on obtient avec approximation jusqu'à l^3

$$\omega = \frac{R + 2R_1}{3R_1}\left[1 + \left(\frac{1}{6} - 0{,}137\right)\frac{R_1 + 2R}{R_1}\operatorname{tang} N . l\right] l.$$

Remplaçant dans cette formule ω par $-\omega_1$, l par $-\frac{R}{R_1}\,l$, R par R_1, ρ par ρ_1 et réciproquement on parvient d'après le § 9 à la formule pour déterminer la longueur de l'arc de cercle, qui forme le profil du flanc de la dent de la roue C_1:

$$\omega_1 = \frac{R_1 + 2R}{3R_1}\left[1 - \left(\frac{1}{6} - 0{,}137\right)\frac{R + 2R_1}{R_1}\operatorname{tang} N . l\right] l,$$

où ω_1 désigne la longueur de l'arc, son rayon étant pris pour l'unité.

On en déduit que la somme

$$\omega + \omega_1$$

est égale à

$$\frac{R + R_1}{R_1}\, l$$

et le produit

$$\rho . \omega$$

avec approximation jusqu'à l^3 se réduit à

$$R\cos N . l + \frac{R(R_1 + 2R)}{6R_1}\sin N . l^2.$$

Cette expression est la même que celle de la corde DE_1 (§ 8), qui résulte de la formule

$$DE_1 = R\cos N.l + R\left(\frac{\omega}{2} + \frac{R-R_1}{6R_1}\,l\right)\sin N.l,$$

après la substitution de la valeur de ω. On conclut de là, que dans le cas présent subsistent les propriétés que nous avons demontrées (§ 8, § 9) pour le cas, où dans le choix des arcs de cercle formant le profil de l'engrenage il n'y a qu'une seule quantité dont on peut disposer pour diminuer les irrégularités du mouvement.

Nous avons vu dans le § 9 que dans ce cas on peut modifier suivant les exigences de la pratique la direction de la normale commune aux dents qui sont en contact sur la ligne des centres, sans changer les positions choisies sur la circonférence DPP_1 (fig. 6) pour les extrémités des profils de la face de la dent de la roue C et de la partie vive du flanc de la dent de la roue C_1. Au contraire, dans le cas que nous examinons à présent la position de ces extrémités définit complétement la direction de la normale commune mentionnée, puisque d'après le § 8 (fig. 5) on a:

$$N = GDT = GDE + EDT = GDE + \frac{\omega}{2}.$$

En portant l'expression connue de ω, où ρ et ρ_1 doivent être remplacés par leurs valeurs, on trouve une équation, qui détermine l'angle N, si l'angle GDE est donné. Si l'on a égard à ce fait que c'est dans ce cas notamment que l'on obtient la plus grande régularité possible avec des engrenages profilés en arcs de cercle, on conclura de ce qui précède que toutes les fois, lorsqu'on choisit la direction de la normale commune AB conformément aux exigences de la pratique, il faut chercher donner à cette normale la direction qui s'écarte le moins possible de celle que l'équation précédente fait connaître.

Les valeurs trouvées de ω et ω_1 avec approximation jusqu'à l donnent

$$\frac{\omega_1}{\omega} = \frac{R_1 + 2R}{R + 2R_1},$$

or d'après le § 8 (fig. 5)

$$\omega = DAE = 2EDT,$$
$$\omega_1 = DBF = 2FDT,$$

donc on a avec approximation jusqu'à la première puissance de l

$$\frac{FDT}{EDT} = \frac{R_1 + 2R}{R + 2R_1}.$$

D'où il ressort que, si la normale commune aux dents en contact AB a la direction indiquée, leur tangente commune DT divisé l'arc EF en deux parties, qui sont entre elles dans le rapport

$$\frac{R_1+2R}{R+2R_1},$$

ce rapport étant exact jusqu'à la première puissance de l.

On en déduit une construction géométrique très-simple pour déterminer approximativement la direction de la tangente DT, correspondant à celle de la normale AB, pour laquelle les irregularites du mouvement de l'engrenage considéré deviennent les moindres possibles.

Remarquons pour terminer, que les angles que les cordes PD et P_1D (fig. 5) font avec le diamètre passant par le point D ont pour valeurs approximatives jusqu'à l^2, respectivement:

$$\frac{R+2R_1}{6R_1}\,l,\ \frac{R_1+2R}{6R_1}\,l.$$

En comparant ces valeurs avec celles des angles

$$PDG=\frac{\omega}{2},\ GDP_1=\frac{\omega_1}{2},$$

qui résultent des formules trouvées, on remarque qu'elles sont respectivement égales avec approximation jusqu'à la deuxième puissance de l. On voit de là, qu'avec ce degré d'approximation le diamètre du cercle DPP_1, passant par le point D, fait avec les cordes DP et DP_1 des angles respectivement égaux à ceux, que la tangente DT aux arcs DE et DF doit faire avec le cordes DE et DF, pour que l'irregularité de la transmission du mouvement par l'engrenage soit réduite au minimum possible.

Sur les quadratures.

1. Dans l'Ouvrage très-important que M. Hermite vient de publier sur l'Analyse mathématique, l'illustre géomètre donne une nouvelle formule pour évaluer approximativement la valeur de l'intégrale

$$\int_{-1}^{+1} \frac{\varphi(x)}{\sqrt{1-x^2}}\, dx.$$

Dans cette formule toutes les valeurs de la fonction $\varphi(x)$ entrent avec un même coefficient; c'est ce qui apporte une différence essentielle entre la formule de M. Hermite et celle de Gauss, et ce qui en rend très-commode l'application numérique. L'utilité des formules approximatives de ce genre m'engage à présenter quelques réflexions sur la recherche de ces formules.

Nous supposerons que, la fonction $F(x)$ étant donnée, on cherche à exprimer le plus près possible les intégrales de la forme

$$\int_{-1}^{+1} F(x)\, \varphi(x)\, dx,$$

quelle que soit la fonction $\varphi(x)$, par la formule

$$k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_n)\right],$$

où $k, x_1, x_2, \ldots x_n$ sont des valeurs qui ne dépendent pas de la fonction $\varphi(x)$. Comme cette formule ne contient que $n+1$ quantités $k, x_1, x_2, \ldots x_n$ dont on puisse disposer, il est impossible de l'identifier avec la valeur de l'intégrale

$$\int_{-1}^{+1} F(x)\, \varphi(x)\, dx$$

au delà des termes qui contiennent les n premières dérivées de la fonction $\varphi(x)$, et, par conséquent, on aura

$$(1)\quad \int_{-1}^{+1} F(x)\,\varphi(x)\,dx - k\left[\varphi(x_1)+\varphi(x_2)+\ldots+\varphi(x_n)\right] = k_1\,\varphi^{(n+1)}(0)+k_2\,\varphi^{(n+2)}(0)+\ldots,$$

en designant par $k_1, k_2, \ldots$ les coefficients de $\varphi^{(n+1)}(0)$, $\varphi^{(n+2)}(0), \ldots$ dans l'expression de la différence

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx - k\left[\varphi(x_1)+\varphi(x_2)+\ldots+\varphi(x_n)\right],$$

que l'on trouve en développant, d'après la formule de Maclaurin, la fonction $\varphi(x)$ sous le signe de l'intégrale et les valeurs $\varphi(x_1)\ \varphi(x_2), \ldots, \varphi(x_n)$ qui sont hors ce signe.

2. Pour trouver, d'après la formule (1), que l'on suppose possible, la valeur du coefficient k et les valeurs $x_1, x_2, \ldots, x_n$ de la variable x, nous remarquons que cette formule, dans le cas particulieur où

$$\varphi(x) = \frac{1}{z-x},$$

z étant une quantité quelconque, se réduit à l'égalité

$$\int_{-1}^{+1} \frac{F(x)}{z-x}\,dx - k\left(\frac{1}{z-x_1}+\frac{1}{z-x_2}+\ldots+\frac{1}{z-x_n}\right) =$$
$$1.2.3\ldots(n+1)k_1 z^{-n-2} + 1.2.3\ldots(n+2)k_2 z^{-n-3} + \ldots$$

où $k, k_1, k_2, \ldots, x_1, x_2, \ldots, x_n$ sont des valeurs qui ne dépendent pas de z. D'autre part, en dénotant par $f(z)$ le produit

$$(z-x_1)(z-x_2)\ldots(z-x_n),$$

on a

$$\frac{f'(z)}{f(z)} = \frac{1}{z-x_1}+\frac{1}{z-x_2}+\ldots+\frac{1}{z-x_n},$$

et, par suite, la formule précédente se réduit à celle-ci:

$$(2)\quad \int_{-1}^{+1} \frac{F(x)}{z-x}\,dx = k\frac{f'(z)}{f(z)} + \frac{1.2.3\ldots(n+1)k_1}{z^{n+2}} + \frac{1.2.3\ldots(n+2)k_2}{z^{n+3}} + \ldots$$

En multipliant cette formule par z et en remarquant que, pour $z = \infty$, les valeurs

$$z \int_{-1}^{+1} \frac{F(x)}{z-x}\,dx = \int_{-1}^{+1} \frac{F(x)}{1-\frac{x}{z}}\,dx,$$

$$\frac{z f'(z)}{f(z)} = \frac{1}{1-\frac{x_1}{z}} + \frac{1}{1-\frac{x_2}{z}} + \ldots + \frac{1}{1-\frac{x_n}{z}},$$

$$\frac{1.2.3\ldots(n+1)k_1}{z^{n+1}}, \qquad \frac{1.2.3\ldots(n+2)k_2}{z^{n+2}}, \ldots$$

sont respectivement égales à

$$\int_{-1}^{+1} F(x)\,dx, \quad n, \quad 0, \quad 0, \ldots,$$

on parvient à cette égalité

$$\int_{-1}^{+1} F(x)\,dx = nk,$$

ce qui nous donne, pour la détermination du coefficient k, la formule suivante:

$$k = \frac{1}{n} \int_{-1}^{+1} F(x)\,dx.$$

3. Pour déterminer la fonction

$$f(z) = (z-x_1)(z-x_2)\ldots(z-x_n),$$

nous remarquons que la formule (2), étant intégrée par rapport à z, nous donne

$$\int_{-1}^{+1} F(x) \log(z-x)\,dx = k \log\frac{f(z)}{C} - \frac{1.2\,3\ldots nk_1}{z^{n+1}} - \frac{1.2.3\ldots(n+1)k_2}{z^{n+2}} - \ldots,$$

où C est une constante, et de là on trouve

$$f(z)\, e^{-\frac{1.2.3\ldots nk_1}{kz^{n+1}} - \frac{1.2.3\ldots(n+1)k_2}{kz^{n+2}} - \ldots} = Ce^{\frac{1}{k}\int_{-1}^{+1} F(x)\log(z-x)\,dx}$$

Comme la fonction cherchée

$$f(z) = (z-x_1)(z-x_2)\ldots(z-x_n)$$

est de degré n et que l'expression

$$e^{-\frac{1.2.3\ldots nk_1}{kz^{n+1}} - \frac{1.2.3\ldots(n+1)k_2}{kz^{n+2}} - \ldots}$$

ne diffère de 1 que par les puissances de z inférieures à z^{-n}, il est clair que la partie entière du premier membre de la formule trouvée est égale à la fonction $f(z)$, et que, par conséquent, on aura

$$f(z) = ECe^{\frac{1}{k}\int_{-1}^{+1} F(x)\log(z-x)\,dx}$$

ou

$$f(z) = CEe^{\frac{1}{k}\int_{-1}^{+1} F(x)\log(z-x)\,dx}, \tag{3}$$

en désignant par E la partie entière de la fonction mise sous ce signe. Dans cette formule, la valeur de la constante k, comme nous l'avons vu, est donnée par l'équation

$$k = \frac{1}{n}\int_{-1}^{+1} F(x)\,dx. \tag{4}$$

Quant à la constante C, on trouvera aisément sa valeur en remarquant que le coefficient de z^n, dans la fonction cherchée, est égal à 1; mais nous n'insisterons pas sur la recherche de la valeur de cette constante, vu qu'elle peut être toujours supprimée sans modifier l'équation

$$f(z) = CEe^{\frac{1}{k}\int_{-1}^{+1} F(x)\log(z-x)\,dx} = 0,$$

dont les racines présentent les valeurs de $x_1, x_2, \ldots, x_n$ dans la formule en question

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx = k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_n)\right].$$

4. Passant aux applications, nous ferons d'abord

$$F(x) = \frac{1}{\sqrt{1-x^2}},$$

ce qui est le cas de M. Hermite, et où l'intégrale

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx$$

se réduit à

$$\int_{-1}^{+1} \frac{\varphi(x)}{\sqrt{1-x^2}}\,dx.$$

ne différe de 1 que par les puissances de z inférieures à z^{-n}, il est clair que la partie entière du premier membre de la formule trouvée est égale à la fonction $f(z)$, et que, par conséquent, on aura

$$f(z) = ECe^{\frac{1}{k}\int_{-1}^{+1} F(x)\log(z-x)\,dx}$$

ou

$$f(z) = CEe^{\frac{1}{k}\int_{-1}^{+1} F(x)\log(z-x)\,dx}, \tag{3}$$

en désignant par E la partie entière de la fonction mise sous ce signe. Dans cette formule, la valeur de la constante k, comme nous l'avons vu, est donnée par l'équation

$$k = \frac{1}{n}\int_{-1}^{+1} F(x)\,dx. \tag{4}$$

Quant à la constante C, on trouvera aisément sa valeur en remarquant que le coefficient de z^n, dans la fonction cherchée, est égal à 1; mais nous n'insisterons pas sur la recherche de la valeur de cette constante, vu qu'elle peut être toujours supprimée sans modifier l'équation

$$f(z) = CEe^{\frac{1}{k}\int_{-1}^{+1} F(x)\log(z-x)\,dx} = 0,$$

dont les racines présentent les valeurs de $x_1, x_2, \ldots, x_n$ dans la formule en question

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx = k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_n)\right].$$

4. Passant aux applications, nous ferons d'abord

$$F(x) = \frac{1}{\sqrt{1-x^2}},$$

ce qui est le cas de M. Hermite, et où l'intégrale

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx$$

se réduit à

$$\int_{-1}^{+1} \frac{\varphi(x)}{\sqrt{1-x^2}}\,dx.$$

quand on fait $k = \frac{2}{n}$, et que l'on prend pour $x_1, x_2, \ldots, x_n$ les racines de l'équation

$$Ee^{\frac{n}{2}\left(\log\frac{(z+1)^{z+1}}{(z-1)^{z-1}} - 2\right)} = 0 \quad \text{ou} \quad E\frac{(z+1)^{\frac{n(z+1)}{2}}}{(z-1)^{\frac{n(z-1)}{2}}} = 0,$$

équation qu'on peut mettre, par le développement en séries, sous la forme suivante:

$$(5) \qquad Ez^n e^{-\frac{n}{2.3\,z^2} - \frac{n}{4.5\,z^4} - \frac{n}{6.7\,z^6} - \ldots} = 0.$$

6. En donnant à n les valeurs les plus simples, telles que

$$n = 2,\ 3,\ 4,\ 5,\ 6,\ 7,$$

on trouve que, pour ces valeurs de n, l'équation (5) devient respectivement

$$z^2 - \frac{1}{3} = 0,$$

$$z^3 - \frac{1}{2}z = 0,$$

$$z^4 - \frac{2}{3}z^2 + \frac{1}{45} = 0,$$

$$z^5 - \frac{5}{6}z^3 + \frac{7}{72}z = 0,$$

$$z^6 - z^4 + \frac{1}{5}z^2 - \frac{1}{105} = 0,$$

$$z^7 - \frac{7}{6}z^5 + \frac{119}{360}z^3 - \frac{149}{6480}z = 0,$$

et, en resolvant ces équations, on obtient les systèmes suivants des valeurs de $x_1, x_2, \ldots, x_n$:

$$n = 2.$$

$$x_1 = -0{,}577350,$$

$$x_2 = +0{,}577350;$$

$$n = 3.$$

$$x_1 = -0{,}707107,$$

$$x_2 = 0,$$

$$x_3 = +0{,}707107;$$

$n = 4.$

$$x_1 = -0{,}794654,$$
$$x_2 = -0{,}187592,$$
$$x_3 = +0{,}187592,$$
$$x_4 = +0{,}794654;$$

$n = 5.$

$$x_1 = -0{,}832497,$$
$$x_2 = -0{,}374541,$$
$$x_3 = \quad 0,$$
$$x_4 = +0{,}374541,$$
$$x_5 = +0{,}832497;$$

$n = 6.$

$$x_1 = -0{,}866247,$$
$$x_2 = -0{,}422519,$$
$$x_3 = -0{,}266635,$$
$$x_4 = +0{,}266635,$$
$$x_5 = +0{,}422519,$$
$$x_6 = +0{,}866247;$$

$n = 7.$

$$x_1 = -0{,}883862,$$
$$x_2 = -0{,}529657,$$
$$x_3 = -0{,}323912,$$
$$x_4 = \quad 0,$$
$$x_5 = +0{,}323912,$$
$$x_6 = +0{,}529657,$$
$$x_7 = +0{,}883862.$$

Avec ces valeurs de $x_1, x_2, \ldots, x_n$, la formule

$$\frac{2}{n}\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_n)\right]$$

donne l'expression approximative de l'intégrale

$$\int_{-1}^{+1} \varphi(x)\, dx,$$

qui, dans certains cas, est plus commode pour les applications que ne l'est celle de Gauss; car, dans cette dernière formule, les valeurs $\varphi(x_1), \varphi(x_2), \ldots, \varphi(x_n)$ entrent munies de divers coefficients. Comme notre expression de l'intégrale $\int_{-1}^{+1} \varphi(x)\, dx$ n'est exacte que jusqu'aux termes en $\varphi^{(n+1)}(0)$, $\varphi^{(n+2)}(0), \ldots$, on devra y prendre, en général, plus de termes que dans la formule de Gauss. Néanmoins, dans le cas où les valeurs de $\varphi(x_1)$, $\varphi(x_2), \ldots, \varphi(x_n)$, d'aprés lesquelles on détermine l'intégrale $\int_{-1}^{+1} \varphi(x)\, dx$, sont affectées d'erreurs inconnues, notablement plus grandes que celle qui résulte des termes rejetés, la formule approchée que nous venons de trouver doit être préférée à celle de Gauss même par rapport au degré de précision, vu que, dans cette formule approchée, la somme des carrés de coefficients, à cause de leur égalité, a la plus petite valeur possible.

7. Revenant au cas résolu par M. Hermite, nous remarquons que l'intégrale

$$\int_{-1}^{+1} \frac{\varphi(x)}{\sqrt{1-x^2}}\, dx$$

pour $x = \cos\theta$ se réduit à

$$\int_{0}^{\pi} \varphi(\cos\theta)\, d\theta;$$

donc la formule donnée par lui peut avoir des applications trés-utiles dans la recherche des valeurs approchées du premier terme du développement de $\varphi(\cos\theta)$ en série

$$A_0 + A_1 \cos\theta + A_2 \cos 2\theta + \ldots$$

Pour trouver une expression pareille du coefficient A_1, on devrait faire, dans les formules du n^0 3,

$$F(x) = \frac{x}{\sqrt{1-x^2}}.$$

Or, pour cette valeur de $F(x)$, l'intégrale $\int_{-1}^{+1} F(x)\, dx$, qui entre dans les formules du n^0 3, se réduit à zéro, ce qui fait voir clairement que, pour le cas en question, ces formules ne sont pas applicables. Nous allons montrer le parti qu'on peut cependant tirer, dans ce cas, de la méthode exposée plus haut.

En remplaçant, dans l'intégrale

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx,$$

la fonction $\varphi(x)$ par son développement en série

$$\varphi(0) + \frac{\varphi'(0)}{1}x + \frac{\varphi''(0)}{1.2}x^2 + \frac{\varphi'''(0)}{1.2.3}x^3 + \ldots,$$

le terme du résultat qui contient $\varphi(0)$ s'annule toutes les fois que l'intégrale $\int_{-1}^{+1} F(x)\,dx$ est égale à zéro; mais il n'en est plus ainsi, évidemment, de son expression sous la forme

$$k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_n)\right]$$

à moins qu'on ne prenne, dans cette formule, la moitié des termes avec le signe —. Nous allons donc chercher à exprimer la valeur approchée de l'intégrale

$$\int_{-1}^{+1} F(x) = 0,$$

dans la supposition de

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx$$

par la formule

$$k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_m) - \varphi(x_{m+1}) - \varphi(x_{m+2}) - \ldots - \varphi(x_{2m})\right],$$

où il y a m termes avec le signe + et m termes avec le signe —.

8. Comme, dans la formule

$$k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_m) - \varphi(x_{m+1}) - \varphi(x_{m+2}) - \ldots - \varphi(x_{2m})\right],$$

il y a $2m+1$ valeurs, savoir: $k, x_1, x_2, \ldots, x_m, x_{m+1}, x_{m+2}, \ldots, x_{2m}$ dont on peut disposer, et que par sa composition, le terme en $\varphi(0)$ s'annule, on peut identifier cette formule avec l'intégrale $\int_{-1}^{+1} F(x)\,\varphi(x)\,dx$ jusqu'aux termes qui contiennent les $2m+1$ premières dérivées de $\varphi(x)$, ce qui nous donne l'équation

$$\int_{-1}^{+1} F(x)\,\varphi(x)dx = k\left[\varphi(x_1) + \varphi(x_2) \ldots + \varphi(x_m) - \varphi(x_{m+1}) - \varphi(x_{m+2}) \ldots - \varphi(x_{2m})\right]$$
$$+ k_1\varphi^{2m+2}(0) + k_2\varphi^{2m+3}(0) + \ldots$$

le cas en question, ces formules ne sont pas applicables. Nous allons montrer le parti qu'on peut cependant tirer, dans ce cas, de la méthode exposée plus haut.

En remplaçant, dans l'intégrale

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx,$$

la fonction $\varphi(x)$ par son développement en série

$$\varphi(0) + \frac{\varphi'(0)}{1}x + \frac{\varphi''(0)}{1.2}x^2 + \frac{\varphi'''(0)}{1.2.3}x^3 + \ldots,$$

le terme du résultat qui contient $\varphi(0)$ s'annule toutes les fois que l'intégrale $\int_{-1}^{+1} F(x)\,dx$ est égale à zéro; mais il n'en est plus ainsi, évidemment, de son expression sous la forme

$$k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_n)\right]$$

à moins qu'on ne prenne, dans cette formule, la moitié des termes avec le signe —. Nous allons donc chercher à exprimer la valeur approchée de l'intégrale

$$\int_{-1}^{+1} F(x) = 0,$$

dans la supposition de

$$\int_{-1}^{+1} F(x)\,\varphi(x)\,dx$$

par la formule

$$k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_m) - \varphi(x_{m+1}) - \varphi(x_{m+2}) - \ldots - \varphi(x_{2m})\right],$$

où il y a m termes avec le signe + et m termes avec le signe —.

8. Comme, dans la formule

$$k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_m) - \varphi(x_{m+1}) - \varphi(x_{m+2}) - \ldots - \varphi(x_{2m})\right],$$

il y a $2m+1$ valeurs, savoir: $k, x_1, x_2, \ldots, x_m, x_{m+1}, x_{m+2}, \ldots, x_{2m}$ dont on peut disposer, et que par sa composition, le terme en $\varphi(0)$ s'annule, on peut identifier cette formule avec l'intégrale $\int_{-1}^{+1} F(x)\,\varphi(x)\,dx$ jusqu'aux termes qui contiennent les $2m+1$ premières dérivées de $\varphi(x)$, ce qui nous donne l'équation

$$\int_{-1}^{+1} F(x)\,\varphi(x)dx = k\left[\varphi(x_1) + \varphi(x_2) \ldots + \varphi(x_m) - \varphi(x_{m+1}) - \varphi(x_{m+2}) \ldots - \varphi(x_{2m})\right]$$
$$+ k_1\varphi^{2m+2}(0) + k_2\varphi^{2m+3}(0) + \ldots$$

on trouve

$$\frac{f_0(z)}{f_1(z)}\, e^{-L_1 z^{-2m-2} - L_2 z^{-2m-3} - \dots} = e^{\frac{1}{k}\int_{-1}^{+1} F(x) \log(z-x)\, dx}.$$

Les fonctions $f_0(z)$, $f_1(z)$ étant de même degré, la fraction $\frac{f_0(z)}{f_1(z)}$ est du degré zéro; de plus, l'expression

$$e^{-L_1 z^{-2m-2} - L_2 z^{-2m-3} - \dots}$$

ne diffère de 1 que par les puissances de z inférieures à z^{-2m-1}; par conséquent, l'équation trouvée nous montre que la fraction $\frac{f_0(z)}{f_1(z)}$ ne diffère de l'expression

$$e^{\frac{1}{k}\int_{+1}^{+1} F(x) \log(z-x)\, dx}$$

que par les termes qui renferment les puissances de z moins élevées que z^{-2m-1} et, par suite, moins élevées que le degré de la fraction $\frac{1}{z\,[f_1(z)]^2}$; car la fonction $f_1(z)$, comme nous l'avons vu, n'est que du degré m. Mais, on le sait, la fraction $\frac{f_0(z)}{f_1(z)}$ ne peut donner une valeur approchée d'une fonction quelconque exacte jusqu'à l'ordre de $\frac{1}{z\,[f_1(z)]^2}$, à moins qu'elle ne soit l'une des fractions convergentes qu'on trouve par le développement en fraction continue, et que le quotient complet, correspondant à cette fraction convergente, ne soit dépourvu du terme en $\frac{1}{z}$. En partant de là, il est aisé de trouver et la constante k et les fonctions $f_0(z)$, $f_1(z)$, qui déterminent les valeurs de $x_1, x_2, \dots, x_m, x_{m+1}, x_{m+2}, \dots, x_{2m}$. A cet effet, on développera l'expression

$$e^{\frac{1}{k}\int_{-1}^{+1} F(x) \log(z-x)\, dx}$$

en fraction continue, en s'arrêtant au quotient qui correspond à une fraction convergente dont les termes sont du degré m. Égalant à zéro le coefficient de $\frac{1}{z}$ dans l'expression complète de ce quotient, on aura l'équation qui déterminera la valeur de la constante k, et, en mettant la valeur de k ainsi déterminée dans deux termes de la fraction convergente, on aura les fonctions cherchées $f_0(z)$, $f_1(z)$.

9. Pour montrer, sur un exemple, l'usage de ce que nous venons d'exposer, supposons qu'il s'agisse de trouver l'expression approximative de l'intégrale

$$\int_{-1}^{+1} x\varphi(x)\, dx.$$

Pour cela on posera, dans les formules du numéro précédent,

$$F(x) = x.$$

Pour cétte valeur de $F(x)$, on obtient

$$\int_{-1}^{+1} F(x) \log (z - x)\, dx = \int_{-1}^{+1} x \log (z - x)\, dx = \frac{z^2 - 1}{2} \log \frac{z + 1}{z - 1} - z,$$

$$e^{\frac{1}{k} \int_{-1}^{+1} F(x) \log (z - x)\, dx} = e^{\frac{z^2 - 1}{2k} \log \frac{z + 1}{z - 1} - \frac{z}{k}}.$$

En développant la dernière expression en fraction continue, on trouve que le quotient complet, correspondant à une fraction convergente dont les termes sont du premier degré, est égal à

$$3kz + 1 - \left(\frac{3}{5} k - \frac{1}{9k}\right) \frac{1}{z} + \dots,$$

et que cette fraction est égale à

$$\frac{3kz - 1}{3kz + 1},$$

d'où nous concluons que, dans l'expression approximative de l'intégrale

$$\int_{-1}^{+1} x \varphi(x)\, dx$$

par la formule

$$k \left[\varphi(x_1) - \varphi(x_2) \right]$$

on doit prendre, pour k, une racine de l'équation

$$\frac{3}{5} k - \frac{1}{9k} = 0,$$

et, pour x_1, x_2, respectivement, les racines des équations

$$3kz - 1 = 0, \quad 3kz + 1 = 0.$$

On trouve ainsi deux valeurs de k:

$$k = +\sqrt{\frac{5}{27}}, \quad k = -\sqrt{\frac{5}{27}}$$

et deux systèmes des valeurs de x_1, x_2:

$$x_1 = +\sqrt{\frac{3}{5}}, \quad x_2 = -\sqrt{\frac{3}{5}},$$

$$x_1 = -\sqrt{\frac{3}{5}}, \quad x_2 = +\sqrt{\frac{3}{5}};$$

mais de ces doubles valeurs de k, x_1, x_2, il ne résulte évidemment qu'une seule valeur de l'expression cherchée, savoir:

$$\sqrt{\frac{5}{27}}\left[\varphi\left(\sqrt{\frac{3}{5}}\right)-\varphi\left(-\sqrt{\frac{3}{5}}\right)\right].$$

Pour trouver une expression approximative à quatre termes de l'intégrale

$$\int_{-1}^{+1} x\varphi(x)\,dx$$

on prendra le quotient de la même fraction continue qui correspond à la fraction convergente dont les termes sont du second degré. Comme la valeur complète de ce quotient s'exprime par la série

$$105\,k^2 z - \frac{5832\,k^4 - 945\,k^2 + 35}{243\,k^2 - 45}\,\frac{1}{z} + \dots$$

et qu'il correspond à la fraction convergente

$$\frac{270\,k^2 z^2 - 90\,kz + 10 - 54\,k^2}{270\,k^2 z^2 + 90\,kz + 10 - 54\,k^2},$$

on trouvera les valeurs de la constante k et de x_1, x_2, x_3, x_4 par les équations

$$5832\,k^4 - 945\,k^2 + 35 = 0,$$

$$270\,k^2 z^2 - 90\,kz + 10 - 54\,k^2 = 0,$$

$$270\,k^2 z^2 + 90\,kz + 10 - 54\,k^2 = 0.$$

En les résolvant, on parvient à ces deux expressions approximatives de l'intégrale en question

$$0{,}23937\left[\varphi(0{,}89224)+\varphi(0{,}50030)-\varphi(-0{,}50030)-\varphi(-0{,}89224)\right],$$

et

$$0{,}32363\left[\varphi(0{,}84905)+\varphi(0{,}18093)-\varphi(-0{,}18093)-\varphi(-0{,}84905)\right].$$

10. En passant à la recherche des expressions approximatives de l'intégrale

$$\int_0^{\pi} \cos\theta\varphi(\cos\theta)\,d\theta \quad \text{ou} \quad \int_{-1}^{+1} \frac{x}{\sqrt{1-x^2}}\,\varphi(x)\,dx,$$

nous poserons dans nos formules

$$F(x) = \frac{x}{\sqrt{1-x^2}}$$

Pour cette valeur de $F(x)$ on obtient

$$\int_{-1}^{+1} F(x)\log(z-x)\,dx = \int_{-1}^{+1} \frac{x}{\sqrt{1-x^2}}\log(z-x)\,dx = -\pi\left(z-\sqrt{z^2-1}\right),$$

$$e^{\frac{1}{k}\int_{-1}^{+1} F(x)\log(z-x)\,dx} = e^{-\frac{\pi}{k}\left(z-\sqrt{z^2-1}\right)}.$$

Développant la dernière expression en fraction continue, on trouve les fractions convergentes

$$\frac{4kz-\pi}{4kz+\pi},\quad \frac{48k^2z^2-12k\pi z+\pi^2-12k^2}{48k^2z^2+12k\pi z+\pi^2-12k^2},\ldots,$$

qui correspondent aux quotients complets

$$4kz+\pi-\frac{12k^2-\pi^2}{12k}\,\frac{1}{z}+\ldots,\quad 12kz-\frac{720k^4-60\pi^2k^2+\pi^4}{20\,(12k^2-\pi^2)\,k}\,\frac{1}{z}+\ldots,$$

d'où, d'après le n° 8: 1°, pour la détermination de k, x_1, x_2 dans l'expression approximative de l'intégrale

$$\int_0^\pi \cos\theta\,\varphi(\cos\theta)\,d\theta$$

par la formule

$$k\left[\varphi(x_1)-\varphi(x_2)\right]$$

résultent ces équations

$$12k^2-\pi^2=0,\quad 4kz-\pi=0,\quad 4kz+\pi=0;$$

et 2°, pour la détermination d'une expression semblable à quatre termes, les équations

$$720k^4-60\pi^2k^2+\pi^4=0,$$

$$48k^2z^2-12k\pi z+\pi^2-12k^2=0,$$

$$48k^2z^2+12k\pi z+\pi^2-12k^2=0.$$

Les expressions approximatives de l'intégrale

$$\int_0^\pi \cos\theta\,\varphi(\cos\theta)\,d\theta,$$

que l'on obtient d'après ces équations, se réduisent à celles qui suivent:

$$\int_0^\pi \cos\theta\,\varphi(\cos\theta)\,d\theta = \frac{\pi}{\sqrt{12}}\left\{\varphi(\cos\theta_0) - \varphi\left[\cos(\pi + \theta_0)\right]\right\},$$

$$\int_0^\pi \cos\theta\,\varphi(\cos\theta)\,d\theta =$$

$$0{,}151765\,\pi\left\{\varphi(\cos\theta_1) + \varphi(\cos\theta_2) - \varphi\left[\cos(\pi + \theta_1)\right] - \varphi\left[\cos(\pi + \theta_2)\right]\right\},$$

où

$$\theta_0 = 30^\circ,\quad \theta_1 = 12^\circ,\quad \theta_2 = 48^\circ\ ^{*)}.$$

On trouverait des expressions plus approchées de l'intégrale

$$\int_0^\pi \cos\theta\,\varphi(\cos\theta)\,d\theta,$$

en prenant plus de termes dans la formule

$$k\left[\varphi(x_1) + \varphi(x_2) + \ldots + \varphi(x_m) - \varphi(x_{m+1}) - \varphi(x_{m+2}) - \ldots - \varphi(x_{2m})\right].$$

Nous n'insisterons pas sur la recherche de ces formules; nous remarquerons seulement que, en remplaçant dans toutes ces formules les termes de la forme $\varphi(\cos\theta_\lambda)$ par

$$\frac{1}{l}\left[\varphi\left(\cos\frac{\theta_\lambda}{l}\right) + \varphi\left(\cos\frac{2\pi + \theta_\lambda}{l}\right) + \ldots + \varphi\left(\cos\frac{2(l-1)\pi + \theta_\lambda}{l}\right)\right],$$

où l est un nombre entier, on obtient les expressions approximatives de l'intégrale

$$\int_0^\pi \cos l\theta\,\varphi(\cos\theta)\,d\theta.$$

Ainsi, en partant des formules précédentes, qui donnent les valeurs approchées, à deux et quatre termes, de l'intégrale

$$\int_0^\pi \cos\theta\,\varphi(\cos\theta)\,d\theta,$$

on passerait aux expressions approximatives à $2l$ et $4l$ termes de l'intégrale

$$\int_0^\pi \cos l\theta\,\varphi(\cos\theta)\,d\theta,$$

---

*) Hormis cette expression, il existe une autre aussi aux quatres termes, où

$$k = 0{,}245562\,\pi,\qquad \theta_1 = 24^0,\qquad \theta_2 = 84^0.$$

A. L.

expressions qui peuvent être présentées ainsi:

$$\frac{\pi}{\sqrt{12}\,l}\sum_{\mu=0}^{\mu=2l}(-1)^{\mu}\,\varphi\left(\cos\frac{\mu\pi+\theta_0}{l}\right),$$

$$\frac{0{,}151765\,\pi}{l}\sum_{\mu=0}^{\mu=2l}(-1)^{\mu}\left[\varphi\left(\cos\frac{\mu\pi+\theta_1}{l}\right)+\varphi\left(\cos\frac{\mu\pi+\theta_2}{l}\right)\right],$$

où les signes de sommations s'étendent à $\mu=0,\ 1,\ 2,\ldots,\ 2l-1$.

Exercice.

27. Théorème. — Cercle des neuf points. *Dans un triangle, les milieux des côtés, les pieds des hauteurs et les milieux des droites qui joignent les sommets au point de concours des hauteurs, sont situés sur une même circonférence.*

EULER*, *Mémoires de Saint-Pétersbourg*, 1765.

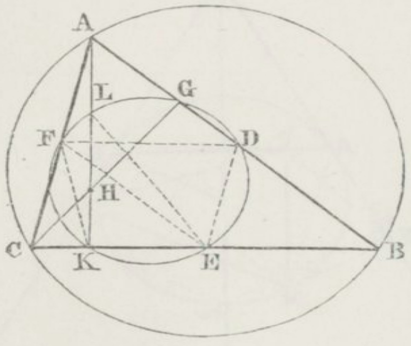

Fig. 11.

Soient D, E, F les points milieux des côtés; AK, CG deux des hauteurs, et L le point milieu de AH.

Circonscrivons une circonférence au triangle DEF.

Pour démontrer le théorème, il suffit de prouver que cette circonférence passe par le pied K, d'une hauteur quelconque, et par le point L, milieu de AH.

1° La droite FK, qui joint le sommet K de l'angle droit au point milieu F de l'hypoténuse, égale la moitié de cette hypoténuse (G., n° 222); donc FK = FC = donc DE.

Ainsi le trapèze EDFK est isocèle; par suite, la circonférence qui passe par E, D, F, passe aussi par le quatrième sommet K.

2° La droite FL, qui joint les points milieux F, L des côtés du triangle ACH, est parallèle à la base CH; d'ailleurs FE est aussi parallèle à AB; donc l'angle EFL égale l'angle AGC, égale donc 90 degrés.

Le quadrilatère EKFL est inscriptible à cause des angles droits EKL, EFL; donc la circonférence qui passe par les trois sommets E, K, F, passe aussi par le quatrième sommet L. *C. Q. F. D.*

28. Scolies. I. *Le centre du cercle des neuf points est au milieu de la droite qui joint le point de concours des hauteurs au centre du cercle circonscrit à ce triangle.*

En effet, le centre se trouve sur les perpendiculaires élevées au milieu de FG et de KE; or ces perpendiculaires passent par le point M, milieu de OH (fig. 12).

---

* EULER, né à Bâle en 1707, mort en 1783, célèbre analyste; perfectionna le *calcul intégral* et fit connaître les cinq surfaces du second degré. (G., n° 857.)

II. — *Le rayon du cercle des neuf points est la moitié du rayon du cercle circonscrit.*

Car $EM = \frac{1}{2} EL = \frac{1}{2} AO$

Cela résulte aussi des triangles semblables EOM, AHO.

III. *La tangente* EJ, *au point milieu d'un côté, et ce même côté sont anti-parallèles par rapport à l'angle opposé.*

Les tangentes EJ, AT sont parallèles, car elles sont perpendiculaires aux rayons parallèles EM, AO ; de plus, l'angle CAT = CBA.

Donc AT et CB ou EJ et CB sont anti-parallèles par rapport à l'angle A.

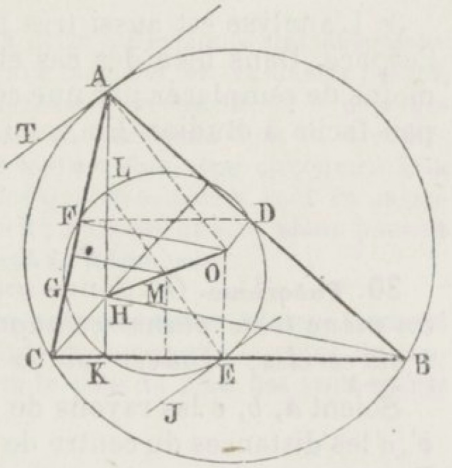

Fig. 12.

Note. Deux droites AT et CB (fig. 12) sont *anti-parallèles* par rapport à un angle CAB, lorsque l'angle CAT, que la première forme avec l'un des côtés de l'angle donné, égale l'angle que forme la seconde droite avec l'autre côté. Ainsi l'angle CAT égale ABC.

La dénomination de lignes anti-parallèles est due à A. ARNAULD *, vers 1667. (*Nouvelles Annales mathématiques* **, 1850, page 409.)

29. Remarque. 1° Le théorème du *cercle des neuf points* peut être démontré de plusieurs manières différentes, mais il n'en est pas de plus élémentaire et de plus rapide que la précédente (n° 27).

2° C'est par l'emploi judicieux de l'analyse que l'on découvre les relations les plus simples qui rattachent entre elles les diverses parties d'une même question et que l'on trouve, par suite, le meilleur mode de démonstration.

---

* ANTOINE ARNAULD, né à Paris en 1612, mort à Bruxelles en 1694, est beaucoup plus connu par son séjour à Port-Royal et par ses œuvres de polémique que par ses *Nouveaux Éléments de géométrie*, publiés en 1667, mais sans nom d'auteur.

** Le journal connu sous le nom de *Nouvelles Annales mathématiques* a été fondé, en 1842, par MM. TERQUEM et GERONO.

M. Terquem, mort en 1862, a été successivement remplacé par MM. E. PROUHET, J. BOURGET, CH. BRISSE, tandis que l'honorable et savant M. GERONO continue à rédiger le journal qu'il a fondé il y a quarante ans.

Nous aurons à citer fréquemment les *Nouvelles Annales*, car cet ouvrage nous a fourni de nombreuses et intéressantes questions et d'utiles renseignements bibliographiques. Les renvois seront indiqués par (N. A., année ..., page ...).

TERQUEM, né à Metz en 1782, mort à Paris en 1862; fut admis à l'École polytechnique en 1801 ; il occupa la chaire de mathématiques transcendantes, au lycée de Mayence, de 1804 à 1814. A partir de cette époque, il fut bibliothécaire au dépôt d'artillerie à Paris, publia divers ouvrages, et collabora assidûment au journal de M. GERONO.

3° L'analyse est aussi très utile lorsqu'il s'agit de la géométrie dans l'espace. Dans bien des cas elle permet de se passer de figure, ou du moins de remplacer par une construction simple une figure compliquée peu facile à étudier. En voici quelques exemples.

Exercice.

30. Théorème. *On donne une sphère et un point fixe* P; *par ce point on mène trois plans rectangulaires deux à deux et qui déterminent trois cercles; prouver que la somme de ces trois cercles est constante.*

Soient a, b, c les rayons de ces cercles, r le rayon de la sphère et a', b', c' les distances du centre de la sphère aux cercles; il faut prouver que l'on a :

$$\pi a^2 + \pi b^2 + \pi c^2 = \text{constante}$$

ou, ce qui revient au même, $a^2 + b^2 + c^2 =$ une valeur constante

mais $a^2 = r^2 - a'^2;\quad b^2 = r^2 - b'^2;\quad c^2 = r^2 - c'^2$

on a donc $a^2 + b^2 + c^2 = 3r^2 - (a'^2 + b'^2 + c'^2)$

Il suffit de prouver que la quantité à soustraire est constante.

Or les trois distances a', b', c', perpendiculaires deux à deux, menées du centre O sur les trois plans rectangulaires, dont P est le point commun, sont les trois arêtes latérales d'un parallélépipède rectangle ayant PO pour diagonale; par suite, la somme des carrés de ces arêtes égale PO^2 (G., n° 439), et le théorème est démontré.

31. Remarque. La détermination de la valeur constante n'offre aucune difficulté.

Ainsi $a^2 + b^2 + c^2 = 3r^2 - PO^2$

donc $\pi a^2 + \pi b^2 + \pi c^2 = 3\pi r^2 - \pi PO^2$

La somme des trois cercles déterminés par le trièdre tri-rectangle dont P est le sommet, égale trois grands cercles moins le cercle qui aurait PO pour rayon.

Exercice.

32. Théorème. *Lorsque les arêtes opposées d'un octaèdre inscrit dans une sphère sont dans un même plan, les trois diagonales de l'octaèdre se coupent au même point. En menant un plan tangent à la sphère par chaque sommet de l'octaèdre, on forme un hexaèdre circonscrit dont les faces, prises quatre à quatre, concourent en un même point.* (G., n° 429.)

1° Les arêtes opposées étant dans un même plan, les deux diagonales qui joignent les extrémités des arêtes opposées se coupent, car elles sont deux à deux dans un même plan. Les trois diagonales de l'octaèdre ne peuvent être

Further Geometry of Differentiation

I Cauchy-Riemann Revealed

1 Introduction

In the previous chapter we began to investigate the remarkable nature of analytic functions in $\mathbb{C}$ by studying mappings in the less structured realm of $\mathbb{R}^2$. In particular the Jacobian provided us with a painless way of deriving the Cauchy-Riemann characterization of analytic functions, and also of computing their amplitwists. However, this approach was rather indirect. In this chapter we will instead study differentiation directly in the complex plane, primarily through the use of infinitesimal geometry. Our first application of this approach will be the rederivation of the Cauchy-Riemann (henceforth " CR) equations, and the discovery of new forms that they can take on.

2 The Cartesian Form

Consider a very fine mesh of squares aligned with the real and imaginary axes. See the top left of [1]. Under an analytic mapping each infinitesimal square will be amplitwisted to produce an image that is also square. We will show that the CR equations are nothing more than a symbolic restatement of this geometric fact.

Zoom in on an individual square and its image, as depicted in the bottom half

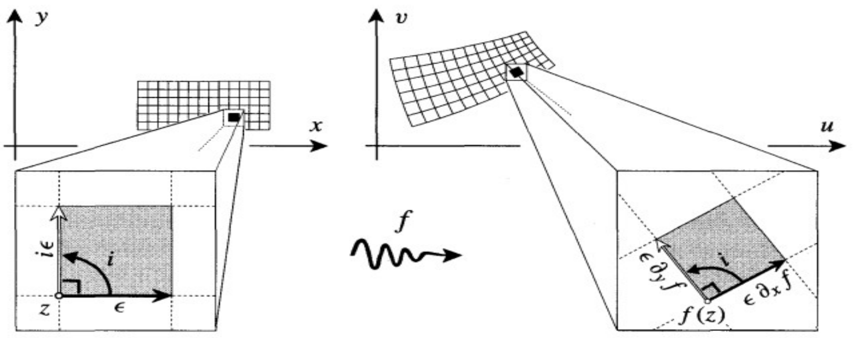

Figure [1]

of [1]. Suppose, as drawn, that the initial square has side ϵ. If we start at z and then move a distance ϵ in the x-direction, the image will move along a complex number given by

$$\text{(change in } x)\cdot\text{(rate of change with x of the image f)} = \epsilon\, \partial_x f.$$

Similarly, if the point moves along the vertical edge by going ϵ in the y-direction, then its image will move along $\epsilon\, \partial_y \mathbf{f}$. Now since these two image vectors span a square they must be related by a simple rotation of $\pi/2$, that is by multiplication with i. After cancelling ϵ, we thus obtain

$$i\,\partial_x f = \partial_y f,$$

et voilà! That this is indeed a compact form of the CR equations may be seen by inserting $\mathbf{f} = u + \mathrm{i}v$:

$$i\,\partial_x(u + \mathrm{i}v) = \partial_y(u + \mathrm{i}v),$$

and then equating real and imaginary parts to yield

$$\partial_x u = \partial_y v \quad \text{and} \quad \partial_x v = -\partial_y u, \tag{1}$$

just as before. To obtain the amplitwist itself, we recall that each infinitesimal arrow is taken to its image by multiplication with $\mathbf{f}'$. Now, since we know what the images are for the two sides of the square, we can deduce

$$\begin{aligned} \epsilon \longmapsto \epsilon\, f' &= \epsilon\, \partial_x f \\ \Rightarrow f' &= \partial_x f \end{aligned}$$

and

$$\begin{aligned} i\epsilon \longmapsto i\epsilon\, f' &= \epsilon\, \partial_y f \\ \Rightarrow f' &= -i\, \partial_y f. \end{aligned}$$

3 The Polar Form

Equation (1) is the most common way of writing CR, but it isn't the only way. It took this form because we chose to describe both complex planes in terms of their real and imaginary parts, that is with Cartesian coordinates. Thus we could briefly describe (1) as being the Cart.-Cart. form. In Ex. 10, p. 212 we retained Cartesian coordinates for the first plane but employed polar coordinates in the image plane; this led to another form (Cart.-Polar) of CR. As the next example of our geometric method we will derive the Polar-Cart. form of the equations.

In order to do this, we begin with an infinitesimal square adapted to polar coordinates. See [2]. If we start at z and increase r by $\mathrm{d}r$, then we obtain $e^{i\theta}\,\mathrm{d}r$

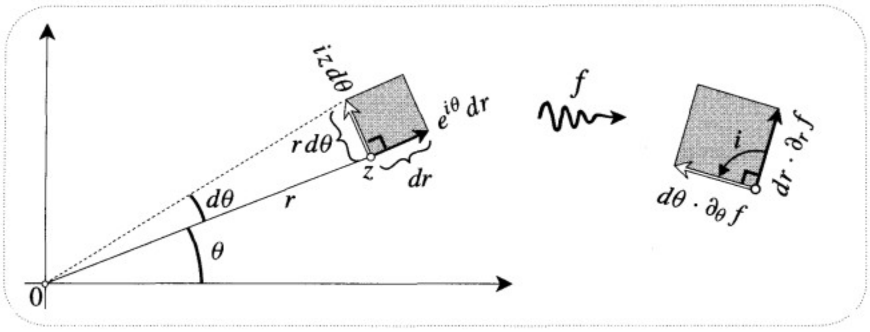

Figure [2]

as the radial edge. If, on the other hand, we increase 0 by $d\theta$, then the point will move in the perpendicular direction given by ie^{iB}. As $d\theta$ tends to zero, this edge is ultimately equal to an infinitesimal arc of circle of length $r\,d\theta$; the complex number describing it will therefore be i $e^{iB}\,r\,d\theta = i\,z\,d\theta$. It's also clear from our picture that

$$\text{initially square} \qquad \mathrm{d\,r} = r\,d\theta. \tag{2}$$

Now look at the image. Just as before, if we increase r by $\mathrm{d\,r}$ then the image will move along $\mathrm{d\,r} \cdot \partial_r \mathrm{f}$; likewise, changing θ by $d\theta$ will move the image along $d\theta \cdot \partial_\theta \mathbf{f}$. If the mapping is analytic then these again span a square, and so the latter must be i times the former:

$$d\theta \cdot \partial_\theta f = i dr \cdot \partial_r f.$$

Substituting (2) into this, and cancelling $d\theta$, we obtain

$$\partial_\theta f = ir\,\partial_r f \tag{3}$$

as the new compact form of CR. By inserting $\mathbf{f} = u + \mathrm{i}v$, the reader may verify that **(3)** is equivalent to the following pair of Polar-Cart. equations:

$$\partial_\theta v = +r\,\partial_r u \tag{4}$$

$$\partial_\theta u = -r\,\partial_r v. \tag{5}$$

By examining the amplitwist that carries each arrow to its image we can also obtain two expressions for the derivative:

$$\begin{aligned} e^{i\theta}\,dr \longmapsto e^{i\theta}\,dr \cdot f' &= dr \cdot \partial_r f \\ \Longrightarrow f' &= e^{-i\theta}\,\partial_r f \end{aligned} \tag{6}$$

and

$$i\,z\,d\theta \longmapsto i\,z\,d\theta \cdot f' \;=\; d\theta \cdot \partial_\theta f$$

$$\Longrightarrow f' \quad = \quad -(i/z)\,\partial_\theta f. \qquad (7)$$

As a simple example let's take $z^3 = r^3\,e^{3i\theta}$. From *(6)* we obtain

$$(z^3)' = e^{-i\theta}\,3r^2\,e^{3i\theta} = 3r^2\,e^{2i\theta} = 3z^2,$$

while from (7) we obtain

$$(z^3)' = -(i/z)\,r^3\,3i\,e^{3i\theta} = -(i/z)\,3i\,z^3 = 3z^2.$$

In obtaining the same answer from both these expressions we have also verified that z^3 actually was analytic in the first place.

Of the four possible ways of writing CR, only one now remains to be found, namely the Polar-Polar form. We leave it to the reader to verify that if we write $f = R\,e^{i\Psi}$ (cf. Ex. *10,* p. 212) then CR takes the form

$$\partial_\theta R = -r\,R\,\partial_r \Psi \quad \text{and} \quad R\,\partial_\theta \Psi = r\,\partial_r R.$$

II An Intimation of Rigidity

A recurring theme in complex analysis is the "rigidity" of analytic functions. By this we mean that their highly structured nature (everywhere locally an amplitwist) enables us to pin down their precise behaviour from very limited information. For example, even if we are only told the effect of an analytic function on a small region, then its definition can be extended beyond these confines in a unique way—like a crystal grown from a seed. In fact, given even the meagre knowledge of how an analytic mapping affects a closed curve (just the points *on* the curve mind you), we can predict precisely what happens to each point *inside!* See [3]. Later we will justify these wild claims, and in Chapter 9 we will even find an explicit formula (due to Cauchy) for w in terms of A, B, C, etc. For the moment, though, we will

CHAPTER 9 CURVES AND VECTORS IN R^2

67. CURVES IN GENERAL. PARAMETRIC EQUATIONS

In Sec. 30 we introduced the notion of a curve as a geometric figure which can be drawn without lifting pen from paper. Then we imposed the extra condition that the figure be the graph of a function (of x). Geometrically, this means that no line parallel to the y-axis intersects the curve more than once, or equivalently, that the pen moves steadily in one direction, from left to right or from right to left. To remove this unnatural restriction, which was only imposed temporarily to keep things simple, we make the point P traced out by the pen a function of a new real variable t, which can be thought of as the *time* at which P occupies one position or another. Thus Figure 9.1 shows a curve C and indicates the positions of a variable point P of C at various times.

More generally, we can think of t as any *parameter*, i.e., any real variable (not necessarily the time) uniquely determining the position of P. This is in keeping with the definition of a parameter on p. 446, as an “arbitrary constant each value of which characterizes a particular member of a set.” For example, in Figure 9.1 we can specify the position of P by giving the values of $t + 1$ or even of e^t, since knowledge of either $t + 1$ or e^t uniquely determines t and hence the position of P. Let x and y be the coordinates of P in a given rectangular coordinate system. Then specifying P as a function of t is the same as specifying x and y as functions of t, i.e., writing down a pair of equations

$$x = f(t), \qquad y = g(t), \tag{1}$$

called *parametric equations* of the curve since they involve a parameter t. Here it is tacitly assumed that the functions f and g have the same domain T. It is also assumed that f and g are not both constant, since otherwise C would reduce to a point. By the *graph* of (1), we mean the geometric figure obtained by plotting the point $P = (x, y) = (f(t), g(t))$ for every $t \in T$. If the graph of $x = f(t)$, $y = g(t)$ is a curve, we often save words by saying merely “the curve $x = f(t)$, $y = g(t)$.”

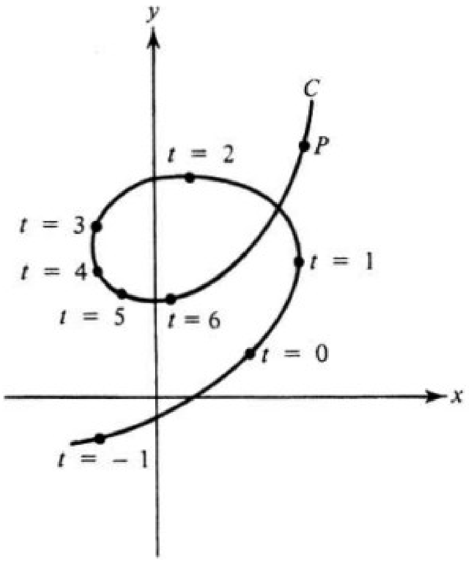

FIGURE 9.1

As on p. 217, we now require that T be some interval (closed, open or half-open, finite or infinite) and that f and g both be continuous in T. In other words, by a *curve* we mean the graph of a pair of parametric equations (1) where *the domain of f and g is an interval in which f and g are both continuous*. More concisely, a curve is the "continuous image of an interval." Roughly speaking, this means that the graph of (1) has no "gaps" and can be drawn without lifting pen from paper.[†] However, the graph of (1) may have no gaps even if the italicized condition is violated. (Why can't a similar complication occur in the case of the graph of a function $y = f(x)$?) For example, the symbol ∅ is most easily drawn by lifting pen from paper, corresponding to a pair of equations (1) with discontinuous f and g, or with a domain T other than an interval. On the other hand, it can also be drawn *without* lifting pen from paper, since we are now allowed to "trace back" over portions of a curve. In other words, ∅ is a curve, since it is the graph of some other pair of equations

$$x = f^*(t), \qquad y = g^*(t) \qquad (t \in T^*),$$

where T^* is an interval with f^* and g^* both continuous in T^*. Hence in talking about a curve $x = f(t)$, $y = g(t)$, $t \in T$, there is no loss of generality in assuming from the outset that T is an interval with f and g both continuous in T, and *we will do so from now on, writing I (for interval) instead of T.*

REMARK. By an *arc* of a curve with parametric equations

$$x = f(t), \qquad y = g(t) \qquad (t \in I),$$

we mean any curve with parametric equations

$$x = f(t), \qquad y = g(t) \qquad (t \in I')$$

where I' is a subinterval of I.

Example 1. The curve

$$y = \varphi(x) \qquad (a \le x \le b)$$

can be “represented in parametric form” by identifying x with the parameter t:

$$x = t, \qquad y = \varphi(t) \qquad (a \le t \le b).$$

Similarly, the graph of

$$x = \psi(y) \qquad (a \le t \le b),$$

(where ψ is continuous) is a curve, as we see by identifying y with the parameter t:

$$x = \psi(t), \qquad y = t \qquad (a \le t \le b).$$

Example 2. The curve with polar equation

$$r = f(\theta) \qquad (\alpha \le \theta \le \beta)$$

can be represented in parametric form with the angle θ as parameter by noting that

$$x = r\cos\theta, \qquad y = r\sin\theta,$$

and hence

$$x = f(\theta)\cos\theta, \qquad y = f(\theta)\sin\theta \qquad (\alpha \le \theta \le \beta)$$

(recall p. 505).

Example 3. The curve

$$x = a\cos t, \qquad y = b\sin t \qquad (0 \le t \le 2\pi) \tag{2}$$

is an ellipse if $a > 0$, $b > 0$, $a \neq b$. In fact, eliminating the parameter t from the two equations, we have

$$\frac{x}{a} = \cos t, \qquad \frac{y}{b} = \sin t,$$

and hence

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = \cos^2 t + \sin^2 t = 1, \tag{3}$$

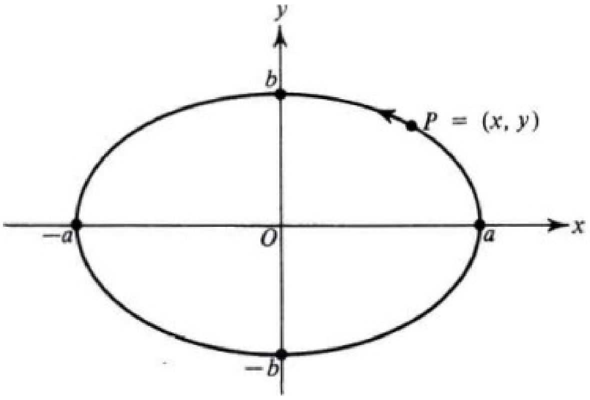

FIGURE 9.2

which we immediately recognize as the equation of the ellipse shown in Figure 9.2. Hence any point satisfying (2) belongs to the ellipse (3).

To see that the graph of (2) *coincides* with the ellipse, we examine the behavior of the variable point $P = (x, y) = (a \cos t, b \sin t)$ as t increases from 0 to 2π. For $t = 0$, P coincides with the vertex $(a, 0)$ of the ellipse. As t increases from 0 to $\pi/2$, x decreases to 0 and y increases to b, so that P describes the part of the ellipse in the first quadrant. As t increases further, P describes the rest of the ellipse, returning to the point $(a, 0)$ for $t = 2\pi$. If t is increased still further, P begins to trace out the ellipse once again. In fact, since cos t and sin t are both periodic, with fundamental period 2π, it is clear that P makes one complete circuit around the ellipse in the counterclockwise direction as P increases from t_0 to $t_0 + 2\pi$i, where r_0 is arbitrary. However, if $\delta < 2\pi$, then P describes only part of the ellipse as t increases from t_0 to $t_0 + \delta$.

It is easy to see that (2) represents the same ellipse (3) even if a or b is allowed to be negative, except that the ellipse is traced out in the clockwise direction if $ab < 0$. If $a = b$, (3) becomes the circle $x^2 + y^2 = a^2$, with parametric representation

$$x = a \cos t, \qquad y = a \sin t \qquad (0 \le t \le 2\pi)$$

(cf. p. 305). There is nothing unique about the parametric representation of a curve. For example, the equations

$$x = a \sin t, \qquad y = a \cos t \qquad (0 \le t \le 2\pi)$$

or even

$$x = a \cos \ln t, \qquad y = a \sin \ln t \qquad (1 \le t \le e^{2\pi})$$

represent the same circle $x^2 + y^2 = a^2$.

If $a = 0$, $b \neq 0$, the curve (2) reduces to the vertical line segment joining the points $(0, -b)$ and $(0, b)$, while if $a \neq 0$, $b = 0$, (2) reduces to the horizontal line segment joining the points $(-a, 0)$ and $(0, a)$, both segments being traversed twice. The case $a = b = 0$ is excluded, since then the curve reduces to the single point $(0, 0)$.

Example 4. Consider the curve

$$x = a \cosh t, \qquad y = b \sinh t \qquad (-\infty < t < +\infty), \tag{4}$$

where $a > 0$, $b > 0$. Eliminating t from the two equations, we get

$$\frac{x}{a} = \cosh t, \qquad \frac{y}{b} = \sinh t,$$

hence

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = \cosh^2 t - \sinh^2 t = 1, \tag{5}$$

which we immediately recognize as the equation of the hyperbola shown in Figure 9.3. Hence any point satisfying (4) belongs to the hyperbola (5). However, there are points of the hyperbola which do not satisfy (4), and in fact (4) represents only the right-hand branch of the hyperbola (the solid curve in Figure 9.3). To see this, we merely note that as t increases from $-\infty$ to 0, x decreases from $+\infty$ to a and y decreases from $-\infty$ to 0 (recall the properties of the hyperbolic functions from Sec. 40), while as t increases from 0 to $+\infty$, x increases from a to $+\infty$ and y increases from 0 to $+\infty$. In other words, the variable point $P = (x, y) = (a \cosh t, b \sinh t)$ moves upward along the right-hand branch of (5). If b is negative, then (4) gives the right-hand branch of (5) traversed in the *downward* direction. On the other hand, if a is replaced by $-a$ ($a > 0$), (4) gives the left-hand branch of (5) (the dashed curve in the figure), traversed in the upward direction if $b > 0$ and in the downward direction if $b < 0$. Moreover, the graph of (4) is the y-axis if $a = 0$, $b = 0$, the interval $(a, +\infty)$ if $a > 0$, $b = 0$, and the interval $(-\infty, -a]$ if a is replaced by $-a$, $b = 0$ (check all these claims).

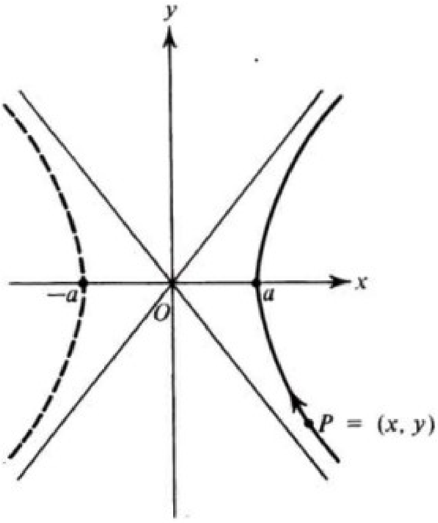

FIGURE 9.3

Example 5. Suppose a circle of radius a rolls without sliding along a horizontal straight line. Find the curve described by a fixed point P of its circumference.

Solution. Let the straight line be the x-axis, and let t be the angle through which the circle has rotated starting from a position in which P coincides with the origin O. Then the curve described by P, called a *cycloid*, has parametric equations

$$x = a(t - \sin t), \qquad y = a(1 - \cos t) \qquad (-\infty < t < +\infty). \tag{6}$$

In fact, examining Figure 9.4, we find that P has abscissa

$$x = |OQ| = |OO'| - a \sin t.$$

But $|OO'|$ equals the length of the arc $\widehat{O'P}$, since the circle rolls without sliding. Thus $|OO'| = at$, and hence

$$x = at - a \sin t = a(t - \sin t).$$

Similarly, we have

$$y = |O'A'| - a \cos t = a(1 - \cos t).$$

Note that this curve is the graph of a function $y = \varphi(x)$, where φ is periodic with period $2\sigma a$. However, to find φ explicitly, we would have to eliminate t from the equations (6) and then solve the resulting equation, of the form $F(x, y) = 0$, for y as a function of x. This is a formidable calculation, and a pointless one at that, since we can find out anything we want to know about the cycloid directly from the parametric equations (6).

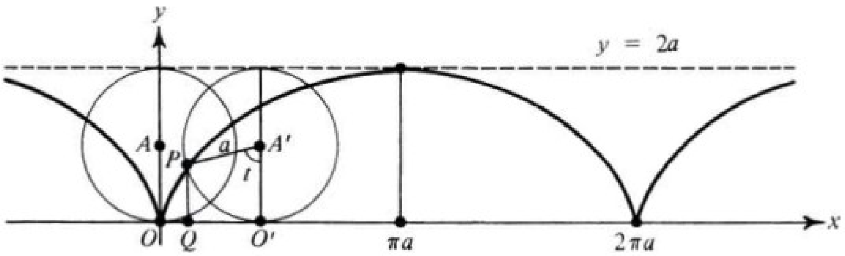

FIGURE 9.4

In general, of course, the curve with parametric equations

$$x = f(t), \qquad y = g(t) \qquad (a \le t \le b)$$

will not be the graph of any function

$$y = \varphi(x) \qquad (A \le x \le B).$$

For example, the unit circle

$$x = \cos t, \qquad y = \sin t \qquad (0 \le t \le 2\pi)$$

cannot be the graph of a function, since every line $x = c$, $-1 < c < 1$ cuts the circle *twice*. In fact, as noted in Example 2, p. 86, the circle is the union of the graph of

$$y = \sqrt{1 - x^2}$$

(the upper unit semicircle) and the graph of

$$y = -\sqrt{1 - x^2}$$

(the lower unit semicircle). On the other hand, every point P of the circle except the points $(-1, 0)$ and $(1, 0)$ belongs to either the upper semicircle or to the lower semicircle, i.e., to an arc of the circle which is the graph of a function.

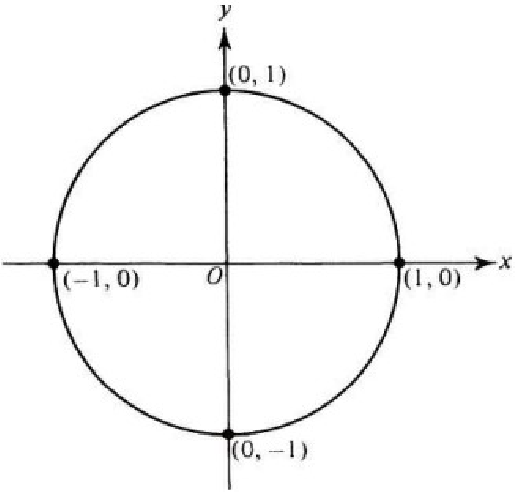

FIGURE 9.5

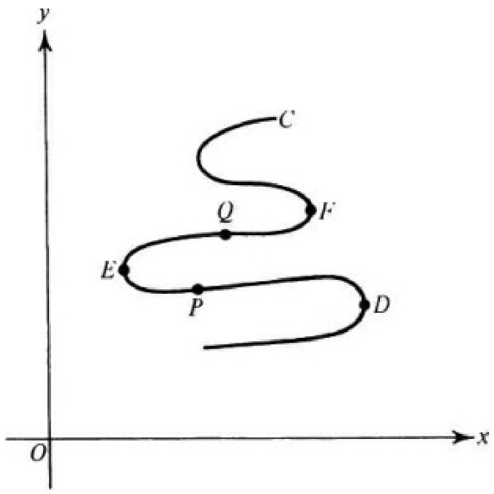

FIGURE 9.6

The same cannot be said of the points (−1, 0) and (1, 0), since any arc of the circle containing one of these points must overlap both the upper and the lower semicircles (see Figure 9.5). Similarly, the point P of the curve C shown in Figure 9.6 belongs to the arc $\widehat{DE}$ which is the graph of a function, the point Q belongs to the arc $\widehat{EF}$ which is the graph of a function, and so on, although the "extreme points" D, E, F themselves cannot be ascribed to arcs of the curve which are graphs of functions. In other words, an arc of a curve may be the graph of a function even though the curve *as a whole* is not. This is the substance of

THEOREM 9.1. *Given a curve*

$$x = f(t), \qquad y = g(t) \qquad (a \le t \le b),$$

where the functions f and g are differentiable in an open interval $(\alpha, \beta) \subset [a, b]$, *suppose the derivative*

$$\frac{dx}{dt} = f'(t)$$

does not change sign or vanish in (α, β). *Then the arc*

$$x = f(t), \qquad y = g(t) \qquad (\alpha < t < \beta) \tag{7}$$

(*part of the original curve*) *is the graph of a differ entiable function*

$$y = \varphi(x) \qquad (A < x < B),$$

and

$$\frac{dy}{dx} = \frac{g'(t)}{f'(t)}. \tag{8}$$

Moreover, if the functions f and g can be differentiated n times, so can the function φ.

Proof. Suppose $f'(t) > 0$ in (α, β). Then it follows from Theorem 6.24, p. 317, that f is increasing in $[\alpha, \beta]$. Therefore, by Theorem 6.9, p. 273, the inverse function $t = f^{-1}(x)$ exists and is continuous in $[f(\alpha), f(\beta)]$. Hence, as asserted, the arc (7) is the graph of the function

$$y = g(t) = g(f^{-1}(x)) \equiv \varphi(x) \qquad (A < x < B),$$

where $A = f(\alpha)$, $B = f(\beta)$.† Moreover, by the rule for differentiating an inverse function (Theorem 6.10, p. 280), dt/dx exists and equals

$$\frac{1}{\dfrac{dx}{dt}} = \frac{1}{f'(t)},$$

since $f'(t)$ does not vanish in (α, β). Hence

$$\frac{dy}{dx} = \frac{dy}{dt}\,\frac{dt}{dx} = \frac{\dfrac{dy}{dt}}{\dfrac{dx}{dt}} = \frac{g'(t)}{f'(t)},$$

by the rule for differentiation of a composite function (Theorem 5.6, p. 232). (The same argument has already been used on p. 506 to find the slope of a curve with polar equation $r = f(\theta)$.) If f and g are differentiable n times in (α, β), then

$$\begin{aligned} \frac{d^2y}{dx^2} &= \frac{d\left(\dfrac{dy}{dx}\right)}{dt}\,\frac{dt}{dx} = \frac{1}{f'(t)}\,\frac{d}{dt}\left[\frac{g'(t)}{f'(t)}\right] \\ &= \frac{g''(t)f'(t) - g'(t)f''(t)}{[f'(t)]^3}, \end{aligned} \tag{9}$$

and similarly for higher-order derivatives. ▌

REMARK 1. The conclusion that the arc (7) can be represented as the graph of $y = \varphi(x)$ remains valid even if $f'(t)$ vanishes at points of (α, β), provided $f'(f)$ is nonnegative (or nonpositive) and does not vanish in any subinterval of (α, β). This follows at once from Theorem 6.24. However, we can only use formula (8) at points where $f'(t) \neq 0$.

REMARK 2. The variables x and y are on a completely equal footing here. Thus suppose the derivative

$$\frac{dy}{dt} = g'(t)$$

does not change sign or vanish in (α, β). Then the arc (7) is the graph of a function of the form

$$x = \psi(y) \qquad (A < y < B)$$

(where now x is the dependent variable and y the independent variable), and

$$\frac{dx}{dy} = \frac{f'(t)}{g'(t)}.$$

For example, every point of the unit circle except the points (0, −1) and (0, 1) belongs to an arc of the circle which is the graph of a function of y, i.e., either to the right-hand semicircle

$$x = \sqrt{1 - y^2}$$

or to the left-hand semicircle

$$x = -\sqrt{1 - y^2}.$$

The same cannot be said about the points (0, −1) and (0, 1), since every arc of the circle containing one of these points must overlap both the right-hand and the left-hand semicircles (see Figure 9.5). However, *every* point of the unit circle belongs to an arc of the circle which is the graph of a function if we allow both functions of x and functions of y. Similarly, the points D, E, F of the curve C shown in Figure 9.6 now belong to arcs of the curve which are graphs of functions of the form $x = \psi(y)$.

Example 6. For the cycloid (6), we have

$$\frac{dx}{dt} = a(1 - \cos t) > 0 \tag{10}$$

unless

$$t = 2n\pi \qquad (n = 0, \pm 1, \pm 2, \ldots),$$

in which case

$$\frac{dx}{dt} = 0.$$

It follows from Theorem 9.1 and Remark 1 that the cycloid *as a whole* is the graph of a function $y = \varphi(x)$, as already noted. Moreover, (8) gives

$$\frac{dy}{dx} = \frac{\dfrac{dy}{dt}}{\dfrac{dx}{dt}} = \frac{\sin t}{1 - \cos t} = \cot\frac{t}{2} \tag{11}$$

if $t \neq 2n\pi$, i.e., if $x \neq 2n\pi a$. If $t = 2n\pi$, we cannot use (11), but then a direct calculation shows that $dy/dx = \infty$, corresponding to the vertical tangents to the cycloid at the points $(2n\pi a, 0)$ (see Figure 9.4).†

Since (10) holds in any interval $(2n\pi, (2n + 1)\pi)$ and the functions (6) can be differentiated any number of times, it follows from Theorem 9.1 that y can be differentiated any number of times with respect to x. In particular, using (9), we get

$$\frac{d^2y}{dx^2} = \frac{(1 - \cos t)\cos t - \sin^2 t}{a(1 - \cos t)^3} = -\frac{1}{a(1 - \cos t)^2} < 0.$$

Hence the curve is concave downward in every interval $(2n\pi, (2n + 1)\pi)$, as confirmed by Figure 9.4.

Problem Set 67

1. For what values of the parameter t does each of the following points lie on the indicated curve:
  - a) $(-9, 0)$ on $x = 3(2 \cos t - \cos 2t)$, $y = 3(2 \sin t - \sin 2t)$;
  - b) $(3, 2)$ on $x = t^2 + 2t$, $y = t^3 + t$;
  - c) $(2, 2)$ on $x = 2 \tan t$, $y = 2 \sin^2 t + \sin 2t$;
  - d) $(0, 0)$ on $x = t^2 - 1$, $y = t^3 - t$?

2. Write parametric equations for the square with vertices (0, 0), (1, 0), (1, 1) and (0, 1).

3. Find dy/dx if
  - a) $x = t^2$, $y = 2t$;
  - b) $x = \cos t$, $y = t + \sin t$;
  - c) $x = a \cos^2 t$, $y = b \sin^2 t$;
  - d) $x = \cos^3 t$, $y = \sin^3 t$;
  - e) $x = e^t \sin t$, $y = e^t \cos t$.

4. Prove that if

$$x = \frac{1 + \ln t}{t^2}, \qquad y = \frac{3 + 2 \ln t}{t} \qquad (t > 0),$$

then

$$y\frac{dy}{dx} = 1 + 2x\left(\frac{dy}{dx}\right)^2.$$

5. Find the slope of the tangent to the curve
  - a) $x = 3 \cos t$, $y = 4 \sin t$ at $(\frac{3}{2}\sqrt{2}, 2\sqrt{2})$;
  - b) $x = t - t^4$, $y = t^2 - t^3$ at $(0, 0)$;
  - c) $x = t^3 + 1$, $y = t^2 + t + 1$ at $(1, 1)$;
  - d) $x = 2 \cos t$, $y = \sin t$ at $(1, -\frac{1}{2}\sqrt{3})$.

6. Find d^2y/dx^2 if
  - a) $x = 2t^2$, $y = 3t^3$;
  - b) $x = a \cos t$, $y = b \sin t$;
  - c) $x = \cos^3 t$, $y = \sin^3 t$;
  - d) $x = t \cos t$, $y = t \sin t$.

7. Prove that if $x = \sin t$, $y = \sin at$, then

$$(1 - x^2)\frac{d^2y}{dx^2} - x\frac{dy}{dx} + a^2y = 0.$$

q_2 = Line$(G_1, I_1) \rightarrow$
$-4.24x + 4.24y =$
-6.36

Jandala

J_1 = Intersect(n, p) → (3, 1.5)

r_2 : Line(J_1, k) → $x = 3$

K_1 = Intersect (l_2, m_2) → (5.12, 3.62)

s_2 : Line(K_1, k) → $x = 5.12$

L_1 = Intersect(b_1, e_1) → (7.24, 5.74)

t_2 : Line(L_1, k) → $x = 7.24$

M_1 = Intersect(s_2, a) → (5.12, 0.62)

N_1 = Intersect (s_2, m_1) → (5.12, 6.62)

O_1 = Intersect (g_1, n_1) → (4.24, 10.24)

a_2 : PerpendicularLine (O_1, l_2) → $y = 10.24$

P_1 = Intersect(r_2, a_2) → (3, 10.24)

Q_1 = Intersect(s_2, a_2) → (5.12, 10.24)

R_1 = Intersect(t_2, a_2) → (7.24, 10.24)

S_1 = Intersect(r_2, n) → (3, 1.5)

b_2 = Segment(S_1, P_1) → 8.74

T_1 = Intersect(s_2, l_2) → (5.12, 3.62)

c_2 = Segment(T_1, Q_1) → 6.62

U_1 = Intersect(t_2, b_1) → (7.24, 5.24)

d_2 = Segment(U_1, R_1) → 4.5

e_2 = Segment(P_1, R_1) → 4.24

V_1 = Intersect(b_1, e_1) → (7.24, 5.74)

f_3 = Segment(S_1, V_1) → 6

α = Angle(V_1, S_1, P_1) → 45°

Source: 8 unidades em 3D →

(2) m01-3D-20210728-05.ggb

Checagem dos passos: (20210728)

A = (0, 0)

B = (0, 6)

C = (6, -3)

D = (6, 3)

E = (1, 1)

F = (7, -2)

G = (1, 7)

H = (7, 4)

f: Ray(A, E) → $-x+y=0$

g: Ray(C, F) → $-x+y=-9$

h: Ray(B, G) → $-x+y=6$

i: Ray(D, H) → $-x+y=-3$

Circles nos pontos
A, B, C e D
usando o segmento
$\overline{AB}$.

Ex:

c : Circle(A, Segment(A, B))
→ $x^2+y^2=36$

d : Circle(B, Segment(A, B))
→ $x^2+(y-6)^2=36$

e : Circle(C, Segment(A, B))
→ $(x-6)^2+(y+3)^2=36$

k : Circle(D, Segment(A, B))
→ $(x-6)^2+(y-3)^2=36$

Intersect das
retas com os
círculos:

I = Intersect(c, f, 1)
→ (4.24, 4.24)

J = Intersect(d, h, 1)
→ (4,24, 10.24)

K = Intersect(e, g, 1)
→ (10.24, 1.24)

L = Intersect(k, i, 1)
→ 10,24, 7.24)

Não deixe visível os
Raios e os Círculos,
deixando os pontos de
intersecção visíveis para
podermos fazer as
retas do cubo.
Apague também os
pontos (esconder):
E, F, G e H.

Erro:

Distância $\overline{AC}=6,71$

tinha que ser 6,00

vou refazer
colocando

2 arestas sobre o
eixo x e y.

(menos chance de
erro)

Check 02 (20210728).

A = Intersect (xAxis, yAxis) - ⇒ (0, 0)

B = Point(xAxis) → (6, 0)

C = Point(yAxis) → (0, 6)

D = (6, 6)

—— 45°

E = (1, 1)

F = (7, 1)

G = (1, 7)

H = (7, 7)

Criar os Rays:

f: Ray(A, E) → $-x + y = 0$

Usarei a mesma reta no ponto D → continuidade da reta

Obs: a mesma reta AE continua em DH.

g: Ray(B, F) → $-x + y = -6$

h: Ray(C, G) → $-x + y = 6$

Criar os círculos e as interseções sobre os Rays $\overline{AE}$, $\overline{BF}$, $\overline{CG}$ e $\overline{DH}$.

Usando a função COMPASS:

c: Circle(A, Segment(A, C))
→ $x^2+y^2=36$

d: Circle(B, Segment(A, C))
→ $(x-6)^2+y^2=36$

e: Circle(C, Segment(A, C))
→ $x^2+(y-6)^2=36$

k: Circle(D, Segment(A, C))
→ $(x-6)^2+(y-6)^2=36$

obs: Alterar as cores destes círculos.

Usar o comando Intersect:

I = Intersect(c, f, 1) → (4.24, 4.24)
J = Intersect(d, g, 1) → (10.24, 4.24)
K = Intersect(e, h, 1) → (4.24, 10.24)
L = Intersect(k, f, 2) → (10.24, 10.24)

Obs: Esconda os círculos e os Rays, deixando apenas as interseções.

Depois, criaremos as retas do cubo.

Fazer os segmentos do Cubo:

i = Segmento(A, C) → 6 (altera a cor já)

j = Segment(B, D) → 6

Crie o ponto M=(3, 3)

Crie os novos segmentos:

l = Segment(C, M) → 4.24

m = Segment(M, D) → 4.24

n = Segment(A, I) → 6 (preto)

p = Segment(B, J) → 6 (preto)

q = Segment(C, K) → 6 (preto)

r = Segment(D, L) → 6 (preto)

s = Segment(I, K) → 6 (vermelho)

t = Segment(J, L) → 6 (Vermelho)

Novos comandos:

a: PerpendicularBisector(I, K) → y = 7.24

obs: Vale para o segmento s(I, K) e t(J, L)

Intersect:

N = Intersect(a, s) → (4.24, 7.24)

O = Intersect(a, t) → (10.24, 7.24)

Obs: Esconda a linha **a**.

Important: Crie:

b: PerpendicularBisector(N, O) → x = 7.24

Importante observar que este ponto coincide com a reta r(D, L) → somente na perspectiva.

Obs: reta a cobre a reta r. (interseção visual, mas não real).

Criemos a interseção:

P = Intersect(a, b) → (7.24, 7.24)

Obs: Agora sim, esconda o segmento **a e b**.

Crie os segmentos:

f_1 = Segment(K, P) → 4.24 (vermelho)

g_1 = Segment(P, L) → 4.24 (vermelho)

Divisão de segmentos:

Segmentos $\overline{CK}$ e $\overline{DL}$ com o comando Bisector

h_1: PerpendicularBisector(C, K):
$\Rightarrow -4.24x - 4.24y = -43.46$

i_1: Perpendicular Bisector(D, L):
$\Rightarrow -4.24x - 4.24y = -68.91$

Intersect:

R = Intersect(h_1, g) → (2.12, 8.12)

S = Intersect(i_1, r) → (8.12, 8.12)

Obs: Esconda h_1 e I_1.

Crie Segment:

j_1 = Segment(R, S) → 6

k_1: Perpendicular Bisector(R, S) ⇒
$x = 5.12$

T = Intersect(k_1, j_1) → (5.12, 8.12)

Esconda j_1 e k_1.

Outros comandos (base cubo)

l_1 : Perpendicular Bisector (A, I) →
$-4.24x - 4.24y = -18$

m_1 : Perpendicular Bisector (B, J) →
$-4.24x - 4.24y = -43.46$

Intersect:

$U = \text{Intersect}(l_1, n) \rightarrow (2.12, 2.12)$
$V = \text{Intersect}(m_1, p) \rightarrow (8.12, 2.12)$
$n_1 = \text{Segment}(U, V) \rightarrow 6$
p_1 : Perpendicular Bisector (U, V) →
$x = 5.12$
$W = \text{Intersect}(p_1, n_1) \rightarrow (5.12, 2.12)$

Obs: Apague o resto e deixe somente este ponto.

$q_1 = \text{Segment}(I, W) \rightarrow 2.3$
$r_1 = \text{Segment}(W, J) \rightarrow 5.54$
$s_1 = \text{Segment}(K, T) \rightarrow 2.3$
$t_1 = \text{Segment}(T, L) \rightarrow 5.54$

Other:

Segmento Inclinado:

a_1 = Segment(A, K) → 11.09

b_1 = Segment(B, L) → 11.09

c_1: Perpendicular Bisector(A, K) →

$-424x - 10.24y = -61.46$

d_1: Perpendicular Bisector(B, L) →

$-4.24x - 10.24y = -86.91$

Z = Intersect(c_1, a_1) → (2.12, 5.12)

A_1 = Intersect(d_1, b_1) → (8.12, 5.12)

e_1 = Segment(Z, A_1) → 6

f_2: Perpendicular Bisector(Z, A_1) →

$x = 5.12$

B_1 = Intersect(e_1, f_2) → (5.12, 5.12)

Important:

Os Pontos M, B_1 e P estão em linha reta.

Distância entre MP → 6 unidades.

Parte Final:

Jandaia

Crie a linha, ligando os pontos K L

i_2 : Line (K, L) → $y = 10.24$

Criemos 3 segmentos com o comando Parallel Line baseado no segmento AC (6 unidades)

j_2 : Line(M, i) → $x = 3$

k_2 : Line(B_1, j_2) → $x = 5.12$

I_2 : Line(P, k_2) → $x = 7.24$ (7.24)

Intersect:

C_1 = Intersect(i_2, j_2) → (3, 10.24)

D_1 = Intersect(i_2, k_2) → (5.12, 10.24)

E_1 = Intersect(i_2, I_2) → (7.24, 10.24)

FINAL:

m_2 = Segment(M, C_1) → 7.24 ⟩ 2.12

n_2 = Segment(B_1, D_1) → 5.12 ⟩ 2.12

p_2 = Segment(P, E_1) → 3

soma

q_2 = Segment(C_1, E_1) → 4.24 =

New simulators:

File: m01-20210730-check_01-001.ggb

c_2: Circle(B_1, M) →

$$(x-5.12)^2+(y-5.12)^2=9$$

Important:

3 Points:

1) Point P (7.24, 7.24)
2) Point B_1 (5.12, 5.12) e
3) Point M (3, 3)

Estes três pontos estão alinhados dentro do círculo c_2 e dois destes pontos estão sobre a circunferência.

Outros 3 pontos:

1) Point T(5.12, 812),
2) Point B_1(5.12, 5.12) e
3) Point W(5.12, 2.12)

⇒ 3 pontos alinhados e 2 pontos sobre a circunferência.

Todos os 6 pontos se encontram num mesmo ponto B_1, ou seja, as retas $\overline{PM}$ e $\overline{TW}$ fazem intersecção no ponto B_1.

De acordo com Pappus Theorem observamos uma reta criada a partir de 3 pontos.
O ângulo entre estas retas é de 45°.

Obs: Simulação em 3D:

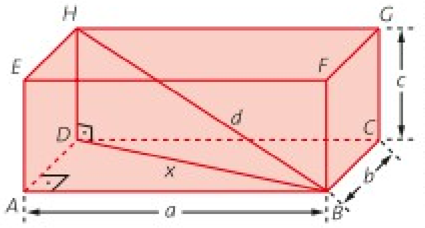
Cálculo da diagonal de um paralelepípedo retângulo e de um cubo

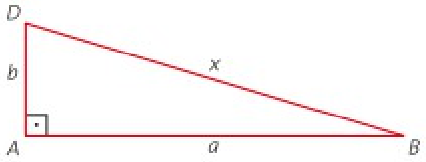
No paralelepípedo de dimensões a, b e c, temos:

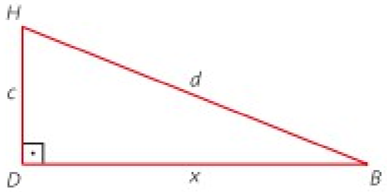


Ilustrações técnicas desta página: Banco de imagens/Arquivo da editora

d = medida da diagonal do paralelepípedo
x = medida da diagonal da base

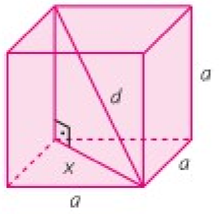
Na figura podemos localizar dois triângulos retângulos:





- Como o triângulo ABD é retângulo em A, temos, pela relação de Pitágoras:
  $x^2 = a^2 + b^2$ Ⓘ
- Como o triângulo DBH é retângulo em D, temos, pela relação de Pitágoras:
  $d^2 = x^2 + c^2$ Ⓘ Ⓘ
- Substituindo Ⓘ em Ⓘ Ⓘ, vem:
  $d^2 = x^2 + c^2 = a^2 + b^2 + c^2 \Rightarrow d = \sqrt{a^2 + b^2 + c^2}$

No cubo, como ele é um caso particular de paralelepípedo reto retangular, temos:



$$d = \sqrt{a^2 + a^2 + a^2} = \sqrt{3a^2} = a\sqrt{3}$$

$$d = a\sqrt{3}$$

features of a situation often appears to have other deep facts built into it, facts that are made obvious only in the technical working out of the formalism.

THE THERMODYNAMIC LIMIT

The existence of a temperature for bulk matter, a measure of the average energy per degree of freedom, is a statement as well that bulk matter might possess what we might call pervasive properties, those size-independent intensive variables. The next task is to demonstrate how and when bulk matter also possesses properties linearly dependent on N, extensive variables. Given that the hydrogen atom, the multielectron atom, and matter composed of lots of atoms are each stable to collapse, matter composed of lots of atoms being bulky (having a size that goes at least as $N^{1/3}$), we need to ask whether some properties of bulk matter can scale with N (rather than being just bounded by N)—what is called the thermodynamic limit—and whether such matter is mechanically stable (so that when it is compressed, its density becomes greater).[35]

We shall first consider an archetype of such proofs, one that does not, on its face, apply to the Coulomb interaction between charged particles. The problem is to divide up bulk matter in such a way that it is seen to be composed of more-or-less independent bulkettes, and so some of its properties will scale with N. Put differently, the task is to build up matter from those bulkettes, combining them to form larger units, ad infinitum. We then consider how that archetype is adjusted so that the Coulomb force, with its infinite range, will still provide for extensive properties ($\approx N$) rather than properties dependent on N^2 (just the number of two-body interparticle interactions, were forces of very long range). In such an account, we find that we are saying something about how we might think of the constitution of matter, in terms of boxes (or balls) geometrically increasing in size and consisting of similar components, and as we get to larger and larger sizes the effect of N on the thermodynamic free energy becomes more and more linear. As we shall see in the next chapter, other accounts of crucial properties of matter suggest rather different constitutions, each of the constitutions to be taken as an aspect of bulk matter, a way we encounter and think about it.

Recall that, through a series of detailed model-dependent calculations, H. A. Kramers (about 1934–1936) came to realize that thermodynamics is a limit science, that thermodynamic properties (intensive variables, such as temperature and pressure, and extensive ones, such as entropy or free energy), and distinctive thermodynamic phenomena such as phase transitions, appear only in the infinite volume limit.[36] While, following Planck and J. W. Gibbs (1902), we might compute the partition function, Q (what Planck called "the sum over states," in German *Zustandsumme*, hence the conventional use of Z for the partition function), a measure of the number of ways of partitioning the energy of the system among its components, what we actually measure and is well defined is the free energy density, f: $\lim_{N \to \infty, N/V \text{constant}} - 1/\beta N \ln Q$ (namely, $\exp - \beta N f = (\exp - \beta f)^{n_B N_B} = Q$, where n_B is the number of atoms in an independent bulkette, and N_B is the number of bulkettes), an infinite volume limit object. (We have seen a similar situation in the Darwin-Fowler derivation in which the temperature $[1/\beta]$ may be in effect "pulled out" as a good intensive variable, when the number of systems considered goes to infinity, the $N_S \to \infty$ limit. Here we might consider each of our bulkettes as a system and so identify N_S with N_B.)

But, having shown that matter is stable to collapse, just which sort of limit are we to take when we are concerned with extensive properties? What is the technical/mathematical construction of "the constitution of matter" (as Lieb and Lebowitz call it) that would enable us to demonstrate the existence of such limits? Put differently, just what is the meaning of a "linear law," as they refer to the thermodynamic limit? (Here I shall be following Lieb and Lebowitz's argument, an epitome and ingenious development of previous work.)[37]

As I have indicated, for these purposes matter's constitution might be archetypally modeled by a hierarchy of bulkettes, perhaps cubes, say each twice the dimensions of its predecessor—at each scale filling all of space; or space is built up out of larger and larger cubes—and so we might go to infinite volume.[38] (See figure 3.2.) Now, no bulkette has more than a limited number of atoms within it. The atoms are in effect impenetrable hard spheres. For recall that we already know, from a proof, that bulk matter is stable, having a lower bound of its energy proportional to N, and bulky, its linear dimensions going as $N^{1/3}$. The atoms' nonzero, finite size (radius a, $\infty > a > 0$), as we shall see, provides for the uniform convergence to the infinite volume limit of the series of approximations for the energy density or for the free energy density;[39] now each component bulkette (or subbulkette) is interacting with its neighbors at best through surface interactions, whose contribution to the energy density or free energy density proves increasingly negligible, so that the series converges, and so that there are extensive properties ($\approx N$) and in general no $N^{1+\epsilon}$, $\epsilon > 0$, properties, which might eventually lead to explosion.

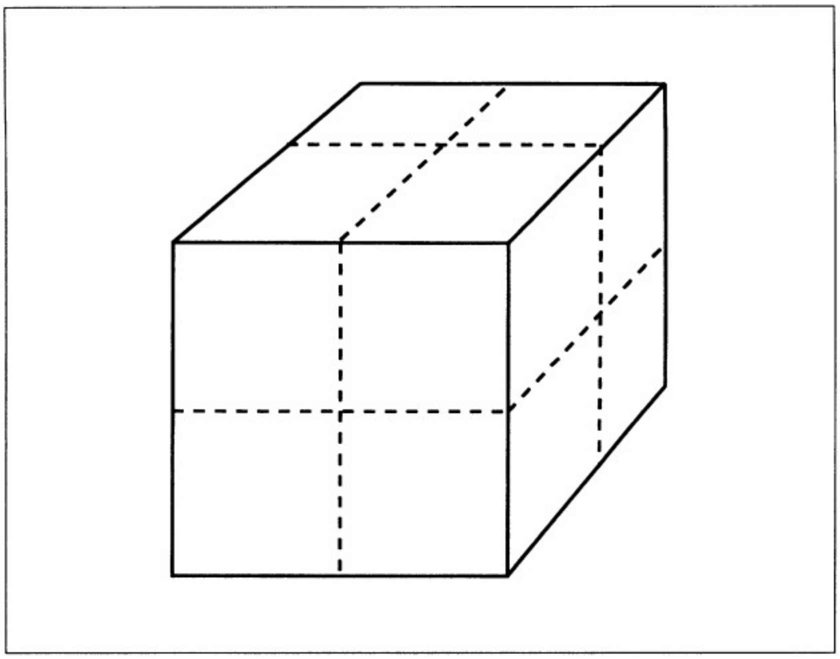

FIGURE 3.2 Hierarchical cubic decomposition of space.

Van Hove, and Yang and Lee, in their respective demonstrations of the existence of a well-defined pressure in ordinary matter (that is, the equivalence of the equation of state of matter in the grand canonical ensemble to that in the canonical ensemble—that one might measure a property of matter, such as pressure, in situ, rather than by isolating the matter ahead of time), and of the impossibility of phase transitions except in the infinite volume limit (if at all), used the apparatus of a decomposition into bulkettes, composed of presumably stable atoms (equal to hard spheres), and interacting through finite-range forces.[40] Again, for the Coulomb interaction ($\approx 1/r$), the finite-range assumption is not at all obvious.

I should note that there are at least two kinds of decomposition in these proofs.[41] The first allows the size of the component cubic bulkettes to grow more slowly than does the volume, so that as one goes to the infinite volume limit the number of components goes to infinity, but more slowly. The second is a geometric series of nested cubes, each twice the size of its predecessor, and therefore eight smaller cubes fit into the next larger cube. As we shall see, when we use balls or spheres as our bulkettes, we have a packing problem and we fill in the interstices (and the interstices of interstices) with increasingly smaller balls (down to a minimum-sized one).

Again, the thermodynamic limit is a large-distance or large-*r* problem, unlike the stability to collapse I discussed earlier, which concerns the small-*r* possibilities. Put simply, if the range of an attractive interaction between particles is very large or "infinite," then we might expect that if we put pieces of matter together there might well be an explosion, the energy per particle rising so rapidly that, rather than a diffusive loss of excess energy through steady state heat conduction, there is shock wave and mechanical explosion. (If the interaction is repulsive, then it would be impossible to produce bulk matter in the first place. And if there were something like critical-mass effects as in radioactive matter, then adding on more matter allows even more matter for mutual interaction, nonlinearly increasing the energy of interaction.) With long-range interactions, bulkettes could not be independent of each other, and putting two in close proximity would produce a bulkette that is qualitatively different than its components. Practically, we could not hope that fluctuations in density would have little effect on thermodynamic properties in equilibrium (rather than, say, leading to explosion, which we surely do worry about for subcritical nuclear assemblies).

We shall want small but still sufficiently large bulkettes to be more or less separated and independent of each other, so that the energy per particle of bulk matter so composed is roughly constant. As we might infer from the Darwin-Fowler derivation, the statistical independence of the bulkettes should allow for sharply defined values of intensive variables and for the volume properties of the bulkettes just adding up; the fact that there is a unique temperature (or saddle point in the Darwin-Fowler derivation) suggests that the convergence to the infinite volume limit would be robust, namely, a uniform convergence, comparatively insensitive to details of the particular actual system or mode of convergence.

Can we so model bulk matter? Each of the proofs I shall discuss depends on finding a canonical way of decomposing matter into bulkettes, that way working out because atoms are of finite size, and so a limited number fit into a finite-sized bulkette—and hence there cannot be, along the way to the infinite volume limit, some bunching up of all the atoms within just one bulkette, or a few. And forces are of finite range, so that bulkette-bulkette interactions are surface- rather than volume-dependent. Such matter will have those extensive properties, its component atoms will not collapse, and the bulk will not explode.

As we approach the thermodynamic limit, it may be useful to recall that proofs of the stability of matter itself, that there is a linear lower bound of the energy, are quantum mechanical, with no need to resort to statistical mechanics as such. (The Thomas-Fermi model employs an average charge density, $n(r)$, but does not use statistical mechanics. There is no partition function. Thomas-Fermi theory is just a quantum mechanical theory.) As we might expect from its name, the thermodynamic limit is in fact statistical, and the partition function is the object of interest; that there is a linear limit for the energy is a statistical mechanical statement. The fluctuations here are not quantum mechanical, but refer to thermal fluctuations in particle number, for example.

The proofs that the energy and that the free energy possess thermodynamic limits are quite similar. In what follows, the free energy plays the central role. In each case, I show a linear N-dependent lower bound (I have already done so for the energy), and then an effectively decreasing sequence of estimates—and so prove the existence of a limit. Note, however, that interactions among the bulkettes contribute differently to the energy (they just add in) than they do to the partition function, $\Sigma \exp - \beta E$ (where they affect the combinatorics as well). In sum, to model and analyze the constitution of matter is to prove that a partition function (and so a free energy density) computed from that model possesses the desirable properties in the thermodynamic limit.

Proving a Thermodynamic Limit: The Free Energy[42]

Technically, one way of saying that matter is composed of bulkettes that are more or less independent is to say that the grand partition function, *GPF*—the partition function of systems when not only the energy but also the number of particles may vary—of some bulk matter (volume V) might be decomposed into the grand partition function of bulkettes of volume V/γ: $GPF(z,V) = \Sigma z^N Q_N(V) = [GPF(z, V/\gamma)]^\gamma$,[43] where the surface contributions to the grand partition function are comparatively small. And, in the infinite volume limit (V to infinity, V/γ constant and suitably large, so that each bulkette has lots of particles—noting that this kind of definition is just what is crucial and an invention), the above relationship holds with no surprises along the way.[44]

The proofs of the theorems of van Hove and of Yang and Lee, concerning the behavior of the partition function and of the grand partition function as the volume goes to infinity, along the way implement these features by several technical moves:[45] If the range of the interparticle forces is fixed and finite (and so volume independent), r_0, then each bulkette can (more or less) only interact with another bulkette along its surface. One sets up r_0-deep "corridors" between the bulkettes, let us say. (See figure 3.3. That one can do this means that there cannot be an explosion, since the interaction among bulkettes goes as $N^{2/3}$ rather than as $N^{1+\epsilon}$, $\epsilon > 0$.) As long as surface to volume ratios are of the usual sort, the contributions of these corridor interactions to the partition function are sufficiently small, in the sense that their contribution to the free energy density or to the grand canonical pressure ($P = (1/\beta V) \ln GPF$), each a logarithm of a partition function then divided by the volume, is negligible. The construction to prove this is by now conventional, but is a crucial invention—namely, how we might break up space into weakly interacting bulkettes: a geometric decomposition into smaller cubes, either an infinite number of such cubes or an infinite nesting of cubes.[46] Given this construction, and a finite range, then the contributions to the partition function (and so to the free energy density or to the grand canonical pressure) from the states in which corridor interactions are allowed stays sufficiently small and is bounded by a function that depends on r_0 alone.

Moreover, one wants to be sure nothing "interesting" happens on the way to infinite volume, that the limits converge nicely enough, hopefully uniformly. What might happen interestingly? There could be some weak $N^{1+\epsilon}$ effect, which when N is large enough starts becoming important. But I have precluded that by the finite-range assumption. Or perhaps all the particles might literally conglomerate into one bulkette, leaving all other bulkettes absent of particles. Now, we might just note that actual matter is bulky, and moreover it does not implode, and so this bunching up is impossible. What turns out to be crucial in the actual proofs, however, is that the particles are presumed to be hard spheres, of nonzero radius, a (namely, they are stable energetically); therefore, only a limited number of them could be packed into any bulkette.

The polynomial in z that is the grand partition function for a bulkette—$GPF = \Sigma z^n Q_n$—has a maximum degree, the maximum number of particles that could fit into a bulkette. The grand partition function for a bulkette or for a finite number of bulkettes is therefore bounded on a compact set for finite z (called the activity or fugacity). (Note that the activity is a measure of the [Gibbs free] energy needed, μ, to add one more particle to the system: $z = \exp \beta\mu$.) This boundedness turns out to be just what is needed to be sure of uniform convergence (namely, bounded derivatives) and so continuity.[47]

In sum, if r_0 were not finite, then interactions among bulkettes would not be bounded. If a were zero, then a single bulkette could have a very large fraction of the particles, and then fluctuation and macroscopic graininess would dominate the bulkiness of matter.

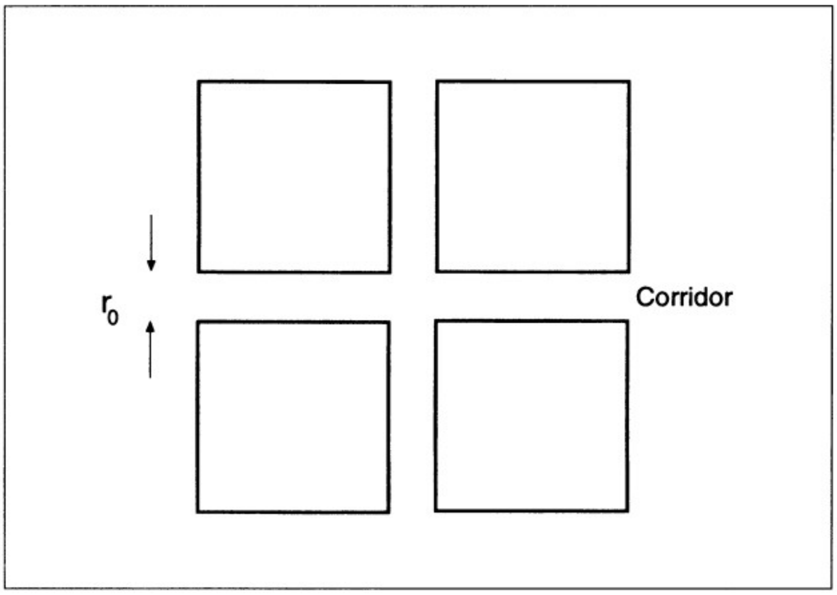

FIGURE 3.3 Corridors between cubes.

As a model for a proof of the thermodynamic limit for Coulomb forces, I have pointed to technical features of some of the proofs of the thermodynamic limit for finite-range forces: the capacity to bound the corridor contributions in a volume-independent way, and the boundedness of the partition function—which are crucial formally and mathematically. And then I suggest that those features reflect deep physical facts about matter, their absence implying a state of matter very different than the one we see everyday.

Still, we do not yet have the wherewithal to provide for a thermodynamic limit. Given the infinite range of the Coulomb force, how are we to apply the technology we have developed for finite-range forces?

Screening

For Coulomb forces, the thermodynamic limit is quite peculiar.[48] For example, were electrons positively charged, there would be no question about the stability of bulk matter: the excess charge would go to the surface, the minimum electrostatic energy would go as $N^2/N^{1/3}$ ($\approx e^2/r$), namely $N^{5/3}$, and there would be no thermodynamic limit: the energy per particle is not at all constant. Moreover, in general, only if the potential falls off as $r^{-(3+\epsilon)}$ would there be such a limit—except here ($1/r$, Coulomb) we are saved by the opposite signs of the charges of the electrons and the protons: "different parts of the system far from each other must be approximately independent, despite the long range nature of the Coulomb force. The fundamental physical, or rather electrostatic, fact that underlies this is *screening* [in effect, there is an r_0 that is finite]; the distribution of the particles must be sufficiently neutral and isotropic locally so that according to Newton's theorem the electric potential far away will be zero. The problem is to express this idea in precise mathematical form."[49]

While "everyone knows" that the Coulomb force is shielded in bulk neutral matter (no net force at a distance, since in net neutral charged matter the distant effects of the positive and the negative charges cancel out), it is not at all apparent how what everyone knows might be used to show that such matter possesses a thermodynamic limit. The crucial insight is that the external effect of a sphere or a ball, isotropically filled with charge, is equivalent to having a point charge at the center ("Newton's [or Gauss's] theorem"). And if that net charge were (almost) zero, there would be (almost) no external force—in effect a finite r_0.[50] The task here is to pack space with such balls, and (as in van Hove and in Yang and Lee) the invention that is crucial is a mode of such packing—so that the spherical bulkettes or balls, at various scales, are of fixed uniform density, something that is automatic when we use cubes but that is not so obvious for spheres, since the leftover unpacked spaces are nontrivial. The development of a workable geometric construction—one that insures that the density of matter is constant, the infinite volume limit in practice—is as crucial here as was the earlier partitioning into cubes.[51] Since any but the smallest ball is filled with smaller balls, the partitioning looks something like figure 3.4. Again, such a partitioning is not only a mathematical device; it also shows how we might think of the constitution of matter, the neutral balls reminding us poignantly about the significance of screening in this realm.

Such a packing of space with neutral balls is not quite a claim that matter is actually composed of neutral balls, that matter is so constituted. It is a very useful assumption, one that is in fact not quite the case. But it is an assumption that can be relaxed enough so that the proof is quite believable as a model of actual matter. (One proves the limit for neutral balls and then shows that any surface charges due to nonneutrality that vanish in the infinite volume limit do not matter.) Namely, for each of the component balls, as long as the excess charge on each "neutral" ball is sufficiently small (its surface-charge density goes to zero) at each scale, and the net total charge on all balls is zero (macroscopic neutrality), all is OK. Hence, the dimensions of the characteristic charge fluctuations in actual matter have to be small compared to the size of the smallest ball considered. It can also be shown that these nonneutral configurations do not contribute much to

.3 6! U 8

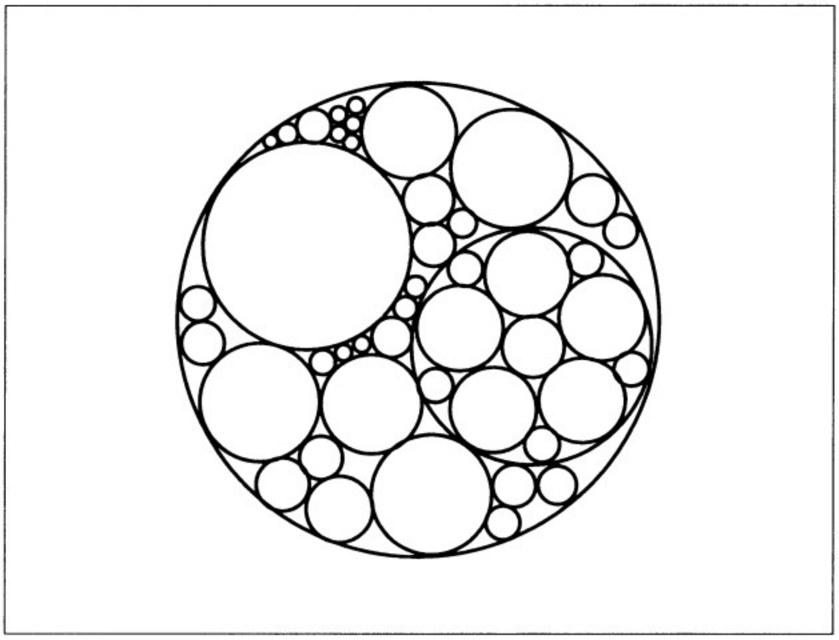

FIGURE 3.4 Filling space with balls.

the grand canonical pressure, the nonneutral parts being much like the corridor contributions in other constructions (as long as the surface-charge density goes to zero as the volume goes to infinity). It is a *façon de parler* to say that matter is constituted of neutral balls, justified by these physical facts.

The neutral-ball construction leads to a suitably convergent series of approximations to the partition function, and so it provides a constitution of matter. More precisely, first, it leads to a recursive sequence of estimates for the free energy density:[52] the free energy density of a ball at size l, f_l, is less than or equal to the free energy density computed by packing the neutral l-sized ball with smaller neutral balls (each of whose free energy density has also been bounded from above by its component balls' free energies), and then summing their contribution to the free energy: namely, $f_l \leq \Sigma_{i=0,\ldots,l-1} f_i \upsilon_i$ (where υ_i is the fraction of volume of the l-sized ball that is covered by the i-sized balls). Now, let us allow for almost neutral balls.

Second, in order to show that the residual Coulomb interaction energy of these almost neutral balls is not out of bounds and possesses a limit, one needs to pack space with l-sized neutral balls (each packed with $(l-1)$–sized and smaller almost neutral balls). What makes the proof go through is that, in computing a bound on the partition function for finite N and V, a sum or average for all configurations, one need consider only the average interaction among all the bulkettes, that is, "the *average* interdomain Coulomb energy in a canonical ensemble in which the Coulomb interaction is present in each subdomain but the. . . domains are independent of each other."[53] And it turns out that, for all overall neutral volumes, that average interdomain energy is zero, by the Newton-Gauss law. Even if fluctuations do give various balls small amounts of nonneutrality, that does not matter, since at each level one is demanding overall neutrality.[54] And when one goes to the next larger size ball, one can relax the neutrality assumption for the now smaller ball.

Crucially, the bulkettes must be statistically independent of each other, again what we would expect of bulk matter that is stable and in equilibrium.[55] Technically, that independence might be understood as an averaging that leads to $1/\sqrt{N}$ effects, damping charge fluctuations. More formally, $Q \geq (\exp - \beta U)\Pi_j Q_j$: the partition function for a finite system is greater than or equal to just $\exp - \beta$(Average Interaction Energy, U), representing the interactions among the bulkettes, times the product of the partition functions of each of the bulkettes that compose it.[56] (Note that, since the average energy is zero, the exponential equals one.) This inequality then defines a sequence of in-effect decreasing estimates for the free energy density as the volume gets larger ($f \leq \Sigma f_j$), and, given the stability of bulk matter (which leads to a bound on the partition function and so to a lower bound on the free energy, for which see the section below, "Limits Are Physical"), we are led to the proof of the existence of an infinite volume limit, the thermodynamic limit we are seeking.[57]

Now, say the actual matter itself were not electrically neutral. Would it still exhibit a thermodynamic limit? As I have suggested already, if the excess charge is small, it should have little effect. Moreover, the long-range character of the Coulomb force demands that, if there is to be a conventional thermodynamic limit, then the system must be effectively neutral—otherwise shape and size effects become important.

Technically, taking into account the amount of excess charge (over neutrality) in taking the thermodynamic limit: if the surface charge density goes to zero, then the limit is the same as for the neutral system; if the surface charge density goes to infinity, then there is no limit (as one might expect); and if it goes to a finite value, to the neutral free energy is added an electrostatic surface energy.[58]

In sum, the thermodynamic limit separates out N-dependence through the use of independent bulkettes. The proofs all depend on the hard-core or nonzero size of the atoms and the finite (that is, noninfinite) range of the interparticle forces. And screening does the finite ranging work for the Coulomb force, once we pack space with effectively neutral balls.

THERMODYNAMIC STABILITY AND MATHEMATICAL PHYSICS AS EMPIRICAL

These mathematical proofs are in effect philosophical analyses of thermodynamics, showing in various contexts the meaning of the infinite volume limit through the demands of technical constructions of the constitution of matter. The technical and mathematical features of the proofs depend upon three contingent physical facts, contingent in the sense that they need not be the case, but surely are the case in our everyday world: (1) The energy is bounded from below, namely, matter is stable, whether that is presumed by some hard-sphere repulsion or derived from the Pauli exclusion principle. The free energy, too, is bounded from below. (2) Bulkette-bulkette interaction terms are small; namely, they are surface terms, their contribution to the energy or the free energy densities being negligible. This smallness depends on the effective finiteness of the range of the interaction. And so space might be usefully partitioned into independent bulkettes—the remaining task being to find a partitioning that in some sense converges, that nicely reaches the infinite volume limit. (3) Hence, nothing interesting will happen, such as all the particles going to one bulkette (granularity), when one allows for larger- (or smaller-) scale bulkettes.[59] The latter fact is, essentially, the uniformity of convergence. Technically, at each stage in the approximation, on the way to the infinite volume limit, one can show that the free energy per unit volume, f_l, l being the scale, converges nicely enough for there to be uniform convergence: $|f_{2l}-f_l| < c/l$.[60]

The convergence to a limit (independent of the mode of sequencing or the shape of the volumes) can be shown to have rather deep and generic physical consequences: matter becomes denser when compressed, and its temperature is raised when heat is added to it (it is "thermodynamically stable"); and in general (except perhaps at phase transition), measurements of properties as a function of density or temperature for large samples will be a good approximation to the infinite volume limit.

For, even if there is a lower bound on the energy, so that matter is energetically stable, and even if there is a thermodynamic limit (asymptotic $1/N$ limit), we have yet to show there is such thermodynamic stability: that the system will not exhibit a negative compressibility, Δdensity$/\Delta$pressure < 0, so that pressing upon it would decrease its

made is the *metrical embodiment of the hypothesised inertial drag field*. It is not hard to see that the inertial frame at a point rotates about a line parallel to the z-axis with angular velocity the value of ω at that point. This is clear if ω is constant and in general, provided ω is continuous, it follows from the locality of inertial frames. So to fit with inertial drag as formulated in (5.1) it is necessary to set $\omega = A/(r+K)$ (at least in the (x,y)-plane). However it is easy to work with a general function ω and specialise when needed. The orbits of particles moving on geodesics in the equatorial plane will now be investigatied and, provided ω decreases like A/r as $r \to \infty$, the orbits will be found to fit observed rotation curves.

The reader might find Figure 5.2 helpful for visualising geodesics in the inertial drag metric and understanding the inertial drag effects. It shows geodesics on a typical cylinder $r = z =$const.

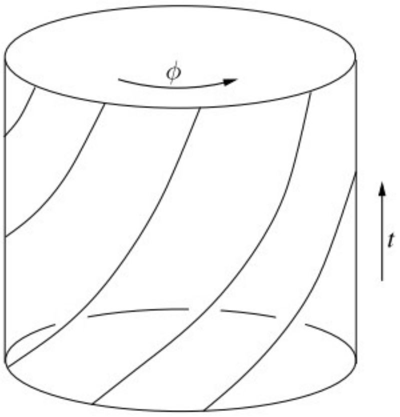

Figure 5.2: Geodesics on the cylinder $r = z =$const in the inertial drag metric

5.4 Conservation of angular momentum

Here now is the analytic derivation of the rotation curve (the relation between v and r) for the orbit of a particle in the equatorial plane moving with total velocity $\mathbf{v}$, which has tangential component v (perpendicular to the line through the origin). Recall from the discussion in Section 5.2 above that there are two opposing effects at work: the slingshot effect, which tends to increase v with r and conservation of angular momentum which tends to decrease it. These two effects are calculated together. The proof works in any inertial drag metric, where the particle moves along a geodesic. (The special case of flat Minkowski space with inertial drag effects was motivated in Section 5.2.)

The derivation starts with a proof of conservation of angular momentum, which is a property of any system with a central force (or space-time geometry which simulates a central force). It is not restricted to Newtonian physics. The proof is adapted from Newton's proof of the equal area law for planetary orbits (which is exactly the same as conservation of angular momentum, see Figure 1.4). For the time being ignore ω (or set it equal to zero).

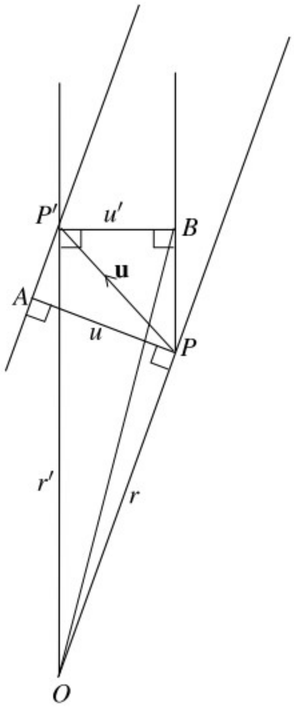

Figure 5.3: Proof of conservation of angular momentum

The idea is to replace the central force by a series of central impulses at equally spaced (small) intervals of time. Consider Figure 5.3. At a particular time the particle (of small unit mass) is at P and has just received a central impulse resulting in velocity $\mathbf{u}$. Its tangential velocity at P is $u = |AP|$. One small interval of time later the particle is at P' and receives another central impulse (along the line OP') which does not change its tangential velocity $u' = |P'B|$. But the triangle OPP' can be regarded as having base $r = |OP|$ and height u or base $r' = |OP'|$ and height u' hence

$$ur = u'r' \tag{5.4}$$

in other words the angular momentum at P is the same as that at P'.

To obtain the result for an arbitrary continuous central force, take the limit of a sequence of central impulses. Note the proof does not use any property of the central force other than that it acts towards the centre. Nor does it assume that r represents a genuine distance in the metric under consideration. All that is needed is that Euclidean geometry correctly describes the relationship between r and distances perpendicular to radii near $P$and P' which is precisely how r was chosen.

5.5 The fundamental relation

Now reinstate ω. Note that "force" in the model is a property of local space-time geometry. In the case that ω is constant, the inertial frame (rotating with ω) is the same as the unrotated case and in this frame the force is central. Therefore by locality it is central in the general case in the inertial frame. Therefore the proof just given makes sense in the inertial frame at P', in other words rotating with angular velocity $\omega' = \omega(P')$, though, as will be seen, in the limit the same result is obtained if it is assumed that the frame is rotating with angular velocity $\omega(P)$. To find the required relationship between v and r write v for the full tangential velocity at P and v' at P'. Since the frame is rotating at ω', $v = u + \omega' r$ and $v' = u' + \omega' r'$. Write $v' = v + \delta v$, $u' = u + \delta u$, $r' = r + \delta r$ and $\omega' = \omega + \delta\omega$.

Since $ur = u'r'$ (Equation 5.4), substituting for u', v' and simplifying gives

$$u\,\delta r + r\,\delta u = 0\,. \tag{5.5}$$

But

$$\delta u = u' - u = v' - \omega' r' - (v - \omega' r) = v' - v - \omega'(r' - r) = \delta v - \omega'\,\delta r$$

and substituting for $u, \delta u$ in (5.5) gives

$$(v - \omega' r)\,\delta r + r(\delta v - \omega'\,\delta r) = 0$$

which gives

$$r\,\delta v = 2r\omega'\,\delta r - v.$$

It is now possible to replace ω' by ω to first order (as forecast) and going to the limit yields the *fundamental relation* between v and r:

$$\boxed{\frac{dv}{dr} = 2\omega - \frac{v}{r}} \tag{5.6}$$

The fundamental relation can be understand intuitively as follows. The slingshot effect intuitively produces an acceleration $dv/dr = \omega$. On the other hand $v_{\text{inert}} = v - \omega r$ is the "inertial" tangential velocity (corrected for rotation of the local inertial frame) and therefore conservation of angular momentum produces a deceleration in v of v_{inert}/r or an acceleration $dv/dr = \omega - v/r$. Adding the two effects gives the relation.

5.6 Solving to find rotation curves

Given ω as a function of r, (5.6) can be solved to give v as a function of r. Rewrite it as

$$r\,\frac{dv}{dr} + v = 2\omega r\,.$$

The LHS is $d/dr\,(rv)$ and the general solution is

$$v = \frac{1}{r}\Big(\int 2\omega r\,dr + \text{const}\Big). \tag{5.7}$$

It is now clear that any prescribed differentiable rotation curve can be obtained by making a suitable choice of continuous ω.

Of interest here are solutions which, like observed rotation curves, are asymptotically constant and inspecting (5.7) this happens precisely when $\int 2\omega r\,dr$ is asymptotically equal to Qr for some Q and this happens precisely when 2ω is asymptotically equal to Q/r. This proves the following result.

Theorem *The equatorial geodesics in the inertial drag metric* (5.3) *have tangential velocity asymptotically equal to constant* Q *if and only if* ω *is asymptotically equal to* A/r *where* $Q = 2A$.

5.7 The basic model

Now specialise to the case $\omega = A/(r+K)$ which gives the value of inertial drag formulated in (5.1).

From (5.7)

$$v = \frac{1}{r}\left(\int \frac{2Ar}{r+K}\,dr + C\right) = \frac{2A}{r}\left(\int 1 - \frac{K}{r+K}\,dr\right) + \frac{C}{r}$$

$$= 2A - \frac{2AK}{r}\log\left(\frac{r}{K}+1\right) + \frac{C}{r} \tag{5.8}$$

where C is a constant depending on initial conditions. For a particle ejected from the centre with $v = r\omega_0$ for r small, $C = 0$, and for general initial conditions there is a contribution C/r to v which does not affect the behaviour for large r. For the solution with $C = 0$ there are two asymptotes. For r small, $v \approx r\omega_0$ and the curve is roughly a straight line through the origin. And for r large the curve approaches the horizontal line $v = 2A$. A rough graph is given in Figure 5.4 (left) where $K = A = 1$. The similarity with a typical rotation curve, Figure 5.4 (right), is obvious. Note that no attempt has been made here to use meaningful units on the left. See Figure 5.6 below for curves from the model using sensible units.

There are other shapes for rotation curves; see [96] for a survey. All agree on the characteristic horizontal straight line. Figure 5.5 is reproduced from [96] and gives a good selection of rotation curves superimposed. In Figure 5.6 is a selection of rotation curves again superimposed, sketched using Mathematica[1] and the model given here. The different curves correspond to choices of A, K and C. The similarity is again obvious. The units used differ. In the model given here natural units are used so that a velocity of .001 is 300km/s and a distance of 45,000 is 15Kpc approx.

6.7 The Higgs Mechanism

The particles of the standard model can be divided into two groups. On the one hand, there are the particles that measure the interactions, namely photons, W^+, W^-, Z^0, and gluons, and on the other, the particles of matter, namely quarks and leptons. The particles that have a mass are W^+, W^-, Z^0, quarks, and leptons.

Unfortunately, a problem that plagued the theory was the fact that the particles of the model had to have zero mass for reasons of symmetry. Some mechanism was necessary to break the symmetry, but in the symmetry breaking, the well-known massless Nambu–Goldstone bosons appeared. A sort of trick was needed to make them disappear or hide. This "trick" is the Higgs mechanism, in which Goldstone bosons are "eaten" by gauge bosons, which become massive. How does this happen?

As we know, particles have a spin, which is often described in classical mechanics and in early quantum theory as a rotation.[7] If we consider an electron, its spin is ½ and in measurements we can find only two *spin states*, or *polarization states*, or *degrees of freedom*, which represent the ways in which a field can vibrate: ½ and −½. Each polarization state can be considered as a different particle or a different degree of freedom. *A fundamental point to remember is that massive particles have three degrees of freedom.*

For a particle with spin 1, we can have two possibilities: if the particle is massive (e.g., in the case of W and Z bosons), we could find the values −1, 0, 1. The particle has three degrees of freedom. This means that the fields of massive particles can have an up-down vibration (and vice versa), a left-right vibration (and vice versa), and forward-backward vibration (and vice versa). If the particle has no mass, as in the case of photons, we would find –1 and +1, that is, only two degrees of freedom.[8] So the fields of massless particles can vibrate only in two ways: up-down (and vice versa) and from right to left (and vice versa). These oscillations are shown in Appendix C (Fig. C1).

---

[7] As already reported, the notion of spin as rotation around an axis is incorrect. This quantity was not foreseen by non-relativistic quantum mechanics; it had been introduced as a result of several experiments. It is automatically obtained in the relativistic version of quantum mechanics, by the Dirac equation, and does not correspond to a rotation around an axis.

To summarize, a scalar field, with spin 0, has only one degree of freedom. Vector fields with spin 1 have two degrees of freedom if they are massless and have excitations perpendicular to the direction of propagation (1, –1). If they have mass, they have three degrees of freedom, with two perpendicular excitations (1, –1) and one longitudinal (0) (see Appendix C).

So how do the particles W^+, W^- and Z^0 acquire their mass?

Before the symmetry breaking, the electroweak interaction was mediated by four fields: the fields B, W_1, W_2, and W_3 (Fig. 6.9) and the corresponding bosons were all massless.

We can consider them as the parents of the fields of the photon γ and those of W^+, W^-, and Z^0. Consequently, they have only two degrees of freedom, excitations perpendicular to the direction of propagation, and zip at the speed of light. To make them massive, one needs a third degree of freedom, the longitudinal one (forward-backward oscillation). We need three scalar particles that, combining with W_1, W_2, W_3, provide each with the missing longitudinal degree of freedom. These scalar particles, the *Goldstone bosons*, are produced at the end of the electroweak era, when the universe had 10^{-12} s and temperature was 10^{15} K in the electroweak symmetry breaking phase mentioned in Chapter 2. As described in Appendix C, the Higgs potential underwent a transformation. The field "slipped" from the false vacuum to the true vacuum, like a ball that descends from the top of a hill to the valley (see Fig. C3).

Fig. 6.9. The electroweak interaction mediators.

---

[8] It should be noted that if 0 is found, this does not mean that the particle has no spin.

In this event, four scalar particles (see Fig. 6.10) were generated which we refer to as H_1, H_2, H_3, and H, or also as H^0, H^+, H^-, and h three of which (H^0, H^+, H^-) are Goldstone bosons, eager to help W_1, W_2, W_3 to become massive. H_1, H_2, H_3, alias H^0, H^+, H^-, provide the degree of longitudinal freedom needed by W_1, W_2, W_3 to become massive.

After W_1, W_2, W_3, absorb H_1, H_2, H_3, that is, the missing degree of freedom, immediately become massive. In Figs. 6.9–6.13, we show some cartoons describing how the bosons W_1, W_2, W_3, by eating H^0, H^+, H^-, transform into W^+, W^-, and Z^0. W_1 and W_2 combine and, eating H^+, give rise to W^+ (Fig. 6.11).

Similarly, W_1 and W_2 combine and eating H^-, give rise to W^- (Fig. 6.12).

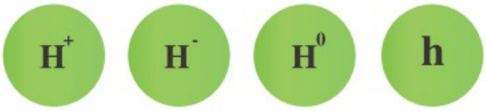

Fig. 6.10. The three massless Goldstone bosons H^+, H^-, H^0, and the (massive) Higgs boson, h.

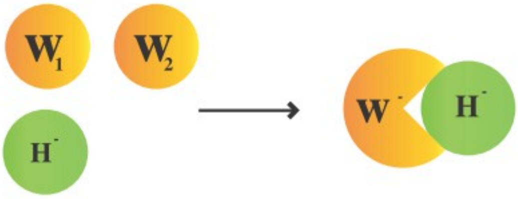

Fig. 6.12. Generation of W^- from the combination of W_1 and W_2 and eating of H^-. Credit: Modification of work by Flip Tanedo, Quantum Diaries.

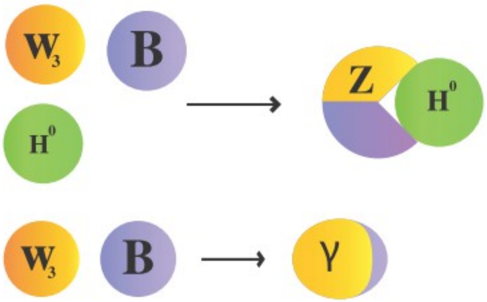

Fig. 6.13. Top: Generation of Z^0 from the combination of W_3 and B and eating of H^0. Bottom: Generation of the photon, γ, from the combination of W_3 and B. Credit: Modification of work by Flip Tanedo, Quantum diaries.

The boson Z is obtained when W_3 and B combine and eat H^0. W_3 and B also combine (Fig. 6.13). No Goldstone boson is left, and then the photon (combination of W_3 and B) remains massless, and h, which is *the Higgs boson* discovered in 2012, remains free.

In Appendix C, a more precise description of the Higgs mechanism is given.

In the case of fermions (quarks and leptons), mass acquisition occurs in a different way, with the so-called extension of the Higgs mechanism to *Yukawa's interaction*, an interaction that couples the fermion field with that of the Higgs. Intuitively, in their motion these particles "feel" the presence of the Higgs field, which fills the whole space, and begin to interact with it. When fermions move in space, they interact with the Higgs field. Using a not very correct, but effective, analogy, the field of Higgs slows them down like honey does with an object that moves in it. Entangled in the Higgs field, the particles find it more difficult to move, as if they had mass and their speed becomes less than that of light. Particles such as electrons assume mass when the Higgs boson "intertwines" the two polarizations of the electron. The operation requires energy, supplied by the Higgs field, which is perceived as the resting mass of the particle. The mass grows as the intensity of the interaction grows.

If we could disable the Higgs field, we would go back to the initial state with four massless bosons. The quarks would lose their mass, the two electron components with different polarization would decouple and lose their mass, and the atoms and matter would be annihilated.

A legitimate question is, why the other fields cannot do what the Higgs field does? What distinguishes the Higgs field from other fields, for example from the electromagnetic one? This difference was described in more detail in section 6.2 when we talked about fields. Unlike the other fields, the Higgs field is always different from zero in its state of minimum activity, $\phi = 0$, as seen in Fig. 6.4 (right panel), and Fig. 6.14. It even occurs that the Higgs field has more energy when it is null, that is, when $\phi = 0$, than when it is not null. Contrary to the usual fields, if we want the Higgs field not to invade space with its bosons, we must supply energy. This is the difference that distinguishes it from other fields. Particles, sensitive to it, always have a certain probability of interacting with it and become massive.

The intuitive description of the Higgs mechanism is due to David Miller, a physicist from University College London. He won the prize offered by Minister William Waldegrave (a bottle of champagne) to the physicist who had managed to explain in an intuitive and exhaustive way how the mechanism works and what it was used to find out.

Miller imagined a salon full of people evenly distributed in space, chatting among themselves as a VIP arrives. As the VIP

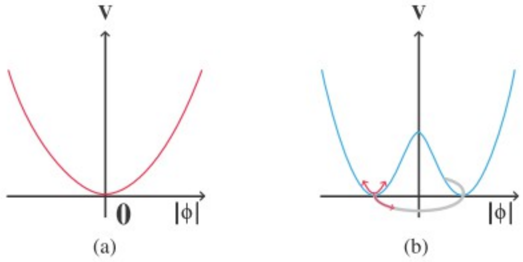

Fig. 6.14. The potential V of a field like the electromagnetic one (left) and that of the Higgs field (right). When the field "falls down" from the hill to the minimum, it can have an up and down oscillation generating the boson H and, on the circumference of the minimum, generating the bosons H_1, H_2, H_3.

moves, he attracts people and a crowd forms. The crowding produces resistance to the movement of the VIP, and it looks as if the VIP is acquiring mass. A particle moving in the Higgs field faces a similar situation.

The concept of the Higgs boson is explained by imagining that someone is circulating a voice in the lounge. Those who listened to it first will report it to the neighbors. The room will be crossed by a wave of "crowds of people" that, like the VIP, "gain mass." The Higgs boson would resemble this crowding.

It is often said that the Higgs boson gives mass to objects. This is not exactly correct. The Higgs mechanism provides mass to only the elementary particles. An important point to note is that the mass of any object, such as a table, is due in minimal part to the Higgs field. Everyday objects are made up of protons and neutrons.

Each proton is made up of two up-quarks, with mass 2.3 MeV, and one down-quark, with mass 4.8 Mev. So if the mass of a proton were all due to quarks, it would have to weigh 2.3 + 2.3 + 4.8 = 9.4 MeV. In reality, the proton has a much larger mass, 938 MeV. This means that the Higgs field that provides mass to the quarks contributes only about 1% to the mass of the proton. The mass of the proton is basically due to the fluctuations of the vacuum (Fig. 6.15). The quarks that

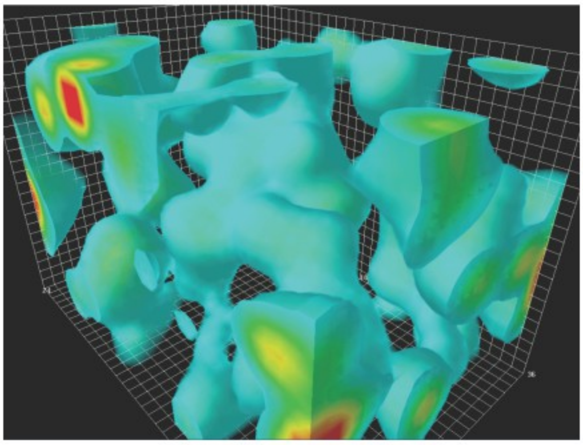

Fig. 6.15. Fluctuations of the vacuum in a proton. Credit: Wikipedia, Derek B. Leinweber.

make up the proton are confined in the proton, within which the quantum vacuum is subject to fluctuations that create and destroy quarks and gluons continuously and in a very short time. The interaction of the quarks that make up the proton with the fluctuations of the vacuum generates energy (see the Casimir, Lamb, and Schwinger effect in Chapter 6).

If the Higgs field did not exist, the quarks and leptons would have no mass and would move in space at the speed of light. The consequence is that protons, neutrons, nuclei, and atoms would not form the universe and, finally, us.

So far, we have talked about the theory of how elementary particles gain mass. Is there evidence that this is really the case? The answer is yes. A large part (3/4) of the Higgs mechanism was discovered in 1983 at CERN by Carlo Rubbia and Simon van der Meer, with the discovery of the W^+, W^-, and Z^0 bosons. The cherry on the cake, or the Higgs boson, was discovered on July 4, 2012, thus completing the construction of the standard model.

6.8 The Dynamics of Colors and the Atomic Nucleus

Meanwhile, the study of cosmic rays had allowed to identify several particles. In 1936 Carl Anderson, the positron discoverer, together with Seth Neddermeyer, discovered a negatively charged particle, like the electron, but about 200 times heavier. It was called *μ meson*.

A meson is a particle made up, as we will see, of two other elementary particles: a quark and an antiquark. These particles "feel" the strong nuclear force.

The reception of the new particle was not the warmest, since it was not clear why there should have been a heavier cousin than the electron. Physicists were so stunned that Isaac Rabi learned of the discovery and exclaimed, "And who ordered it?"

Moreover, physicists had not understood that in reality the particle was not a meson but precisely a cousin of the electron, about 200 times heavier. It belongs, together with neutrinos, to the family of leptons that "feel" the weak nuclear force. In the 1970s, history repeated itself and another cousin of the electron and muon was discovered, the *tau*, or *tau meson*, having a mass approximately 3,500 times that of the electron. Only in 1947 were the mesons predicted by Yukawa really discovered: the *pion*, or π *meson*, and the *kaon*, or *k meson*. To study the deep structure of matter, in the 1950s, particle accelerators began to be built. Accelerators allow to produce collisions with energies much greater than those of the particles involved in the collision, thus producing particles of greater mass. According to the equation $E = mc^2$, for a particle to be generated it is necessary that the energy be greater than its mass at rest. As the accelerator energies increased, the number of particles produced became so large that there was talk of a *zoo of particles*.

Murray Gell-Mann and Yuval Ne'eman showed that the particles could be arranged in a two-dimensional scheme that indicated a wider but also more approximate symmetry, called "the way of the octet," since they remembered the geometric structure of the octets.

The new particles belonged to the hadron family. Physicists began to think that these particles were not really elementary, and in 1964 Gell-Mann and Zweig proposed the *quark model*, confirmed in 1968 with experiments at the Stanford Linear Accelerator (SLAC), distinguishing the properties of the quarks with the terms *up* (u), *down* (d), and *strange* (s). The model described the proton as consisting of the three *uud* quarks and the neutron constituted by the *udd* combination. Particles such as pions are composed of a quark and an antiquark. However, the model had a flaw. The particle (baryon) Δ^{++} consisted of three up-quarks, and this violated the Pauli exclusion principle. The solution proposed by Han, Nambu, and Greenberg was to assume that there is a new quantum number for quarks called color. It was later recognized that it was a sort of charge (similar to the notion of electric charge, but at the same time with various differences with it), called *color*. So each of the quarks had three different colors, and suddenly the number of quarks tripled. Han and Nambu suggested that the strong interaction was mediated by eight gauge bosons, called *gluons*. These are the ideas behind the strong interaction theory, *quantum chromodynamics*, which takes its name from color, in Greek *chróma*. Gross, Wilczek, and Politzer showed that the color force, unlike electromagnetism, weakened with distance, an effect called *asymptotic freedom*. In addition, the color strength increases when quarks are trying to move away, resulting in the inability to see free quarks. This phenomenon is called *confinement*. Today, in addition to the up, down, and strange quarks, we know that there are three other quarks: *charm* (c), *bottom* (b) (or beauty), and *top* (t) (or truth). The quarks are combined into three pairs — (u, d), (c, s), (t, b) — of increasing mass, and each with the same pair of charges, 2/3 e^-, –1/3 e^-. The quarks therefore have three generations of particles and similarly the leptons: (e^-, ν_e), (μ, ν_μ), (τ, ν_τ). Quarks were discovered between the '70s and the '90s. The last and heaviest of the quarks, the top, was observed at Fermilab in 1995.

6.9 Summary: Particles and Interactions of the Standard Model

6.9.1 *Particles*

The fundamental building blocks that make up the world are the fields. However, their oscillations manifest themselves as particles. The standard model contains two large families of particles: fermions and bosons.

Fermions take their name from Enrico Fermi and obey the *Pauli exclusion principle*. They follow the *Fermi–Dirac statistic* and therefore have a half-integer spin (1/2 $\hbar$, 3/2 $\hbar$, 5/2 $\hbar$ …) and are the constituents of matter. There are two types of fermions: the quarks, constituting the protons and neutrons, and the leptons, constituting electrons, muons, tauons, neutrinos, and their respective antiparticles.

The *bosons* take their name from Satyendranath Bose, they follow the *Bose-Einstein statistic* and from the *spin-statistic theorem,* they have integer spin (0 $\hbar$, 1 $\hbar$, 2 $\hbar$…).

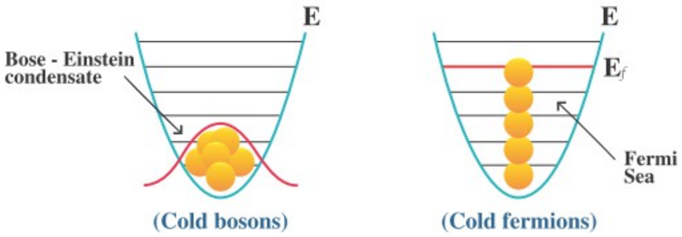

Fig. 6.16. Bosons and fermions.
Source: Modification of work by Fred Bellaiche.

Fermions, following the Pauli exclusion principle, occupy much more space than bosons, as shown in Fig. 6.16. On the left side is represented a gas of bosons and on the right one of fermions at temperatures close to absolute zero (–273.16 degrees centigrade). The boson gas collapses to form a *Bose–Einstein condensate*. Fermions cannot place themselves in a state that takes up little space. They arrange to occupy energetic states of increasing energy up to a state of maximum energy called *Fermi energy*. This is why fermions are the constituents of matter, while bosons are the vectors of interactions

Bosons are distinguished in *gauge bosons* or vectors that mediate the forces and in *mesons*, stable particles consisting of a quark and its antiparticle, antiquark. Particles composed of a large number of particles, such as protons and neutrons, and atomic nuclei can behave like bosons or fermions depending on the total spin. Another classification of the particles according to the forces to which they are subjected or their mass is as follows:

1. *Hadrons* (from the Greek "strong") are particles subject to strong nuclear force and can be divided into

    - *Barions* (from the Greek "heavy"): They are fermions. They consist of nuclear particles, the baryons, such as protons, neutrons, the particle *Λ*, *Sigma*, Δ, Ξ, Ω (and their respective antiparticles), and heavier and non-nuclear particles, *hyperons*. Baryons are not elementary particles, but made up of *quarks*. There are six types of quarks: *up* (u), *down* (d), *strange* (s),

charm (c), *bottom* (b) (or *beauty*), and *top* (t) (or *truth*). The quarks are combined in three pairs — (u, d), (c, s), (t, b) — of increasing mass, and each with the same pair of charges 2/3 e^-, −1/3 e^- (where e^- is the electron charge). Each quark has *three colors*, so we have 18 quarks. Protons consist of two up- (u) and one down-quark (d): (uud). Neutrons from one up- and two down-quarks (udd). Protons have a mass of about 938 MeV and neutrons are slightly more massive, 939 MeV, and have a size of the order of 10^{-15} m. Outside the nucleus, neutrons are unstable and have an average life of approximately 15 minutes. Protons are almost immortal particles, given that their average life is greater than 10^{34} years, much greater than the age of the universe. The average life of the proton is important because some Grand Unification Theories (GUTs), theories that unify strong, weak, and electromagnetic nuclear forces, require that the proton decay. The baryons are assigned the so-called *baryonic number*, which is $B = +1$ for baryons and $B = -1$ for anti-baryons. For the other particles, mesons and fermions, $B = 0$. The baryon number is an almost always preserved quantity, that is, the baryon number before a reaction is the same as the one after.

- *Mesons* (from the Greek "middle"): They are bosons subject to a strong nuclear force with intermediate masses between the baryons and the leptons. They consist of a quark and an antiquark.
- *Leptons* (from the Greek "light"). They have no strong interaction, are elementary particles, and are fermions with spin 1/2. Examples of this family are charged particles such as electrons with a mass of about 10^{-30} kg (0.511 MeV) and dimensions less than 10^{-22} m, *muons* with a mass 207 times that of the electron, *tauons* with a mass about 3500 times larger than that of electrons, and their respective antiparticles. The family also contains neutral particles, the *neutrinos*. Neutrinos have a very small mass, between 10,000 and 1 million times smaller than that of the electron. They come in three flavors: *electron*, *muon*, and *tau neutrino* and can oscillate, that is, transform into each other (*neutrino oscillations*). Like quarks, leptons have three generations of particles $(e, \nu e)$, $(\mu, \nu\mu)$, (τ, ν_{τ}). Like baryons, leptons are assigned a leptonic number: $L = +1$ for particles, $L = -1$ for antiparticles, and $L = 0$ for hadrons.

Ultimately, we have three families of leptons, six particles, and three of baryons, another six particles. To each of the particles corresponds an antiparticle of equal mass and opposite charge.

A very interesting point is that matter is made of fermions and only of particles of the first family, namely quarks u and d and electrons. A legitimate question at this point is, why are there two other families of particles if they do not constitute matter, and why is there a mass hierarchy? This and many other questions, as we will see at the end of this section, show the limitations of the *standard model*.

Another discrepancy of the model is that neutrinos have no mass, while the phenomenon of neutrino oscillation, that is, the transformation of one of the three types of neutrinos into another type, implies that they have mass, however small. One of the possible solutions, better described in Appendix D, is that there is another neutrino, the *sterile neutrino*, which interacts with other particles only with gravity and can interact with other neutrinos also with the mechanism of neutrino oscillations. The *seesaw mechanism* (Fig. 6.18) ensures that the mass of the neutrino is inversely proportional to that of the sterile neutrino. If this latter has a mass of the order of 10^{16} GeV, the neutrino has a mass of about 10^{-2} eV, which is the expected mass for neutrinos.

This mechanism is based on the existence of new physics at the scale of the Grand Unification Theory, 10^{15}–10^{16} GeV.

6.9.2 *Interactions*

In nature, there are four interactions or forces: *gravitational*, *electromagnetic*, *strong nuclear*, and *weak nuclear force*.

The standard model only describes the last three.

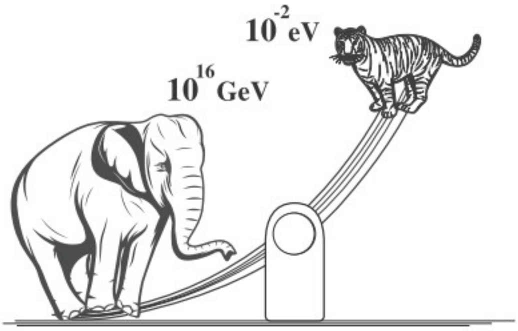

Fig. 6.18. The seesaw mechanism. The larger the mass of the right-handed, sterile, neutrino (see Appendix D), the smaller the mass of the usual neutrino.

- *Electromagnetic force*: It can be attractive and repulsive and decays with the square of the distance. It is responsible for electromagnetic phenomena (emission and absorption of radiation) and chemical reactions. It holds electrons around nuclei. The electromagnetic force is mediated by the *photon*.
- *Strong nuclear force*: It is the most intense. It is responsible for the existence of the atomic nucleus, has a range of action in the order of the size of the proton, and grows as the distance decreases. It is mediated by eight bosons, the *gluons*.
- *Weak nuclear force*: It is responsible for radioactive decay and contributes to making the stars shine. It has three mediators, the bosons W^+, W^-, Z^0, which, unlike the mediators of the other forces, have mass, respectively 90 and 100 times heavier than that of the proton. Their mass comes directly from the Higgs mechanism. The weak and electromagnetic forces are manifestations of a single force, the *electroweak force*.
- *Gravitational force*: Although not described by the standard model, it is of fundamental importance. It has a never-observed theoretical mediator, the *graviton*. It is the weakest of forces, 10^{25} times less intense than the weak one, 10^{36} than the electromagnetic one, and 10^{38} than the strong one, but it dominates in large spaces and in the universe. It is always attractive and responsible for the formation of structures and the rotation of planets around stars, galaxies, and so on.

The *Higgs boson*, discovered in 2012, supplies mass to elementary particles such as quarks and W^+, W^-, Z^0 bosons. Its measured mass is 125 GeV, much smaller than the theoretical expected value. This problem, which we discuss in the next chapter, is usually indicated with the *hierarchy problem*, and its solution implies the existence of physics beyond the standard model.

The 12 elementary particles (not counting quark color, which would bring them to 24) do not feel the various forces in the same way. All "feel" the gravitational force, while only the charged ones perceive the electromagnetic force. Strong force is felt only by quarks.

Protons, neutrons, and electrons form *atoms*. The simplest one, the hydrogen atom, is made of a proton and an electron. A gold atom has 79 protons and 118 neutrons, and for electrical neutrality, 79 electrons. An atom is basically an empty structure in quantum mechanics.[9] To get an idea, if the core had the diameter of a tennis ball (7 cm in diameter), the closest electron would be at a distance of 3 km.

Although the standard model is a very successful theory with incredible precision, it is not a complete theory, because it is not able to fully explain the nature of the world. Several open questions remain. For example, why is the world made only by a generation of quarks and leptons but in nature there are three of them? Are quarks and leptons really elementary particles? The mass of the particles is not given by the model but is obtained experimentally. Is there any way to get it from theory? That is, why does the standard model not foresee the mass of the particles? And again, the universe contains only matter, and if so, why? How can gravitation be integrated into the model? Is it possible to build a theory in which all forces are unified? How can we solve the hierarchy problem (we will discuss this issue in Chapter 7).

Finally, the standard model does not provide the existence of dark matter and energy. Other theories besides the standard model, which we will illustrate later, have been proposed that introduce models for dark matter and dark energy. However, they have never been confirmed experimentally.

---

[9] In quantum field theory, this is no longer the case. The space between electrons and protons contains virtual particles.

CHAPTER VII

RIEMANN'S SYMBOLS AND PROPERTIES RELATING TO CURVATURE; RICCI'S AND EINSTEIN'S SYMBOLS; GEODESIC DEVIATION

1. Cyclic displacement and the relations between parallelism and curvature.

Schouten,[1] by his vector methods, and independently of him Pérès,[2] by ordinary calculus methods, have demonstrated the great importance, for determining the geometrical properties of a V_n, of the displacement of a direction round a closed circuit; in particular the importance of infinitesimal circuits in investigating local properties at a generic point P.

Consider a generic direction (a unit vector) $\mathbf{u}$ drawn from P, and give it a parallel displacement round a closed curve T of infinitesimal length so that it comes back again to P; after the displacement we shall have a direction $\mathbf{u}_1$, also drawn from P, but not in general coinciding with $\mathbf{u}$. The change in the contravariant components u^r due to the displacement round the circuit will in general depend on the *area* of the circuit, on its *configuration* (i.e. on the orientation in V_n of the element of surface on which the circuit is drawn), and on the *metrical properties* of the V_n at P. The influence of the last-named properties is exerted through the first and second derivatives of the a_{ik}'s; these derivatives occur in certain characteristic groups which are called *Riemann's symbols*, and which are composed of Christoffel's symbols and their first derivatives. In the particular case of a surface, these expressions reduce to one, which is that known in geometry as the (Gaussian) *curvature* of the surface; for any V_n the consideration of Riemann's symbols provides a convenient way of extending the notion of curvature.

In this chapter we shall first consider displacement round a particular form of infinitesimal circuit, namely, an elementary parallelogram. We shall then discuss some of the properties of Riemann's symbols, which occur in the investigation of the displacement, and shall use these properties to obtain the formula for changing the order of two successive covariant differentiations, by determining the difference between the derivatives. Lastly, we shall return to the question of displacement round any circuit whatever, and shall deduce from it the notion of curvature, first for a surface, then for any V_n whatever.

---

[2] "Le parallélisme de M. Levi-Civita et la courbure riemannienne", in *Rend. della R. Acc. dei Lincei*, (5), Vol. XXVII (first half-year, 1919). pp. 425–428.

2. **Cyclic displacement round an elementary parallelogram.**

Let two elementary vectors, δP, $\delta' P$, be drawn from a generic point P of a V_n. We shall interpret the first as an elementary displacement PP_1, and give the vector $\delta' P$ a parallel displacement along it; let Q be the position of the extremity of $\delta' P$ after this displacement. If we apply the same process to δP, and give it a parallel displacement along the path PP_2, we reach the same point Q (as we have already shown in Chapter V, § 19), even if we retain terms of the type $\delta\delta' P$, $\delta'\delta P$, while neglecting terms of the second order in δP and $\delta' P$. We can therefore, in any V_n, consider an *elementary parallelogram* PP_1QP_2.

We shall adopt the obvious convention of representing by δq the change in any quantity q (scalar or vector) in passing from P to P_1 and by $\delta' q$ the analogous change in passing from P to P_2. For a vector, we shall calculate these changes by the formulæ of parallelism.

Now let $D_1 q$ be the change in q on passing from P to Q along the path PP_1Q, and $D_2 q$ the analogous change on passing along the other pair of sides PP_2Q which with the first pair make up the circuit.

It will be seen at once that (neglecting second order terms as explained above) the total change Δq on going round the entire circuit in the sense PP_1QP_2P is $D_1 q - D_2 q$. We shall first examine $D_1 q$.

The change denoted by δ corresponds to the displacement along PP_1; hence, if the value of our quantity was q at P, its value at P_1 will be

$$q + \delta q = q_1.$$

The displacement along P_1Q changes q_1 into $q_1 + \delta' q_1$, so that at Q we shall have the quantity

$$\begin{aligned} &q + \delta q + \delta'(q + \delta q) \\ &= q + \delta q + \delta' q + \delta'\delta q \end{aligned}$$

so that

$$D_1 q = \delta q + \delta' q + \delta'\delta q.$$

As $D_2 q$, by its definition, differs from $D_1 q$ only by interchanging P_1 and P_2, and therefore δ and δ', we get

$$D_2 q = \delta' q + \delta q + \delta\delta' q.$$

It follows that the change caused by the displacement round the circuit is

$$\Delta q = (\delta'\delta - \delta\delta')q. \quad . \quad . \quad . \quad . \quad (1)$$

We must now find an explicit form for this expression, supposing that the quantity q is a vector $\mathbf{u}$, and calculating the increments δ and δ' by the formulæ of parallelism. By these formulæ, the changes δu^r of the contravariant components will be given by the Pfaffian (Chapter V, equation (52))

$$\delta u^r = -\sum_1^n{}_{ih} \{ih, r\}\, u^i\, \delta x_h, \quad . \quad . \quad . \quad (2)$$

while the changes $\delta' u^r$ will be given by the same Pfaffian relative to the increments $\delta' x_h$. From (1) we see that we have to calculate the bilinear covariant (cf. Chapter II, § 4) of this Pfaffian.

Differentiating (2) with the symbol δ' we get

$$\delta'\delta u^r = -\sum_1^n{}_{ih} \delta'\{ih, r\}\, u^i\, \delta x_h - \sum_1^n{}_{ih} \{ih, r\}\, \delta' u^i\, \delta x_h$$
$$- \sum_1^n{}_{ih} \{ih, r\}\, u^i\, \delta'\delta x_h.$$

To expand the first sum, we note that the expressions $\{ih, r\}$ are functions of the x's, and therefore

$$\delta'\{ih, r\} = \sum_1^n{}_k \frac{\partial}{\partial x_k} \{ih, r\}\, \delta' x_k.$$

The second, on substituting for $\delta' u^i$ the expression analogous to (2), becomes

$$\sum_1^n{}_{ihkl} \{ih, r\} \{kl, i\}\, u^l\, \delta' x_k\, \delta x_h,$$

or, interchanging i and l in order to get the factor u^i here too,

$$\sum_1^n{}_{ihkl} \{lh, r\} \{ki, l\}\, u^i\, \delta' x_k\, \delta x_h.$$

We have, therefore, taking out the factors $u^i\,\delta x_h\,\delta' x_k$ in the first two sums,

$$\delta'\delta u^r = -\sum_1^n{}_{ihk}\left[\frac{\partial}{\partial x_k}\{ih,\,r\} - \sum_1^n{}_l\{lh,\,r\}\{ki,\,l\}\right]u^i\,\delta x_h\,\delta' x_k$$
$$-\sum_1^n{}_{ih}\{ih,\,r\}\,u^i\,\delta'\delta x_h.$$

The expression for $\delta\delta' u^r$ can be obtained from this by interchanging δ and δ'; in the first sum we shall also interchange h and k, giving

$$\delta\delta' u^r = -\sum_1^n{}_{ihk}\left[\frac{\partial}{\partial x_h}\{ik,\,r\} - \sum_1^n{}_l\{lk,\,r\}\{hi,\,l\}\right]u^i\,\delta' x_k\,\delta x_h$$
$$-\sum_1^n{}_{ih}\{ih,\,r\}\,u^i\,\delta\delta' x_h.$$

In taking the difference $\delta'\delta u^r - \delta\delta' u^r$ the third sum cancels out, because $\delta\delta' x_h = \delta'\delta x_h$ (cf. Chapter II, § 4), and there remain the terms involving the indices i, h, k, in which $u^i\,\delta x_h\,\delta' x_k$ can be taken out as a common factor. If we introduce *Riemann's symbols of the second kind*,

$$\left.\begin{aligned}\{ir,\,hk\} = \frac{\partial}{\partial x_k}\{ih,\,r\} - \frac{\partial}{\partial x_h}\{ik,\,r\}\\ -\sum_1^n{}_l[\{lh,r\}\{ik,l\} - \{lk,r\}\{ih,l\}]\end{aligned}\right\}(i,\,r,\,h,\,k = 1,\,2,\,\ldots\,n),\quad (3)$$

we shall therefore have

$$\Delta u^r = (\delta'\delta - \delta\delta')u^r = -\sum_1^n{}_{ihk}\{ir,\,hk\}\,u^i\,\delta x_h\,\delta' x_k. \quad . \quad (4)$$

This formula shows that the required increment $\Delta\mathbf{u}$ depends on the vector $\mathbf{u}$, on the two vectors δP, $\delta' P$ which define the parallelogram, and lastly, on the metric of the manifold, through the quantities $\{ir,\,hk\}$. From (4) it follows as a particular case that for Euclidean spaces Riemann's symbols as just defined are all zero, whatever may be the co-ordinates x chosen for reference. In fact, for such a manifold, we have $\Delta u^r = 0$ $(r = 1,\,2,\,\ldots\,n)$, since any vector resumes its original value after parallel displacement round any closed circuit whatever. Hence the right-hand side of (4) vanishes for every r, and for any value of the vector **u** and of the displacements δP, $\delta' P$, i.e. for any values of the arguments u^i, δx_h, $\delta' x_k$. The coefficients $\{ir, hk\}$ must therefore vanish separately.

It will be useful to point out at once the following two properties of the operator Δ:

(*a*) When applied to a product, it behaves like a symbol of ordinary differentiation, i.e.

$$\Delta(\psi\phi) = \psi\Delta\phi + \phi\Delta\psi,$$

which can be verified directly, by calculating first $\delta(\psi\phi)$, then $\delta'\delta(\psi\phi)$, &c.;

(*b*) when applied to a function of position, the result is zero, as is obvious from the meaning of the symbol.

If instead of the increments Δu^r we wish to find those of the covariant components, we can use the relation

$$u_j = \sum_1^n{}_r\, a_{jr}\, u^r,$$

and therefore, from the properties of the operator Δ,

$$\begin{aligned}\Delta u_j &= \sum_1^n{}_r\, a_{jr}\, \Delta u^r \\ &= -\sum_1^n{}_{rihk}\, a_{jr}\, \{ir, hk\}\, u^i\, \delta x_h\, \delta' x_k.\end{aligned}$$

If we introduce *Riemann's symbols of the first kind*,

$$(ij, hk) = \sum_1^n{}_r\, a_{jr} \{ir, hk\}, \quad . \quad . \quad . \quad . \quad (5)$$

we can sum with respect to r, and can then write

$$\Delta u_j = -\sum_1^n{}_{ihk}\, (ij, hk)\, u^i\, \delta x_h\, \delta' x_k, \quad . \quad . \quad (4')$$

which is analogous to (4).

Solving (5) we get Riemann's symbols of the second kind in terms of those of the first kind by the formula (the inverse of (5))

$$\{ir, hk\} = \sum_1^n{}_j\, a^{jr}\, (ij, hk.) \quad . \quad . \quad . \quad (5')$$

3. **Fundamental properties of Riemann's symbols of the second kind.**

As can be seen from their definition (3), Riemann's symbols of the second kind are functions of position, depending on the coefficients a_{ik}, their first derivatives (contained in Christoffel's symbols) and second derivatives (contained in the derivatives of Christoffel's symbols). They have the following fundamental properties:

(*a*) They are antisymmetrical in the last two indices, i.e.

$$\{ir, hk\} = -\{ir, kh\}, \quad . \quad . \quad . \quad (6)$$

whence in particular

$$\{ir, hh\} = 0.$$

This property follows immediately from (3).

(*b*) They constitute a mixed tensor,[1] contravariant with respect to the second index and covariant with respect to the other three, so that the symbol $\{ir, hk\}$ could also be denoted (as is sometimes done) by a^r_{ihk}. To prove this, consider the invariant

$$F = \sum_1^n{}_r \, p_r u^r,$$

where the p's are given (but completely arbitrary) functions of position, so that $\Delta p_r = 0$. If we give F a displacement round an infinitesimal circuit, we find (remembering the behaviour of the operator Δ)

$$\Delta F = \sum_1^n{}_r \, (u^r \Delta p_r + p_r \Delta u^r)$$
$$= \sum_1^n{}_r \, p_r \Delta u^r.$$

As F is invariant, this quantity must also be so; replacing Δu^r in it by its expression (4), we get the quadrilinear form

$$\Delta F = -\sum_1^n{}_{ihkr} \{ir, hk\} \, p_r u^i \delta x_h \delta' x_k, \quad . \quad . \quad (7)$$

which expresses the required property of the Riemann's symbols, since the simple systems p_r, u^i, δx_h, $\delta' x_k$ are all arbitrary.

---

[1] Very generally, especially in works on the Theory of Relativity, called the *Riemann-Christoffel tensor.*

We can use the tensor character of Riemann's symbols to obtain a second proof of the fact that Riemann's symbols are all zero for a Euclidean V_n (the first proof is an immediate consequence of (4), as was shown in the preceding section). In fact, the definition (3) shows at once that they vanish in Cartesian co-ordinates, and in consequence they vanish in any other system of co-ordinates.

(*c*) They have an important cyclic property with respect to the three indices of covariance, namely,

$$\{ir, hk\} + \{hr, ki\} + \{kr, ih\} = 0. \quad . \quad . \quad (8)$$

To prove this, we again take F and formula (7), but we suppose that in them the p's are derivatives of an invariant function f of position (whose numerical values are otherwise arbitrary), and we also take as vector $\mathbf{u}$ an infinitesimal displacement with components $u^r = dx_r$, which is also arbitrary. With this choice, F becomes

$$F = \sum_1^n{}_r \frac{\partial f}{\partial x_r} dx_r = df,$$

and (7) becomes

$$(\delta'\delta - \delta\delta')\, df = -\sum_1^n{}_{ihkr} \{ir, hk\}\, p_r\, dx_i\, \delta x_h\, \delta' x_k. \quad . \quad (9)$$

Interchanging cyclically the three infinitesimal vectors denoted by the operators d, δ, δ', we get the other two formulæ:

$$(d\delta' - \delta' d)\, \delta f = -\sum_1^n{}_{ihkr} \{ir, hk\}\, p_r\, \delta x_i\, \delta' x_h\, dx_k, \qquad (9')$$

$$(\delta d - d\delta)\, \delta' f = -\sum_1^n{}_{ihkr} \{ir, hk\}\, p_r\, \delta' x_i\, dx_h\, \delta x_k. \quad (9'')$$

Now on the right-hand side of these last two formulæ we can arrange to have the product $dx_i\, \delta x_h\, \delta' x_k$ in the general term, merely by a suitable interchange of the indices of summation. We can then add (9), (9′), and (9″); the left-hand side gives 0, since the terms cancel out in pairs (e.g. $\delta'\delta df - \delta' d\delta f = \delta'(\delta df - d\delta f) = 0$, since f is a function of position); and we get

$$0 = \sum_1^n{}_{ihkr} [\{ir, hk\} + \{hr, ki\} + \{kr, ih\}]\, p_r\, dx_i\, \delta x_h\, \delta' x_k.$$

As p_r, dx_i, δx_h, $\delta' x_k$ are arbitrary, (8) follows at once.

4. Fundamental properties and number of Riemann's symbols of the first kind.

Riemann's symbols of the first kind, as defined by (5) (i.e. the quantities obtained by compounding the quadruple system of the symbols of the second kind with the system of coefficients a_{ik}) have the following properties:

(*a*) They are *covariant with respect to all four indices*, so that they may be denoted, as is often done, by $a_{ij,\,hk}$; this follows from the definition, in consequence of the law of contraction.

The remark that a Euclidean V_n has all its Riemann's symbols zero is true here too, whatever may be the system of reference.

(*b*) They are *antisymmetrical* with respect to each pair of indices, so that we have identically

$$(ij,\, hk) = -(ij,\, kh), \quad . \quad . \quad . \quad . \quad . \quad (10)$$

$$(ij,\, hk) = -(ji,\, hk). \quad . \quad . \quad . \quad . \quad . \quad (11)$$

The identity (10) follows at once from (5), and from the analogous property of the symbols of the second kind. To prove (11) we shall follow a method analogous to that used in § 3 (*b*), taking as invariant the scalar product of two arbitrary vectors **u**, **v**,

$$F = \overset{n}{\underset{1}{\Sigma}}{}_j\, v_j\, u^j.$$

Applying the operator Δ and remembering that in a parallel displacement the scalar product does not change (so that $\Delta F = 0$) we get

$$0 = \overset{n}{\underset{1}{\Sigma}}{}_j\, v_j\, \Delta u^j + \overset{n}{\underset{1}{\Sigma}}{}_j\, u^j\, \Delta v_j. \quad . \quad . \quad . \quad (12)$$

The expression for Δu^j is given by (4), by writing j in it instead of r; that for Δv_j is given by (4′). Substituting, we get

$$0 = \overset{n}{\underset{1}{\Sigma}}{}_{jihk}\, v_j \{ij,\, hk\}\, u^i\, \delta x_h\, \delta' x_k + \overset{n}{\underset{1}{\Sigma}}{}_{jihk}\, u^j\, (ij,\, hk)\, v^i\, \delta x_h\, \delta' x_k. \qquad (12')$$

In the first sum we express v_j in terms of the contravariant components v_r, and then, remembering (5), we sum with respect to j; we get successively

$$\overset{n}{\underset{1}{\Sigma}}{}_{jihkr}\, a_{jr}\, v^r \{ij,\, hk\}\, u^i\, \delta x_h\, \delta' x_k = \overset{n}{\underset{1}{\Sigma}}{}_{ihkr}\, v^r\, (ir,\, hk)\, u^i\, \delta x_h\, \delta' x_k;$$

lastly, changing the indices i and r into j and i respectively (to get the term in the same form as the second part of (12′)), we get

$$\sum_{1}^{n}{}_{jihk}\, v^i\,(ji,\, hk)\; u^j\,\delta x_h\,\delta' x_k.$$

We can now return to (12′), and taking out the common factor $v^i\, u^j\, \delta x_h\, \delta' x_k$ we get

$$0 = \sum_{1}^{n}{}_{jihk}\, [(ji,\, hk) + (ij,\, hk)]\; v^i\, u^j\,\delta x_h\,\delta' x_k; \qquad (13)$$

from this, since u^j, v^i, δx_h, $\delta' x_k$ are arbitrary, we get formula (11).

(*c*) Riemann's symbols of the first kind have also a *cyclic property* analogous to that of the symbols of the second kind and immediately deducible from the latter, namely,

$$(ij,\, hk) + (hj,\, ki) + (kj,\, ih) = 0, \quad . \quad . \quad (14)$$

where the second index remains fixed and the other three are permuted cyclically. This formula follows directly from (8), on multiplying by a_{jr} and summing with respect to r.

As each of the terms in this sum is antisymmetrical, we can at once obtain from (14) a similar identity

$$(ij,\, hk) + (ih,\, kj) + (ik,\, jh) = 0, \quad . \quad . \quad (14')$$

in which the first index remains fixed and the other three are permuted cyclically.

(*d*) Lastly, for the symbols of the first kind, there is a property of *permutability*, which is a consequence of the foregoing properties, and according to which we can interchange the two pairs of indices without altering the value of the symbol; namely,

$$(ij,\, hk) = (hk,\, ij). \quad . \quad . \quad . \quad . \quad (15)$$

To prove this, take (14′) and the three other identities obtained from it by cyclic permutation of the four indices in the order i, j, h, k, or

$$\begin{aligned}
\underline{(ij,\, hk)} + (ih,\, kj) + (ik,\, jh) &= 0,\\
(jh,\, ki) + (jk,\, ih) + \underline{(ji,\, hk)} &= 0,\\
\underline{(hk,\, ij)} + (hi,\, jk) + (hj,\, ki) &= 0,\\
(ki,\, jh) + (kj,\, hi) + (kh,\, ij) &= 0.
\end{aligned}$$

Adding the first and fourth and subtracting the second and third of these identities, and using the property of antisymmetry, we see that the terms cancel out in pairs, except the four underlined, which give

$$2(ij,\,hk) - 2(hk,\,ij) = 0,$$

whence the required property follows.

We shall now calculate the *number of independent Riemann's symbols of the first kind.* A quadruple system (cf. Chapter IV, § 2) has in general n^4 elements, if there are n independent variables. The number of distinct Riemann's symbols of each kind is smaller, however, as these symbols are connected by the identities we have just proved. We shall determine this number for the symbols of the first kind, dividing them into three classes, and counting separately those in each class, as follows:

(1) Symbols with only two different indices: these are of the type $(ij,\ ij)$, since the other possible arrangements are either reducible to this, or give zero values. Each pair of unequal indices i, j therefore gives a single symbol of this class, which thus contains

$$\frac{n(n-1)}{2};$$

(2) Symbols with three different indices: these are of the type $(ij,\,ih)$, since here too the other possible arrangements are reducible to this or give zero values. Every triplet of unequal indices will give three symbols of this type (since the repeated index may be any one of the three); since there are $\frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}$ triplets, the number of distinct symbols of the class we are considering amounts to

$$\frac{n(n-1)(n-2)}{2};$$

(3) Symbols with four different indices: a set of four different indices i, j, h, k will give the three symbols

$$(ij,\,hk),\quad (ih,\,kj),\quad (ik,\,jh),$$

while every other possible arrangement gives a symbol reducible to one of these. But these three are not independent, on account of the cyclic relation (14′). It follows that each of the

$\dfrac{n(n-1)(n-2)(n-3)}{1 \cdot 2 \cdot 3 \cdot 4}$ sets of four indices gives two distinct symbols, so that the total number of these is

$$\frac{n(n-1)(n-2)(n-3)}{12}.$$

Adding these three partial totals, and simplifying, we get the total number N of independent Riemann's symbols of the first kind:

$$N = \frac{n^2(n^2-1)}{12}.$$

Thus for an ordinary surface ($n = 2$) we have $N = 1$; for a three-dimensional space, $N = 6$; for a four-dimensional space, $N = 20$.

5. **Bianchi's identities.**[1]

Bianchi's identities are cyclic relations between the covariant derivatives of Riemann's symbols of both the first and second kinds. They are obtained as follows:

Take formula (3), which defines the symbol of the second kind $\{ir, hk\}$, and differentiate it with respect to x_l. We note, however, that on differentiation the last part, which consists of terms of the second order in Christoffel's symbols, gives terms made up of the product of one such symbol by the derivative of another: the essential point for us is that, with reference to a specified point P, by choosing co-ordinates which are geodesic at that point, we can make all these terms vanish. We cannot, however, treat the first part in the same way, as the geodesic co-ordinates make Christoffel's symbols vanish but not their derivatives. We shall therefore have the formula, valid at the point P for co-ordinates geodesic at P,

$$\frac{\partial}{\partial x_l}\{ir, hk\} = \frac{\partial^2}{\partial x_k \, \partial x_l}\{ih, r\} - \frac{\partial^2}{\partial x_h \, \partial x_l}\{ik, r\}.$$

---

[1] These identities were stated without proof by PADOVA, on the strength of a verbal communication of RICCI (cf. "Sulle deformazioni infinitesime", in *Rend. della R. Acc. dei Lincei*, (4), Vol. V (first half-year, 1889), p. 176). They were then forgotten even by Ricci himself. BIANCHI rediscovered them and published a proof obtained by direct calculation in 1902 (*Ibid.*, (5), Vol. XI (first half-year, 1902), pp. 3–7).

Write down also the two other formulæ obtained from this by cyclic permutation of the indices h, k, l, leaving i and r fixed;

$$\frac{\partial}{\partial x_h}\{ir, kl\} = \frac{\partial^2}{\partial x_l \partial x_h}\{ik, r\} - \frac{\partial^2}{\partial x_k \partial x_h}\{il, r\},$$

$$\frac{\partial}{\partial x_k}\{ir, lh\} = \frac{\partial^2}{\partial x_h \partial x_k}\{il, r\} - \frac{\partial^2}{\partial x_l \partial x_k}\{ih, r\}.$$

Adding the terms on the left and right of these three equations we get

$$\frac{\partial}{\partial x_l}\{ir, hk\} + \frac{\partial}{\partial x_h}\{ir, kl\} + \frac{\partial}{\partial x_k}\{ir, lh\} = 0, \quad (16)$$

which holds at the point P, in the particular system of co-ordinates chosen. Now consider the following mixed tensor of rank five

$$A^{r}_{ihkl} = \{ir, hk\}_l + \{ir, kl\}_h + \{ir, lh\}_k,$$

in which the suffixes outside the brackets denote covariant differentiation. This system, referred to the point P and to co-ordinates geodesic at P, is identical with the left-hand side of (16), since in these conditions the covariant and ordinary derivatives are identical; all its elements are therefore equal to zero, and it will therefore be identically zero whatever may be the system of reference (cf. Chapter IV, § 12). We have thus proved the identity

$$\{ir, hk\}_l + \{ir, kl\}_h + \{ir, lh\}_k = 0, \quad . \quad (17)$$

which is a first form of the result established by Bianchi.

For the symbols of the first kind the analogous relation is easily proved from the definition of these symbols given by (5). In fact, taking the covariant derivative of this formula, and using Ricci's lemma, we find that

$$(ij, hk)_l = \sum_{1}^{n}{}_r \, a_{jr}\{ir, hk\}_l.$$

From this, permuting cyclically the indices h, k, l and summing, we get, by (17),

$$(ij, hk)_l + (ij, kl)_h + (ij, lh)_k = 0, \quad . \quad . \quad (17')$$

which is the second form of Bianchi's identity.

6. Commutation rule for the second covariant derivatives.

An important application of Riemann's symbols occurs in the formula which gives the relation between the two systems

$$A^{(j)}_{(i)hk} \quad \text{and} \quad A^{(j)}_{(i)kh},$$

obtained by double covariant differentiation from a generic tensor $A^{(j)}_{(i)}$, where (i) stands for the aggregate of indices of covariance $i_1 \ldots i_m$ and (j) for the aggregate of indices of contravariance $j_1 \ldots j_\mu$. To simplify the formulæ we shall consider a mixed double system A^j_i, with the remark that the procedure is similar if there are more indices.

We start as usual from the bilinear form

$$F = \overset{n}{\underset{1}{\Sigma}}{}_{ij}\, A^j_i\, \xi^i\, u_j,$$

the invariance of which determines the law of transformation of the A's; the ξ^i's are the contravariant components of an arbitrary vector $\boldsymbol{\xi}$, and the u_j's are the covariant components of another arbitrary vector $\mathbf{u}$. The procedure will consist in calculating, in two different ways, the quantity ΔF corresponding to a cyclic displacement round an elementary parallelogram (cf. § 2), and in equating the two expressions so obtained.

A first way of calculating ΔF is as follows. We associate the increments δ, δ' with two sides of the parallelogram, as in § 2, and use (1). Note first that from the definition of the covariant derivative (cf. Chapter VI, § 1) δF is given by

$$\delta F = \overset{n}{\underset{1}{\Sigma}}{}_{ijh}\, A^j_{i|h}\, \xi^i\, u_j\, \delta x_h.$$

Similarly, applying the symbol δ' to this expression, we shall get

$$\delta'\delta F = \overset{n}{\underset{1}{\Sigma}}{}_{ijhk}\, A^j_{i|hk}\, \xi^i\, u_j\, \delta x_h\, \delta' x_k.$$

From this, interchanging δ and δ', we get

$$\delta\delta' F = \overset{n}{\underset{1}{\Sigma}}{}_{ijhk}\, A^j_{i|hk}\, \xi^i\, u_j\, \delta' x_h\, \delta x_k;$$

subtracting these two equations, after interchanging the indices h and k in the second, we get

$$\Delta F = \overset{n}{\underset{1}{\Sigma}}{}_{ijhk} \left(A^j_{i\,|\,hk} - A^j_{i\,|\,kh}\right) \xi^i\, u_j\, \delta x_h\, \delta' x_k. \quad . \quad (18)$$

The other method of calculating this quantity consists in applying the operator Δ directly to the expression for F. Remembering the fundamental properties of Δ (§ 2) we shall get

$$\Delta F = \overset{n}{\underset{1}{\Sigma}}{}_{ij} A^j_i \left(u_j\, \Delta \xi^i + \xi^i\, \Delta u_j\right),$$

or, substituting for $\Delta \xi^i$ and Δu_j the expressions given by (4) and (4′),

$$\Delta F = -\overset{n}{\underset{1}{\Sigma}}{}_{ijlhk} A^j_i \{li,\, hk\}\, u_j\, \xi^l\, \delta x_h\, \delta' x_k$$
$$- \overset{n}{\underset{1}{\Sigma}}{}_{ijphk} A^j_i\, (pj,\, hk)\, u^p\, \xi^i\, \delta x_h\, \delta' x_k.$$

In order to get the second sum in the same form as the first, we shall express it in terms of symbols of the second kind and of the covariant components of $\mathbf{u}$; to do this we first use the property of antisymmetry with respect to the first pair of indices, and express the u^p's in terms of the u_l's, so that the sum becomes

$$+ \overset{n}{\underset{1}{\Sigma}}{}_{ijphkl} A^j_i\, (jp,\, hk)\, a^{pl}\, \xi^i\, u_l\, \delta x_h\, \delta' x_k.$$

Summing with respect to p, and using (5′), we get

$$\overset{n}{\underset{1}{\Sigma}}{}_{ijhkl} A^j_i \{jl,\, hk\}\, \xi^i\, u_l\, \delta x_h\, \delta' x_k.$$

Now, in order to reconstruct the second expression for ΔF in a suitable form, we shall first interchange some indices, so as to be able to take out the factor $\xi^i\, u_j\, \delta x_h\, \delta' x_k$ which occurs in (18). We must interchange l and i in the first sum, and l and j in the (modified) second; we shall then get, collecting both sums under a single summation sign,

$$\Delta F = -\overset{n}{\underset{1}{\Sigma}}{}_{ijhkl} \left[\, A^j_l \{il,\, hk\} - A^l_i \{lj,\, hk\} \right] \xi^i\, u_j\, \delta x_h\, \delta' x_k.$$

Comparing this expression with (18), and remembering that $\boldsymbol{\xi}$, $\mathbf{u}$, the δx's, and the $\delta' x$'s are arbitrary, we get the *commutation formula*

$$A^{j}_{i|hk} - A^{j}_{i|kh} = -\sum_{1}^{n}{}_{l} \left[A^{j}_{l} \{il, hk\} - A^{l}_{i} \{lj, hk\} \right]. \quad (19)$$

If the system from which we start has m indices of covariance and μ of contravariance, we must consider m vectors $\boldsymbol{\xi}$, determined by their contravariant components, and μ vectors $\mathbf{u}$, determined by their covariant components; by an analogous process we shall find

$$\left.\begin{aligned} A^{(j)}_{(i)|hk} - A^{(j)}_{(i)|kh} = -\sum_{1}^{n}{}_{l} \Bigg[& \sum_{1}^{m}{}_{r} A^{(j)}_{i_1 \ldots i_{r-1} l i_{r+1} \ldots i_m} \{i_r l, hk\} \\ & - \sum_{1}^{\mu}{}_{\rho} A^{j_1 \ldots j_{\rho-1} l j_{\rho+1} \ldots j_\mu}_{(i)} \{l j_\rho, hk\} \Bigg]. \end{aligned}\right\} \quad (20)$$

7. Cyclic displacement round any infinitesimal circuit.

We now return to the order of ideas interrupted at § 2. Given a direction $\mathbf{u}$ at a point P, we shall give $\mathbf{u}$ a parallel displacement (in V_n) round a closed curve T, infinitesimal, but of any shape whatever, and of course passing through P; we propose to calculate the change Du^r in a generic parameter of $\mathbf{u}$ caused by the cyclic displacement. The formula we shall find will be merely a generalization of (4), and must reduce to (4) if as a particular case we take for T an infinitesimal parallelogram.

For an elementary displacement dx_h we know that the change in u^r is

$$du^r = -\sum_{1}^{n}{}_{ih} \{ih, r\} u^i \, dx_h,$$

so that it has the form of a Pfaffian

$$\psi_r = \sum_{1}^{n}{}_{h} X_{rh} \, dx_h, \quad . \quad . \quad . \quad . \quad (21)$$

in which the X's are functions of position (since they contain Christoffel's symbols) and of the u^i's which are defined *along* *the curve T* by the equations of parallelism $du^r = \psi_r$. We have to calculate the integral

$$Du^r = \int_T \psi_r = \int_T \sum_1^n{}_h X_{rh}\, dx_h, \quad . \quad . \quad (22)$$

where we use the operator D to indicate the increment resulting from displacement right round the circuit. We shall now consider any surface σ containing the curve T, and we shall call Γ the region of this surface which is within T, and is such that T constitutes its complete boundary. We propose to transform the integral round the circuit T, which occurs in (22), into an integral over the surface Γ. To do this, we shall first introduce a system of co-ordinates q_1 and q_2 on the surface in question, defining them by the parametric equations

$$x_i = x_i(q_1, q_2) \qquad (i = 1, 2, \ldots n).$$

The dx's will consequently be linear functions of dq_1 and dq_2; substituting their expressions in the Pfaffian (21), this will take the form

$$du^r = \psi_r = Q_1\, dq_1 + Q_2\, dq_2, \quad . \quad . \quad (21')$$

where the quantities Q_1 and Q_2, like the X's, are defined along the curve T. The integral to be calculated will thus be

$$Du^r = \int_T (Q_1\, dq_1 + Q_2\, dq_2). \quad . \quad . \quad (22')$$

We shall suppose the curvilinear co-ordinates q_1, q_2 so chosen that the sense of integration round T is the same as that determined on Γ (at a generic point) by the rotation (through the angle less than 180°) from the positive direction of the line q_1 (i.e. in the sense of q_1 increasing) to the positive direction of the line q_2.

The transformation of the line integral (22′) into a surface integral taken over Γ could be effected at once if the Q's were defined as functions of position in the interior of Γ as well as on its boundary. But instead of this they contain the u^r's, which are given at P, and at points on T have values resulting from the parallel displacement along T itself, but are not defined for a point M within Γ, their values at M depending on the path followed in the parallel displacement of **u** from P to M. We shall, however, show that if Γ is infinitesimal the influence of the path of displacement on the values of the u^r's at M is negligible, and therefore we may consider the u^r's, and in consequence the X's or the Q's, as functions of position over the whole area Γ, which will enable us to make the required transformation of (22').[1]

We shall make some preliminary remarks on orders of magnitude, using for this purpose the general existence theorem for integrals of systems of ordinary differential equations. Such a system is constituted by the equations

$$du^r = \psi_r \qquad (r = 1, 2, \ldots n),$$

which define the functions u^r, along a generic line T, starting from a given set of initial values at P (cf. Chapter II, § 5).

Now the existence theorem assures us that in general (i.e. when certain not very restrictive conditions of continuity and differentiability are satisfied) the initial values define the integrals uniquely, and these integrals and their derivatives are continuous functions for values of the independent variable within an interval which is not shorter than some assignable quantity.

In our case, granting, what will naturally be the case, that the coefficients a_{ik} of ds^2 and the reciprocals a^{ik} are finite and continuous, as well as their first and second derivatives, in a certain region round P, and supposing also that the length of the vector **u** at P is limited, i.e. is not greater than some specified, but arbitrary, constant U, it can easily be deduced from the above-mentioned existence theorem that—considering the arc of the curve of displacement as the independent variable—the u^r's are defined (as continuous, differentiable, &c., functions), with P as starting-point, along any curve whatever, for a segment of the curve of length not greater than a certain quantity Λ

---

[1] We shall in fact here limit the discussion to an indication of the general lines of the argument, without pausing over the details needed to justify the various steps of the proof with complete rigour. There is an exhaustive proof in the article by H. TIETZE: "Ueber Parallelverschiebung in Riemann'schen Raümen", in *Math. Zeitschrift*, Vol. 16, 1923, pp. 308–317.

which depends exclusively on the metric of the manifold and on U. Hence it follows in particular that the differences between the u^r's and their initial values are of the same order[1] of magnitude as the length L of the arc along which the integration of the system $du^r = \psi_r$ is effected.

Further, the area Γ which we are considering on the surface σ is infinitesimal, in the sense that we propose to make it diminish indefinitely. It is therefore perfectly legitimate to suppose that it is already so small that every point in it can be reached from P by a line of length not greater than Λ and that the length of the whole contour T is also less than Λ.

We thus have the result that if **u** undergoes a parallel displacement from P to a point M within the area Γ, or on its boundary T, the u^r's at M differ from their values at P by quantities of the same order as L, if $L\,(\leqslant \Lambda)$ is the maximum length of the lines considered. As a first approximation, in which quantities of the same order as L are neglected, we can therefore take the components u^r as constant and $= u^{r(0)}$ over the whole area Γ, including its boundary.

We can find a closer approximation if we calculate the u^r's at M by integrating the Pfaffian (21) along a curve PQ, substituting, however, for the coefficients X_{rh} their values at P. This process involves an error of order L in the values of these coefficients, and therefore an error of order L^2 in the values found for the u^r's at M; the choice of the curve PM is indifferent, as in this case the Pfaffian becomes an exact differential. As the coefficients are constants, the integration can be at once effected, and will give linear functions of the x's for the u^r's. We shall thus have obtained the u^r's as functions of position at all points (including the boundary) of the area Γ, neglecting quantities of order L^2.

We can get a third approximation by substituting these approximate linear expressions of the u^r's in the coefficients X_{rh}. The X's will thus become functions of position, as was required, defined throughout Γ, including its boundary T, and coinciding on T (if we neglect L^2) with their accurate values as already defined. These values of the X's can be used to calculate the integral (22), which will give the value of Du^r, the error being now of order L^3. It was necessary to carry the approximation thus far, since the other two approximations make ψ an exact differential, and would give the value zero for Du^r, the obvious meaning of this being that Du^r is a quantity of order L^2.

---

[1] This means that the differences in question are not greater than the product of L by a certain *finite* coefficient, which does not depend on L or on the curve of integration, but only on P, U, and the metric of the manifold.

We shall therefore return to (22), giving the X's the meaning just explained, and transform it into the form (22′) by using the parametric equations of the surface σ; Q_1 and Q_2 will now represent functions of position defined at all points of Γ. In consequence[1] we can transform the line integral into a surface integral, getting

$$Du^r = \int_\Gamma \left(\frac{\partial Q_2}{\partial q_1} - \frac{\partial Q_1}{\partial q_2}\right) dq_1\, dq_2,$$

or also

$$Du^r = \int_\Gamma \left[\frac{\partial}{\partial q_1}(Q_2\, dq_2)\, dq_1 - \frac{\partial}{\partial q_2}(Q_1\, dq_1)\, dq_2\right]. \qquad (23)$$

We must now find the value of the integrand on the right of (23), which can be done by means of the following considerations, without writing out the expressions for Q_1 and Q_2 at full length.

Let the operator δ denote the increment of a quantity corresponding to a displacement along the line $q_2 =$ constant, when

---

[1] By the ordinary formulæ,

$$\int_\Gamma \frac{\partial f}{\partial q_1} dq_1 dq_2 = \int_T f dq_2, \quad \int_\Gamma \frac{\partial f}{\partial q_2} dq_1 dq_2 = -\int_T f dq_1, \quad . \quad (G)$$

where f is a function of q_1 and q_2 which is continuous, together with its first derivatives. Usually in these formulæ q_1 and q_2 are interpreted as Cartesian co-ordinates in a plane, and the sense in which the curve T is described is defined by the condition that the pair of directions s, n (s the tangent to the boundary in the sense in which it is described, n the normal to T drawn inwards) is congruent in the plane with the pair q_1, q_2. The formulæ obviously hold, however, independently of this interpretation in plane geometry, and can therefore be applied even if q_1, q_2 are any curvilinear co-ordinates whatever, the sense of describing the curve being determined by an analogous criterion to that just explained, provided that we introduce, at a generic point of the boundary curve, the directions tangential to q_1 (i.e. $q_2 =$ constant) and q_2, in the sense in which the respective parameters increase. Now we have already supposed (p. 187) that the auxiliary curvilinear co-ordinates q_1, q_2 behave as regards sense in precisely this way. Hence the equations (G) hold both in magnitude and in sign.

q_1 increases by dq_1; similarly, δ' corresponds to an increase dq_2 in q_2 alone. We shall therefore have

$$\left.\begin{aligned}\delta x_i &= \frac{\partial x_i}{\partial q_1}\,dq_1,\\ \delta' x_i &= \frac{\partial x_i}{\partial q_2}\,dq_2,\end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \qquad (24)$$

and analogous expressions for any function of position. Now note that in (21′) the first term represents precisely the increment of u^r due to a displacement of the first type ($dq_2 = 0$), so that

$$\delta u^r = Q_1\,dq_1,$$

and, the second term having an analogous meaning,

$$\delta' u^r = Q_2\,dq_2.$$

We can therefore write (23) in the form

$$\begin{aligned}Du^r &= \int_\Gamma \left[\frac{\partial}{\partial q_1}(\delta' u^r)\,dq_1 - \frac{\partial}{\partial q_2}(\delta u^r)\,dq_2\right]\\ &= \int_\Gamma [\delta\delta' u^r - \delta'\delta u^r];\end{aligned}$$

and from this, remembering equation (4), we get

$$Du^r = \int_\Gamma \sum_1^n{}_{ihk} \{ir, hk\}\, u^i\,\delta x_h\,\delta' x_k.$$

Now let us put ξ, η for the parameters (in V_n) of the lines $q_2 =$ constant, $q_1 =$ constant, i.e.

$$\xi^i = \frac{\delta x_i}{\delta s}, \quad \eta^i = \frac{\delta' x_i}{\delta' s},$$

where δs, $\delta' s$ are the lengths of the displacements, along the lines $q_2 =$ constant, $q_1 =$ constant, whose components are δx_i, $\delta' x_i$. Then we can also write

$$Du^r = \int_\Gamma f_r\,\delta s\,\delta' s, \quad . \quad . \quad . \quad . \qquad (25)$$

where for shortness we have put

$$f_r = \sum_1^n {}_{ihk} \{ir, hk\} u^i \xi^h \eta^k.$$

We can now remark that if ϑ is the angle between the coordinate lines q_1, q_2, the element of area (cf. Chapter V, § 7) is

$$d\Gamma = \delta s\, \delta' s \sin\vartheta,$$

and therefore (25) becomes

$$Du^r = \int_\Gamma \frac{f_r}{\sin\vartheta}\, d\Gamma.$$

By the mean value theorem, if $\left[\frac{f_r}{\sin\vartheta}\right]_{M_0}$ denotes the value of the function of position $\frac{f_r}{\sin\vartheta}$ at a suitable point M_0 (not known *a priori*) within Γ, and $D\Gamma$ the area of the region Γ, we can also write

$$Du^r = \left[\frac{f_r}{\sin\vartheta}\right]_{M_0} D\Gamma.$$

Now the value at M_0 of the function of position $\frac{f_r}{\sin\vartheta}$ differs from its value at P by quantities of order L (since the distance M_0P is of this order); since the area $D\Gamma$ is of order L^2, the error caused by substituting the value at P for that at M is of order L^3, which we have agreed to neglect. We shall therefore have

$$Du^r = \frac{f_r}{\sin\vartheta} D\Gamma,$$

or

$$Du^r = \frac{D\Gamma}{\sin\vartheta} \sum_1^n {}_{ihk} \{ir, hk\} u^i \xi^h \eta^k. \quad . \quad . \quad (26)$$

In this formula the quantities ξ^h and η^k represent the parameters of the lines q_1, q_2 at P, and ϑ is the angle between these lines; the values of the u^i's and of the Riemann's symbols refer to the point P. It will be seen that the influence of the circuit of displacement appears in this formula in three geometrical elements, which serve substantially to determine the circuit itself, namely: two directions $\boldsymbol{\xi}$, $\boldsymbol{\eta}$ (*a priori* any whatever) which determine the section on which the circuit is supposed drawn, together with the angle between them; and the area $D\Gamma$ of the circuit itself (measured according to the metric of V_n).

8. Pérès's formula.

From (26) we immediately get the fundamental formula which serves as a link between parallelism and curvature.

Take any (fourth) direction $\mathbf{v}$ drawn from P. Let α be the angle between $\mathbf{v}$ and $\mathbf{u}$, and $\alpha + D\alpha$ the angle between $\mathbf{v}$ and $\mathbf{u} + D\mathbf{u}$; we propose to calculate $D\alpha$. To do this we take the scalar product

$$\mathbf{u} \times \mathbf{v} = \cos\alpha$$

(assuming that $\mathbf{u}$, like $\mathbf{v}$, is a unit vector), and differentiate with the symbol D, remembering that $D\mathbf{v} = 0$ since $\mathbf{v}$ is a fixed vector. We get

$$\mathbf{v} \times D\mathbf{u} = -\sin\alpha\, D\alpha,$$

or, substituting for the scalar product on the left its expression $\sum_1^n{}_r\, v_r\, Du^r$, and using (26),

$$\sin\alpha\, D\alpha = -\frac{D\Gamma}{\sin\vartheta} \sum_1^n{}_{irhk} \{ir,\, hk\}\, u^i\, v_r\, \xi^h\, \eta^k.$$

If in this formula we express the v_r's in terms of the v^j's, and sum with respect to r (remembering (5)), we get

$$\sin\alpha\, D\alpha = -\frac{D\Gamma}{\sin\vartheta} \sum_1^n{}_{ijhk} (ij,\, hk)\, u^i\, v^j\, \xi^h\, \eta^k.$$

Now if the directions $\mathbf{u}$, $\mathbf{v}$ coincide or are opposite, this formula reduces to an identity of no interest, since on the left we have $\sin\alpha = 0$, and the right-hand side vanishes from the antisymmetry of the Riemann's symbols. Excluding this case, we can divide the whole equation by $\sin\alpha$, and we get *Pérès's formula*

$$D\alpha = \frac{-D\Gamma}{\sin\alpha \sin\vartheta} \sum_1^n{}_{ijhk} (ij,\, hk)\, u^i\, v^j\, \xi^h\, \eta^k. \quad . \quad (27)$$

9. Application to surfaces. Gaussian curvature of a V_2.

In considering the particular case of a V_2, i.e. an ordinary surface, the directions $\mathbf{u}$, $\mathbf{v}$ must of course be contained in the section (the only one there is) defined by $\boldsymbol{\xi}$, $\boldsymbol{\eta}$. Since the only purpose of these last two vectors is to specify the section on which the circuit is drawn, we can make them coincide with **u** and **v** without loss of generality; (27) will then become

$$D\alpha = \frac{-D\Gamma}{\sin^2\alpha} \sum_{1}^{n}{}_{ijhk} (ij,\, hk)\, u^i v^j u^h v^k. \quad . \quad . \quad (27')$$

Since for $n = 2$ Riemann's symbols which do not vanish are represented by the single arrangement of indices (12, 12), this formula can be further reduced to

$$D\alpha = \frac{-D\Gamma}{\sin^2\alpha} (12,\, 12)\, (u^1 v^2 - u^2 v^1)^2;$$

or finally, remembering the expression for $\sin\alpha$ in terms of the parameters of the two directions **u**, **v** (cf. Chapter V, § 4, formula (9′)), we get

$$D\alpha = -\frac{D\Gamma}{a} (12,\, 12).$$

It is usual to put

$$\frac{(12,\, 12)}{a} = K, \quad . \quad . \quad . \quad . \quad . \quad (28)$$

so that the foregoing formula becomes

$$\frac{D\alpha}{D\Gamma} = -K. \quad . \quad . \quad . \quad . \quad . \quad (29)$$

From this it will be seen that the function of position K defined by (28) is an invariant; it depends on the coefficients a_{ik} and their first and second derivatives, and is identical with the quantity which in the theory of surfaces is known as the *total*, or *Gaussian*, *curvature* (the product of the curvatures of the principal sections).[1] The equation (29) can be put in a more instructive form if we introduce the *angle of parallelism* ϵ, i.e. the angle between **u** and $\mathbf{u} + D\mathbf{u}$ (or between **u** and its parallel obtained by displacement round the circuit), measured in the sense in which the circuit is described. We can also say that ϵ is the angle through which **u** has been rotated as a result of the cyclic displacement. It is obvious that ϵ has the same absolute value as $D\alpha$, but we shall see that as regards sign the precise relation is

---

[1] See also below, Chapter IX, § 5.

$$\epsilon = -D\alpha.$$

To show this we need only remember the convention adopted above (§ 7) that the circuit is to be described in the positive sense with respect to the co-ordinate lines q_1, q_2, or from the versor $\boldsymbol{\xi}$ to the versor $\boldsymbol{\eta}$. As $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$ now coincide with $\mathbf{u}$ and $\mathbf{v}$ the sense in which the circuit is described is from $\mathbf{u}$ to $\mathbf{v}$ (through the convex angle). Accordingly (see fig. 3) if $D\alpha > 0$, $\mathbf{u} + D\mathbf{u}$ is outside the convex angle $\widehat{\mathbf{uv}}$, and is therefore reached from $\mathbf{u}$ by moving in the negative sense ($\epsilon < 0$), and vice versa. We can therefore write (29) in the form

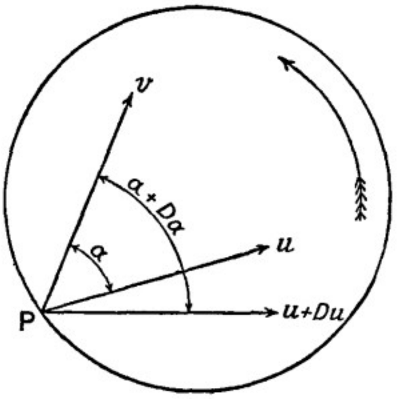

Fig. 3

$$\frac{\epsilon}{D\Gamma} = K, \quad . \quad . \quad . \quad . \quad . \quad (29')$$

which gives the following important interpretation of the curvature K: K *is the ratio of the angle of parallelism* (taken with its proper sign in relation to the sense of describing the circuit) *to the area of the circuit.*

In the case of a Euclidean V_2 Riemann's symbol is zero (cf. § 4) and therefore $K = 0$. This can also be deduced from the geometrically obvious fact (already used in § 2) that the parallel displacement is integrable (i.e. that the result does not depend on the curve of displacement).

10. **Riemannian curvature of a V_n.**

If instead of a surface we consider any V_n whatever, the notion of curvature becomes less simple. If P is a fixed point of the V_n, then with every section through P determined by two arbitrary directions $\boldsymbol{\xi}$, $\boldsymbol{\eta}$ drawn from P we can associate an invariant K, which is called the *Riemannian curvature* of the V_n at P with respect to the section considered. Following Riemann, we construct the geodesic surface determined by the point P and the two directions $\boldsymbol{\xi}$, $\boldsymbol{\eta}$, and then take the Gaussian curvature K of this geodesic surface as the curvature of the V_n at the point and in the section in question. In general the Riemannian curvature differs in the different sections.

The foregoing considerations enable us to give another important definition of the Riemannian curvature, and to find the analytical expression for it.

Given the elements P, $\boldsymbol{\xi}$, $\boldsymbol{\eta}$, construct the geodesic surface g defined by them and consider an infinitesimal circuit on g, passing through P, of area $D\Gamma$. Take one of the given directions, say $\boldsymbol{\xi}$, and give it a parallel displacement with respect to the surface g round the circuit, in the sense $\boldsymbol{\xi} \rightarrow \boldsymbol{\eta}$. Now calculate by Pérès's formula the change $D\alpha$ in the angle between $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$, i.e. the difference between its values before and after the displacement. The curvature K will then be given by (29). Now from Severi's theorem that an infinitesimal parallel displacement with respect to the surface g (using the metric of g) can be replaced by the analogous infinitesimal parallel displacement in V_n, it follows at once that this method of calculating K does not really involve the use of the geodesic surface g. Hence the Riemannian curvature K can be defined as *the ratio* (*with sign changed*) *of* $D\alpha$ *to* $D\Gamma$, *where* $D\alpha$ *is the change in the angle between the given directions* $\boldsymbol{\xi}$, $\boldsymbol{\eta}$ *caused by the parallel displacement in* V_n *of one of these directions round an infinitesimal circuit of area* $D\Gamma$, *belonging to the section* $\boldsymbol{\xi}$, $\boldsymbol{\eta}$, and described in the sense $\boldsymbol{\xi} \rightarrow \boldsymbol{\eta}$. We therefore have

$$K = -\frac{D\alpha}{D\Gamma}, \quad . \quad . \quad . \quad . \quad . \quad (30)$$

as in the V_2.

The explicit expression for K corresponding to this can be obtained from (27′), and we get

$$K = \frac{1}{\sin^2\alpha} \sum_{1}^{n}{}_{ijhk} (ij, hk)\, u^i v^j u^h v^k. \quad . \quad . \quad (31)$$

The symmetry of the right-hand side in $\mathbf{u}$ and $\mathbf{v}$ provides formal confirmation of the fact that it is immaterial whether we displace **u** or **v**, as we get in either case the same value for $D\alpha$ and the same value for K.

A third definition of the Riemannian curvature can be obtained from the proof of the following lemma.

Take any three points P, P', P'' on a surface V_2, and join them in pairs by arcs of geodesics, forming a so-called *geodesic triangle*. If ϕ, ϕ', ϕ'' are the angles of this triangle, the quantity

$$\epsilon = \phi + \phi' + \phi'' - \pi \quad . \quad . \quad . \quad . \quad (32)$$

is called the *geodesic excess*.

Now take any point on the triangle, and give a parallel displacement round the triangle to the direction of the side at that point, or of one of the sides if the point is a vertex; e.g. starting from P, the direction **u** at P of the side PP' (taken in the sense $P \rightarrow P'$).

We want to show that the angle between the initial and final positions of **u** (measured from the initial position in the sense which at each vertex is dependent on the sense $PP'P''$ in which the circuit is described), i.e. *the angle of parallelism* (relative in this case to a circuit of a special kind, but without the restriction of being infinitesimal), *is the same as the geodesic excess* ϵ.

For the proof we shall follow **u** in a cyclic displacement round the circuit $PP'P''$, noting in the first place that from P to P' **u** remains tangential to the side PP', on account of the autoparallelism of geodesics (cf. Chapter V, § 11). On arriving at P', **u** is thus inclined at an angle $\pi - \phi'$ (outside the triangle at P') to the side $P'P''$ (in the sense indicated by these letters); more precisely, **u** is behind the tangent to the side $P'P''$ by an angle of $\pi - \phi'$, the sense of rotation at P', as we have already said, being determined by the sense of description $PP'P''$. In the displacement from P' to P'' this angle remains unchanged; at P'' there will be a further loss of $\pi - \phi''$ (with respect to the new side $P''P$); and finally at P yet another loss of $\pi - \phi$ (with respect to PP'). Taking all these together, we see that in its final position the parallel to **u** has been rotated away from its initial position through an angle of $3\pi - (\phi + \phi' + \phi'')$ in the negative direction, or $\epsilon - 2\pi$ in the positive direction. Now in the pencil of directions at a point an angle is determined geometrically by a quantity of the form $\theta \pm 2n\pi$, where n is any integer; hence we have proved that *one value of the angle of parallelism is the geodesic excess* ϵ. Now in a Euclidean space the geodesic excess is zero, and in any manifold whatever, for an infinitesimal triangle, the excess is infinitesimal; we therefore see that for reasons of continuity the value adopted for the angle of parallelism is in fact the most suitable, being that which tends to zero with the triangle.

The lemma just proved is rigorously true in a V_2, whatever may be the magnitude of the geodesic triangle considered. If in particular we apply it to an infinitesimal triangle, we can substitute ϵ for $-D\alpha$ in (29), so getting

$$K = \frac{\epsilon}{D\Gamma},$$

a formula which defines the Riemannian curvature as *the ratio of the geodesic excess to the area of an infinitesimal geodesic triangle lying in the section considered, and having one vertex at the given point* P. It will be seen that this is an obvious extension to n-dimensional manifolds with any metric of an elementary theorem in spherical geometry (the area of a spherical triangle = the spherical excess × the square of the radius); the latter theorem, however, unlike the former, holds also for a finite triangle.

We must confine ourselves to a mere reference to the important researches of Professors Schouten[1] and Bompiani[2] on the simultaneous cyclic displacement of several directions, and even of the whole sheaf of directions drawn from a single point. Their work throws light on the theory of Riemannian curvature under various new aspects.

11. Case of a V_3. The tensors a_{ik} of Ricci and G_{ik} of Einstein.

For a manifold of three dimensions the symbols of the first species (ij, hk) which do not vanish reduce substantially, in virtue of (10), (11), and (14), to the scheme

$$(i+1 \;\; i+2, k+1 \;\; k+2) \qquad (i, k = 1, 2, 3),$$

---

[1] See references given in note (1), p. 172.

[2] "Studi sugli spazi curvi", in *Atti del R. Ist. Veneto*, Vol. LXXX, 1921, pp. 355–386, 839–859, 1113–1145.

with the convention (Chapter VI, § 9) of regarding as equivalent two indices which differ by a multiple of 3.

Using this notation, we now introduce after Ricci the double symmetric system

$$\alpha^{ik} = \frac{(i+1\ \ i+2,\ \ k+1\ \ k+2)}{a} \qquad (i, k = 1, 2, 3), \quad (33)$$

which constitutes, as we shall now show, a *contravariant tensor*. In fact, if we make use of the contravariant system ϵ (Chapter VI, § 8) we see that (33) is equivalent to

$$\alpha^{ik} = \tfrac{1}{4} \overset{3}{\underset{1}{\Sigma}}{}_{pqrs}\, \epsilon^{ipq}\, \epsilon^{krs}\, (pq, rs) \qquad (i, k = 1, 2, 3): \ . \quad (33')$$

which proves the assertion. The verification of this last formula is immediate, when we remember that of the various determinations *a priori* possible for the pair p, q, there are only two,

$$p = i + 1, \ \ q = i + 2$$

and $$p = i + 2, \ \ q = i + 1,$$

corresponding to which ϵ^{ipq} has a value different from zero, viz. $\frac{1}{\sqrt{a}}$ in the former case, $-\frac{1}{\sqrt{a}}$ in the latter. Similarly, for the other pair r, s, the only determinations to which there corresponds a non-vanishing ϵ^{krs} are

$$r = k + 1, \ \ s = k + 2$$

and $$r = k + 2, \ \ s = k + 1.$$

The sum $\overset{3}{\underset{1}{\Sigma}}{}_{pqrs}$ reduces therefore to four terms all expressible as

$$\frac{(i+1\ \ i+2,\ \ k+1\ \ k+2)}{a},$$

thus giving the result stated in (33).

The name *Ricci's symbols* is sometimes given to the α^{ik}'s just defined, or, more specifically, to *the elements*

$$\alpha_{ik} = \overset{3}{\underset{1}{\Sigma}}{}_{jh}\, a_{ij}\, a_{hk}\, \alpha^{jh} \qquad (i, k = 1, 2, 3) \quad . \quad (34)$$

of the reciprocal covariant tensor.

It is worth noting that equations (33), if we take account of the properties of Riemann's symbols in respect of symmetry and antisymmetry, can be solved so as to give the values of these symbols in the form

$$(ij, hk) = \sum_{1}^{3}{}_{\nu\rho}\, a^{\nu\rho}\, \epsilon_{\nu ij}\, \epsilon_{\rho hk}. \quad . \quad . \quad . \quad (33'')$$

In fact, expanding the second member and attending to the definition of the covariant system ϵ, we find the value zero corresponding to every set of four i, j, h, k for which the first member vanishes, and the value aa^{ik} corresponding to a set of four of the type $i+1, i+2, k+1, k+2$; (33″) therefore follows from (33).

By contracting the Ricci tensor α by means of the fundamental tensor (the coefficients of ds^2, or their reciprocals) we obtain the *linear invariant* of the tensor α

$$\mathcal{M} = \sum_{1}^{3}{}_{ik}\, a_{ik}\, \alpha^{ik} = \sum_{1}^{3}{}_{ik}\, a^{ik}\, \alpha_{ik}. \quad . \quad . \quad . \quad (35)$$

We may point out another formal relation of which use will be made in Chapter XII. For any V_n whatever we can derive from the Riemannian tensor, by contraction with respect to two indices, the covariant double tensor

$$G_{ik} = \sum_{1}^{n}{}_{jh}\, a^{jh}\, (ij, hk), \quad . \quad . \quad . \quad . \quad (36)$$

which, in virtue of equations (5), can also be written in the form

$$G_{ik} = \sum_{1}^{n}{}_{h} \{ih, hk\}. \quad . \quad . \quad . \quad . \quad (36')$$

This tensor was noticed by Ricci, who applied it to the study of the local distribution of curvatures in a V_n; it was afterwards taken up by Einstein, who gave it a fundamental place in the theory of relativity (in which $n = 4$): it is commonly known as the *Einstein tensor*.

For $n = 3$ the α_{ik}'s are related in a simple way to the G_{ik}'s. To bring out the connexion simply and neatly, it is convenient to make use of two properties of the ternary systems ϵ: one expressed by the identity (which can be verified immediately)

$$\sum_{1}^{3}{}_{j}\, \epsilon^{pqj}\, \epsilon_{rsj} = \delta^p_r \delta^q_s - \delta^p_s \delta^q_r \qquad (p, q, r, s = 1, 2, 3), \quad . \quad (37)$$

the δ's having the usual meaning (0 for different indices, 1 for equal indices); and the other translating, as it were, the definition of a^{jh} as a reciprocal element

$$a^{jh} = \frac{1}{2} \sum_{1}^{3}{}_{pqrs} \epsilon^{pqj} \epsilon^{rsh} a_{pr} a_{qs}.$$

Substitute in equations (36), in place of the a^{jh}'s, the second member here; and, in place of the (ij, hk)'s, the expression for them in (33″), with $\epsilon_{\rho hk}$ changed into $-\epsilon_{\rho kh}$. Taking account of (37) we find

$$G_{ik} = \frac{1}{2} \sum_{1}^{3}{}_{pqrs\nu\rho} a_{pr} a_{qs} \alpha^{\nu\rho} (\delta^p_\nu \delta^q_i - \delta^p_i \delta^q_\nu)(\delta^r_k \delta^s_\rho - \delta^r_\rho \delta^s_k).$$

Of the four terms obtained by expanding the product of the bracketed expressions, the two which are positive are merely interchanged by interchange of p with q and of r with s, which does not alter the product $a_{pr} a_{qs}$; and similarly with the negative terms. We can therefore confine our attention to one term only of each kind, and suppress the factor $\frac{1}{2}$. If we take, e.g.

$$\delta^p_\nu \delta^q_i (\delta^r_k \delta^s_\rho - \delta^r_\rho \delta^s_k),$$

and bear in mind the meaning of the symbols δ, we find that the sum reduces to one with respect to ν and ρ only, giving

$$G_{ik} = \sum_{1}^{3}{}_{\nu\rho} (a_{\nu k} a_{i\rho} \alpha^{\nu\rho} - a_{\nu\rho} a_{ik} \alpha^{\nu\rho}),$$

or finally, having regard to (34), (35),

$$G_{ik} = \alpha_{ik} - \mathcal{M} a_{ik} \qquad (i, k = 1, 2, 3). \quad . \quad (38)$$

12. Curvature of a manifold of three dimensions around a point. Principal directions and invariants.

Consider in a V_3 a generic section or *facet*, f, defined by two directions (versors) **u**, **v**, whose parameters are u^i, v^i $(i = 1, 2, 3)$, issuing from the same point P. Let **w** be their vector product (Chapter VI, § 8), the moments of which are

$$w_\nu = \sum_{1}^{3}{}_{ij} \epsilon_{\nu ij} u^i v^j \qquad (\nu = 1, 2, 3). \quad . \quad . \quad (39)$$

Corresponding to the section f in our manifold V_3 we have the

Riemannian curvature K given by (31), with $n = 3$. In the sum $\overset{3}{\underset{1}{\Sigma}}_{ijhk}$ of (31) it is convenient to introduce, in place of Riemann's symbols (ij, hk) the expressions for them given in (33″). Taking account of (39), we find immediately

$$K = \frac{1}{\sin^2 \alpha} \overset{3}{\underset{1}{\Sigma}}_{\nu\rho}\, a^{\nu\rho}\, w_\nu\, w_\rho. \quad . \quad . \quad . \quad (40)$$

Deferring for a moment the illustration of this formula, we recall the fact that in general the length w of the vector $\mathbf{u} \wedge \mathbf{v}$ (the vector product of $\mathbf{u}$ and $\mathbf{v}$) is given by the product of the lengths of $\mathbf{u}$, $\mathbf{v}$ by the sine of the angle between them. For the Euclidean V_3 this implies, as already mentioned (Chapter VI, § 8), the identity of the moments (39) referred to Cartesian co-ordinates with the ordinary components (orthogonal projections) of the vector product $\mathbf{u} \wedge \mathbf{v}$. For a general V_3, it is sufficient to remember that we can choose co-ordinates which are *locally Cartesian* at any assigned point P, so that the a_{ik}'s have the values δ_i^k (and so that also—though this is not important for the present purpose—their first derivatives vanish). Now both in the measures of the lengths and the angular distances of vectors proceeding from the point P, and in the definition (39) of the w_ν's, there enter only the components of the vectors and the values of the a_{ik}'s at P. Locally then everything is the same as for Euclidean space.[1]

Turn now to our case, in which $\mathbf{u}$ and $\mathbf{v}$ are unit vectors. It follows that $w = \sin\alpha$, whence $\frac{w_i}{w} = \frac{w_i}{\sin\alpha}$ constitute the

---

[1] We can also of course calculate the length of $\mathbf{w}$. Thus we note that, besides (39), we have the equivalent formulæ defining the contravariant components:

$$w^\nu = \overset{3}{\underset{1}{\Sigma}}_{hk}\, \epsilon^{\nu hk}\, u_h\, v_k.$$

Hence, in view of (37) (the index of summation in which we may suppose transferred to the first place),

$$\begin{aligned} w^2 &= \overset{3}{\underset{1}{\Sigma}}_\nu\, w^\nu w_\nu = \overset{3}{\underset{1}{\Sigma}}_{ijhk}\, u^i v^j u_h v_k \left(\delta_i^h \delta_j^k - \delta_j^h \delta_i^k\right) \\ &= \overset{3}{\underset{1}{\Sigma}}_i\, u^i u_i \overset{3}{\underset{1}{\Sigma}}_j\, v^j v_j - \overset{3}{\underset{1}{\Sigma}}_i\, u^i v_i \overset{3}{\underset{1}{\Sigma}}_j\, v^j u_j \\ &= u^2 v^2 - (uv \cos\alpha)^2 = u^2 v^2 \sin^2\alpha. \end{aligned}$$

moments λ_i of the direction $\boldsymbol{\lambda}$ normal to the section *f*. The *sense* assigned to the normal by (39) is characterized by the system ϵ or, geometrically, by the sense of the trihedron formed at P by the positive directions of the co-ordinate lines. In fact, from these equations (39), if we suppose, for example, that the lines 1, 2 are taken in the directions **u**, **v**, there results

$$w_1 = w_2 = 0, \qquad w_3 = \frac{\sqrt{a}}{\sqrt{a_{11}\, a_{22}}} > 0,$$

so that (Chapter V, § 22) **w** makes an acute angle with the positive direction of the line 3, whose parameters are

$$s_3^1 = s_3^2 = 0, \qquad s_3^3 = \frac{1}{\sqrt{a_{33}}} > 0.$$

Thus $\boldsymbol{\lambda}$ is perpendicular to f at P, and directed so that the trihedron **u, v,** $\boldsymbol{\lambda}$ has the same sense as the trihedron formed by the positive directions of the co-ordinate lines at the same point P.

Equation (40) now takes the form, given by Ricci,

$$K = \sum_1^3{}_{\nu\rho}\, a^{\nu\rho}\, \lambda_\nu\, \lambda_\rho = \sum_1^3{}_{\nu\rho}\, a_{\nu\rho}\, \lambda^\nu\, \lambda^\rho, \quad . \quad . \quad (40')$$

which defines the curvature of a variable section f *through* P *as a homogeneous quadric in the parameters* λ^ν *(or in the moments* λ_ν*) of the normal to* f, the sense of the normal being indifferent, since the expressions in (40′) do not change when we change the signs of the λ's.

The dependence of K on the direction $\boldsymbol{\lambda}$ of the section with centre at P is of purely local nature. We can therefore, in accordance with an observation made above, make use of the elementary criteria of analytical geometry just as if it were a question of ordinary space—we have only to take co-ordinates which are *Cartesian and orthogonal at* P. The λ^ν's then become direction cosines, and we have for K (except for a different signification of the coefficients $a_{\nu\rho}$) the same expression as the one which characterizes the distribution of moments of inertia (of an assigned material system) with respect to the ∞^2 axes coinciding with the lines of the versors $\boldsymbol{\lambda}$ proceeding from P. As we know, the law of variation of K becomes expressible geometrically if we introduce the ellipsoid of inertia E, of centre P: to any direction of $\boldsymbol{\lambda}$ there belongs a value of K, viz. $\frac{1}{PQ^2}$, where Q is the intersection of the line of $\boldsymbol{\lambda}$ with the ellipsoid E; the three axes of E correspond to stationary values of K (with respect to neighbouring directions), the axes of maximum and minimum length in particular corresponding respectively to minimum and maximum values of K.

That being so, the same law of variation will hold for K the curvature; but in the general V_3 interpretation is necessary. This implies merely that the ellipsoid E (like, for example, Dupin's indicatrix for the case of an ordinary surface) takes us in thought outside the V_3, as an auxiliary representative element to be associated with the Euclidean three-dimensional space which is tangential to the V_3 at P when, as is always allowable (Chapter V, § 21), we imagine the V_3 immersed in a Euclidean S_N $(N \geqslant 6)$.

The outstanding result is that *there exist at every point* P *at least three mutually orthogonal directions* $\boldsymbol{\lambda}_1$, $\boldsymbol{\lambda}_2$, $\boldsymbol{\lambda}_3$ *to which* (or rather to the normal sections perpendicular to which) *belong curvatures which are stationary with respect to those of adjacent sections.* These directions are called *principal directions of curvature*, and the corresponding values ω_1, ω_2, ω_3 of K *principal curvatures.* In general, that is when the three ω's are distinct, the principal directions are uniquely determinate (ellipsoid with three unequal axes); when two principal curvatures are equal but differ from the third (ellipsoid of revolution), e.g. $\omega_1 = \omega_2 \neq \omega_3$, only the principal direction $\boldsymbol{\lambda}_3$ is uniquely determinate, while every pair of directions $\boldsymbol{\lambda}_1$, $\boldsymbol{\lambda}_2$ orthogonal to $\boldsymbol{\lambda}_3$ and to each other can be considered principal. If the three principal curvatures coincide (sphere) the curvature K is the same for all sections, and every set of three mutually orthogonal directions is a principal set.

All this of course can be established by purely algebraic methods: we have only to avail ourselves of the theory of quadratic forms and their transformations. Let

$$\phi = \sum_{1}^{n}{}_{ij}\, a_{ij} \lambda^i \lambda^j, \quad \psi = \sum_{1}^{n}{}_{ij}\, a_{ij} \lambda^i \lambda^j \quad . \quad . \quad (41)$$

be two quadrics, *one of which at least is definite,* say ϕ; the independent variables being λ^i ($i = 1, 2, \ldots n$). Then the following facts are well-known[1]:

(1) If we consider the ratio

$$\omega = \frac{\psi}{\phi}$$

as a function of the λ's, and look for the values of these variables which make $\delta\omega = 0$, we are led to the system of n linear homogeneous equations

$$\sum_1^n{}_j (\alpha_{ij} - \omega a_{ij}) \lambda^j = 0 \qquad (i = 1, 2, \ldots n); \quad . \quad (42)$$

these are satisfied by values not all null of the λ's if and only if the determinant of the coefficients vanishes, so that the ω's are roots of the equation of degree n:

$$\| \alpha_{ij} - \omega a_{ij} \| = 0, \quad . \quad . \quad . \quad . \quad (43)$$

called the *characteristic equation.*

(2) If λ^i, λ'^i are two solutions of equations (42) corresponding to two distinct roots ω, ω' of the characteristic equation, there exists between them the relation (of orthogonality)

$$\sum_1^n{}_{ij} a_{ij} \lambda^i \lambda'^j = 0.$$

(3) The characteristic equation (43) has its n roots $\omega_1, \omega_2, \ldots \omega_n$ *all real* (distinct or coincident).

(4) To each simple root ω_h of (43) corresponds, in the manifold V_n the ds^2 of which has the a_{ij}'s as its coefficients, one and only one direction $\boldsymbol{\lambda}_h$ whose parameters λ_h^i satisfy (42) for $\omega = \omega_h$. With each root of multiplicity μ (> 1) we can in an infinite number of ways associate μ mutually orthogonal directions in V_n, whose parameters are independent solutions of equations (42) when we give ω the value of the said multiple root.

From all this there results that it is possible in every case to set up at least one set of n mutually orthogonal directions $\boldsymbol{\lambda}_h$ ($h = 1, 2, \ldots n$), (uniquely determined in the general case, in which the roots of (43) are all simple), the parameters λ_h^j of which satisfy the system (42), with ω equal to the corresponding ω_h.

---

[1] For proofs, see for example: BIANCHI, *Lezioni di geometria analitica,* Appendix; (Pisa: Spoerri, 1915): or BROMWICH, *Quadratic Forms and their Classification* . . . (Cambridge tracts on Mathematics . . . No. 3).

By means of these $\boldsymbol{\lambda}_h$'s we can obtain the so-called canonical expressions. We begin by introducing the moments

$$\lambda_{h|i} = \sum_1^n{}_j\, a_{ij}\, \lambda_h^j \qquad (h, i = 1, 2, \ldots n), \quad . \quad (44)$$

and observe that, by associating with the n identities

$$\sum_1^n{}_j\, \lambda_h^j\, \lambda_{h|j} = 1 \qquad (h = 1, 2, \ldots n)$$

the $\frac{1}{2}n(n - 1)$ conditions of orthogonality of two different directions $\boldsymbol{\lambda}_h$, $\boldsymbol{\lambda}_k$ of the n-ple set

$$\sum_1^n{}_j\, \lambda_h^j\, \lambda_{k|j} = 0 \qquad (h \neq k),$$

we obtain altogether the n^2 relations

$$\sum_1^n{}_j\, \lambda_h^j\, \lambda_{k|j} = \delta_h^k \qquad (h, k = 1, 2, \ldots n),$$

which express the noteworthy fact that *the* n^2 *parameters* λ_h^j *of an* n*-ple orthogonal set are the elements reciprocal (in an algebraic sense) to the* n^2 *moments in the determinant* $\| \lambda_{h|j} \|$ *which they form; and vice versa that the moments are the reciprocals of the parameters in the corresponding determinant* $\| \lambda_h^j \|$ (cf. Chapter IV, § 6).

Further, besides the relations just written which refer to the columns, their analogues with respect to the rows also hold good; these may be written

$$\sum_1^n{}_h\, \lambda_h^j\, \lambda_{h|i} = \delta_i^j \qquad (i, j = 1, 2, \ldots n). \quad . \quad (45)$$

Taking account of this, if we multiply (44) by $\lambda_{h|k}$ and sum with respect to h, there results immediately

$$a_{ik} = \sum_1^n{}_h\, \lambda_{h|i}\, \lambda_{h|k} \qquad (i, k = 1, 2, \ldots n), \quad . \quad (46)$$

which are *expressions for the fundamental tensor* a$_{ik}$ *in terms of the moments of any orthogonal* n*-ple set.*

Consider in particular the n-ple set (or one of the n-ple sets) $\boldsymbol{\lambda}_h$, the parameters of which, λ_h^j, satisfy (42) where, for each index h, $\omega = \omega_h$. These equations, in virtue of (44), may be written

$$\sum_1^n{}_j\, a_{ij}\,\lambda_h^j = \omega_h\,\lambda_{h|i} \qquad (h, i = 1, 2, \ldots n).$$

Multiplying by $\lambda_{h|k}$, and summing with respect to the index h, while attending to (45), we obtain the canonical expression for the a_{ik}'s to be associated with (46), viz.

$$a_{ik} = \sum_1^n{}_h\, \omega_h\,\lambda_{h|i}\,\lambda_{h|k} \qquad (i, k = 1, 2, \ldots n). \quad . \quad (47)$$

After this the simultaneous reduction of the two quadrics to orthogonal form is easily effected by substituting for the original variables λ^i the n linear combinations

$$z_h = \sum_1^n{}_i\, \lambda_{h|i}\,\lambda^i \qquad (h = 1, 2, \ldots n). \quad . \quad (48)$$

In fact, when we substitute in (41) the values (46), (47) of the coefficients, taking account of (48), there results

$$\phi = \sum_1^n{}_h\, z_h{}^2, \quad \psi = \sum_1^n{}_h\, \omega_h\, z_h{}^2. \quad . \quad . \quad . \quad (49)$$

The condition that the λ^i's should be parameters, that is to say that the expression (41) for ϕ should have the value 1, becomes in the new variables z, $\sum_1^n{}_h\, z_h{}^2 = 1$. The mode of variation of ψ, when the λ's are parameters of direction, is identical with that of the ratio $\frac{\psi}{\phi}$, when the variables are independent; or, if we wish, of the quadric $\psi = \sum_1^n{}_h\, \omega_h\, z_h{}^2$, when the z's are connected the relation $\sum_1^n{}_h\, z_h{}^2 = 1$.

Moreover, the stationary values of ψ in these cases are precisely the roots of the characteristic equation (43).

The form

$$\psi = \sum_1^n{}_{ij}\, a_{ij}\,\lambda^i\,\lambda^j$$

is an obvious generalization, for any value of n, of the expression (40′) for K, which defines the local distribution of curvature in a V_3.

The above considerations manifestly apply also to the behaviour of the curvature K when the direction of the section is supposed to vary, a topic which has already been discussed in a more elementary way.

13. **Geodesics infinitely near a given geodesic.**

We shall conclude this chapter with a discussion of the extension to n dimensions of a classical formula due to Jacobi, which defines in a very simple way the aggregate of those geodesics g of a surface which are infinitely near a given geodesic B, called the geodesic *base*. Jacobi gives the linear equation

$$\frac{d^2y}{d\sigma^2} + Ky = 0, \tag{J}$$

where y denotes the distance (normal) of any point M of g from the base, σ the arc of the base measured from an arbitrary origin O up to the projection P of M upon B, and $K(\sigma)$ the Gaussian curvature of the surface at P.

(J) is simply, in Poincaré's phrase, the *equation of variations* of geodesics starting from B. There can be deduced from it, as we know,[1] some very remarkable consequences with respect to the behaviour of geodesics in the immediate neighbourhood of the base, the nature of the surface intervening only through its total curvature K. This is obviously an *intrinsic* question, depending entirely on the metric of the surface (as defined by its ds^2), and not at all on the different configurations which the surface can present in space.

It naturally suggests itself that we should try to extend the study of this subject of geodesic deviation to a Riemannian manifold V_n of any number of dimensions. We have long had, of course, the equations of Lagrange defining the geodesics of a V_n, in a form the convenience of which, whether from the point of view of theory or of notation, is all that could be desired.

---

[1] See, for example, DARBOUX, *Théorie des surfaces*, Vol. III (Paris, Gauthier-Villars, 1894; new impression 1923), Chap. V; or BLASCHKE, *Vorlesungen über Differentialgeometrie*, Vol. I (2nd edition, Berlin, Springer, 1924), §§ 83–88.

These equations we may therefore use for the purpose of forming the equations of variations. Then with the help of Bianchi's idea (Chapter V, § 26) of the *derivative* of a vector attached to the points of a line of V_n, we reduce these equations to a condensed form, geometrically suggestive and of course invariant. The actual construction of the equations (linear of the second order, n in all, with the same number of unknowns) requires no further data than the base B and the metric of the manifold (especially Riemann's symbols) along that curve.

We find that this system of equations admits a linear first integral, which in its turn leads to a linear relation in finite terms among the unknowns. We are thus left with a system of $n - 1$ equations or, in the special case of an ordinary surface, with a single equation, as in Jacobi's classical result.

To bring the final system of equations to as simple a form as possible we have to make a suitable choice of variables. Now we have already seen (Chapter VI, § 11) that it is possible, beginning with any co-ordinates x, to define new co-ordinates y in terms of which ds^2 becomes locally Cartesian, in the sense that the derivatives of the coefficients a_{ik} all vanish at an assigned point O. We have also seen (Chapter VI, § 11, footnote) that it is possible, any curve B being given, to choose co-ordinates y for which ds^2 has this locally Cartesian character *at every point of* B. When B is a geodesic, the system of co-ordinates y which (§ 17) will finally be used has the following properties, which we merely state here without proof.[1] Let M be any point in the immediate neighbourhood of B, P the orthogonal projection of M upon B. Then y_n is the arc of the base B measured from an arbitrary origin O up to P; the y_α's ($\alpha = 1, 2, \ldots n - 1$) may be regarded as components of the elementary vector PM in $n - 1$ directions mutually perpendicular and all perpendicular to B, chosen arbitrarily at O and carried by parallelism along B.

14. Geodesic deviation in an n-dimensional manifold.

Consider, along with the geodesic B, any other geodesic g (more precisely, an arc of g) belonging to the immediate neighbourhood of B.[1] Corresponding to every point M of g, take the point P of B having the same y_n as M and the rest of its y's $= 0$. It is important for what follows to fix precisely the relation between an elementary arc ds of g and the corresponding arc $d\sigma = dy_n$ of B. Throughout the neighbourhood of B we have, for the coefficients b_{ik} of ds^2 in terms of the co-ordinates y, the Euclidean values

---

[1] For a complete development of this point, compare the paper "Sur l'écart géodésique" in *Mathematische Annalen* (Vol. 97).

$$b_{ik} = 0 \quad (i \neq k), \quad b_{ii} = 1,$$

neglecting quantities of the second order.

It follows that for any curve whatever

$$ds = dy_n \sqrt{1 + \sum_{1}^{n-1}{}_{a} \left(\frac{dy_a}{dy_n}\right)^2},$$

the quantity under the radical differing from its exact value only by terms of the second order. For g, both the y_a and the $\frac{dy_a}{dy_n}$ may be regarded as infinitely small. It follows that

$$\frac{ds}{dy_n} = \frac{ds}{d\sigma} = 1$$

to a second approximation—a generalization of the elementary fact that a segment infinitely near (with respect to direction) a given right line differs from its projection on the line by an infinitesimal of the second order.

15. **Invariant form of the equations defining geodesic deviation.**

We have now to form the equations defining in general co-ordinates the behaviour of any geodesic g infinitely near B.

Put

$$x_i = \phi_i(\sigma) + \xi^i, \quad . \quad . \quad . \quad . \quad (50)$$

where the ξ^i's and their derivatives with respect to σ are infinitely small.

The ξ^i's represent the increments of the co-ordinates x_i of a point P of B which passes to a corresponding point M of g: they can be regarded as the contravariant components of the elementary vector $PM = \boldsymbol{\xi}$. Adopting a more general point of view, we shall now regard this vector as not necessarily perpendicular to B, its orientation depending on the law of correspondence between the points P and M of our two geodesics. We can therefore no longer assume that the elementary arc ds of g is (as in § 14) equal to the corresponding arc $d\sigma$ of B; but, the displacement in question being always infinitely small, we can foresee all the same that, if we put

---

[1] In the *strict* sense, that is to say, with the understanding that not only are changes of position of corresponding points on B and g to be small, but also changes of direction of corresponding tangents.

$$\frac{ds}{d\sigma} = 1 + \lambda, \quad . \quad . \quad . \quad . \quad . \quad (51)$$

the *elongation* (or coefficient of dilatation) λ remains infinitely small with the ξ^i's and their derivatives. This will be proved formally in a moment. Meantime, differentiate the formulæ (50) with respect to σ. We have

$$\frac{ds}{d\sigma}\dot{x}_i = \dot{\phi}_i + \frac{d\xi^i}{d\sigma}, \quad . \quad . \quad . \quad . \quad . \quad (50')$$

where $\dot{x}_i$ is written for $\frac{dx_i}{ds}$, and $\dot{\phi}_i$ for $\frac{d\phi_i}{d\sigma}$.

A second differentiation gives

$$\left(\frac{ds}{d\sigma}\right)^2 \ddot{x}_i + \frac{d^2s}{d\sigma^2}\dot{x}_i = \ddot{\phi}_i + \frac{d^2\xi^i}{d\sigma^2}.$$

From (51),
$$\frac{d^2s}{d\sigma^2} = \frac{d\lambda}{d\sigma},$$

and (50′) can be written

$$\dot{x}_i - \dot{\phi}_i = -\lambda\dot{x}_i + \frac{d\xi^i}{d\sigma};$$

all this holds without any assumption concerning the smallness of λ.

Considering now λ *and* $\frac{d\lambda}{d\sigma}$ *as infinitesimal*, and neglecting all terms of the second order, we may replace $\frac{d^2s}{d\sigma^2}\dot{x}_i = \frac{d\lambda}{d\sigma}\dot{x}_i$ by $\frac{d\lambda}{d\sigma}\dot{\phi}_i$, and consequently take the equation for $\ddot{x}_i$ to be

$$\left(\frac{ds}{d\sigma}\right)^2 \ddot{x}_i = \ddot{\phi}_i + \frac{d^2\xi^i}{d\sigma^2} - \frac{d\lambda}{d\sigma}\dot{\phi}_i. \quad . \quad . \quad (50'')$$

Now (Chapter V, § 24) for any geodesic g we have

$$\ddot{x}_i = -\sum_1^n{}_{jh}\{jh, i\}\,\dot{x}_j\,\dot{x}_h \qquad (i = 1, 2, \ldots n).$$

Multiply these equations by $\left(\frac{ds}{d\sigma}\right)^2$, and make the following substitutions: (50) in the $\{jh, i\}$, (50′) in the $\frac{ds}{d\sigma}\,\dot{x}_j$, (50″) in the $\left(\frac{ds}{d\sigma}\right)^2\ddot{x}_i$.

Remembering that

$$\ddot{\phi}_i = -\sum_1^n{}_{jh}\{jh, i\}\,\dot{\phi}_j\,\dot{\phi}_h,$$

since B is a geodesic, and of course retaining terms of the first order only, we find

$$\frac{d^2\xi^i}{d\sigma^2} - \frac{d\lambda}{d\sigma}\dot{\phi}_i = -\sum_1^n{}_{jhk}\frac{\partial\{jh, i\}}{\partial x_k}\,\xi^k\,\dot{\phi}_j\,\dot{\phi}_h - 2\sum_1^n{}_{jh}\{jh, i\}\,\dot{\phi}_j\,\frac{d\xi^h}{d\sigma}.$$

Next, for the sake of showing explicitly the contravariance of the $\dot{\phi}_i$ (parameters of the direction tangential to B), put

$$\dot{\phi}_i(\sigma) = b^i \qquad (i = 1, 2, \ldots n). \quad . \quad . \quad (52)$$

The equations just obtained (if we also change the indices i and j into r and i) become

$$\frac{d^2\xi^r}{d\sigma^2} - \frac{d\lambda}{d\sigma}b^r + 2\sum_1^n{}_{jh}\{jh, r\}b^j\frac{d\xi^h}{d\sigma}$$
$$= -\sum_1^n{}_{ihk}\frac{\partial\{ih, r\}}{\partial x_k}\,b^i\,b^h\,\xi^k. \quad (53)$$

We proceed to transform these equations for the sake of showing their invariant structure with reference to any change of coordinates. For this purpose we introduce Bianchi's conception of the *derivative* vector of a vector $\boldsymbol{\xi}$ given as a function of the points of a line (Chapter V, § 26).

If B is the line, the contravariant components of the vector $D\boldsymbol{\xi}$, the derivative of $\boldsymbol{\xi}$, are given by the equations

$$(D\boldsymbol{\xi})^r = \frac{\partial\xi^r}{\partial\sigma} + \sum_1^n{}_{ih}\{ih, r\}\,b^i\,\xi^h \qquad (r = 1, 2, \ldots n). \quad (54)$$

For co-ordinates which are Cartesian either rigorously, or else locally along the line B, we have simply

$$(D\boldsymbol{\xi})^r = \frac{d\xi^r}{d\sigma}.$$

With the help of the vector $\boldsymbol{\xi}$, it is easy to give an explicit expression for the elongation λ, without making any hypothesis as to its order of magnitude, the equations (50) and (50′), which we shall use, being exact.

On g we have identically

$$\overset{n}{\underset{1}{\Sigma}}{}_{ir}\, a_{ir}\, \dot{x}_i\, \dot{x}_r = 1.$$

If we multiply on both sides by $\left(\frac{ds}{d\sigma}\right)^2$, and replace (in the a_{ir}'s) the x_i's by their values (50) and the $\frac{ds}{d\sigma}\dot{x}_i$'s by (50′), we find at once (neglecting terms of the second order with respect to ξ)

$$\left(\frac{ds}{d\sigma}\right)^2 = 1 + 2\overset{n}{\underset{1}{\Sigma}}{}_{ir}\, a_{ir}\, \dot{\phi}_i \frac{d\xi^r}{d\sigma} + \overset{n}{\underset{1}{\Sigma}}{}_{irh} \frac{\partial a_{ir}}{\partial x_h} \dot{\phi}_i\, \dot{\phi}_r\, \xi^h.$$

We have, moreover, the well-known identities (Chapter V, § 16)

$$\frac{\partial a_{ik}}{\partial x_l} = \overset{n}{\underset{1}{\Sigma}}{}_h \left[a_{hi}\{kl, h\} + a_{hk}\{il, h\}\right].$$

If in the last sum of the expression for $\left(\frac{ds}{d\sigma}\right)^2$ we replace the indices r, h by k, l and take account of the identity just written down, replacing also, as in (52),

$$\overset{n}{\underset{1}{\Sigma}}{}_i\, a_{ir}\, \dot{\phi}_i, \quad \overset{n}{\underset{1}{\Sigma}}{}_i\, a_{hi}\, \dot{\phi}_i, \quad \overset{n}{\underset{1}{\Sigma}}{}_k\, a_{hk}\, \dot{\phi}_k,$$

$$\text{by } b_r,\ b_h,\ b_h,$$

we find, on account of (54),

$$\left(\frac{ds}{d\sigma}\right)^2 = 1 + 2\overset{n}{\underset{1}{\Sigma}}{}_r\, (D\boldsymbol{\xi})^r\, b_r.$$

The vector $D\boldsymbol{\xi}$ is infinitely small at the same time as the ξ^i's and their derivatives. We have, therefore, by extracting the root, neglecting terms of the second order, and attending to the definition (51) of the elongation λ,

$$\lambda = \overset{n}{\underset{1}{\Sigma_r}}\, (D\boldsymbol{\xi})^r\, b_r, \qquad . \quad . \quad . \quad . \quad . \quad (51')$$

which shows its infinitesimal character.

Naturally $D\boldsymbol{\xi}$ admits in its turn a derivative vector $D^2\boldsymbol{\xi}$. Its contravariant components are defined, from (54), by

$$(D^2\boldsymbol{\xi})^r = \frac{d(D\boldsymbol{\xi})^r}{d\sigma} + \overset{n}{\underset{1}{\Sigma_{kl}}}\, \{kl, r\}\, b^k\, (D\boldsymbol{\xi})^l.$$

Introducing on the right-hand side the expressions (54) for $(D\boldsymbol{\xi})^r$ and $(D\boldsymbol{\xi})^l$ (after making some literal changes in the indices), we obtain

$$(D^2\boldsymbol{\xi})^r = \frac{d^2\xi^r}{d\sigma^2} + \frac{d}{d\sigma}\left(\overset{n}{\underset{1}{\Sigma_{ih}}}\, \{ih, r\}\, b^i\, \xi^h\right)$$
$$+ \overset{n}{\underset{1}{\Sigma_{kl}}}\, \{kl, r\}\, b^k \frac{d\xi^l}{d\sigma} + \overset{n}{\underset{1}{\Sigma_{ihkl}}}\, \{kl, r\}\, \{ih, l\}\, b^k\, b^i\, \xi^h, \quad (55)$$

the second members, like the first, constituting a contravariant system. Bringing out explicitly the differentiation with respect to σ, and making some changes of indices, we can write

$$(D^2\boldsymbol{\xi})^r = \frac{d^2\xi^r}{d\sigma^2} + 2\,\overset{n}{\underset{1}{\Sigma_{jh}}}\, \{jh, r\}\, b^j \frac{d\xi^h}{d\sigma} + \Xi^{(r)}, \qquad (55')$$

where we put for brevity

$$\Xi^{(r)} = \overset{n}{\underset{1}{\Sigma_{ihk}}}\, \frac{\partial\{ik, r\}}{\partial x_h}\, b^i\, b^h\, \xi^k + \overset{n}{\underset{1}{\Sigma_{lk}}}\, \{lk, r\}\, \xi^k \frac{db^l}{d\sigma}$$
$$+ \overset{n}{\underset{1}{\Sigma_{ihkl}}}\, \{lh, r\}\, \{ik, l\}\, b^i\, b^h\, \xi^k.$$

We may note in passing that, in the auxiliary quantities $\Xi^{(r)}$, the index r is purely ordinal: we have placed it above, but in brackets, so as to avoid the suggestion that the $\Xi^{(r)}$'s form a contravariant system, which they do not.

For our purpose it is sufficient to replace in $\Xi^{(r)}$ the derivatives $\frac{db^l}{d\sigma} = \ddot{\phi}_l$ by their values

$$-\overset{n}{\underset{1}{\Sigma}}_{ih}\,(ih,\,l)\,b^i\,b^h,$$

as given by the equations for geodesics (Chapter V, § 24), so that we may write

$$\Xi^{(r)} = \overset{n}{\underset{1}{\Sigma}}_{ihk}\,\frac{\partial\,\{ik,\,r\}}{\partial\,x_h}\,b^i\,b^h\,\xi^k$$
$$+\overset{n}{\underset{1}{\Sigma}}_{ilhk}\,[\{lh,\,r\}\,\{ik,\,l\} - \{lk,\,r\}\,\{ih,\,l\}]\,b^i\,b^h\,\xi^k. \quad (56)$$

If then we add $\Xi^{(r)}$ to the two members of equations (53), attending to (55′) and to the definition of Riemann's symbols (§ 2), the equations take the *invariant form*

$$(D^2\boldsymbol{\xi})^r - \frac{d\lambda}{d\sigma}\,b^r = -\overset{n}{\underset{1}{\Sigma}}_{ihk}\,\{ir,hk\}\,b^i b^h\,\xi^k \qquad (r = 1, 2, \ldots n). \quad (57)$$

16. Geodesic deviation. Specification of the differential system. First integral. Linear relation in finite terms.

The system (57), taken along with the value of λ given in (51′), contains $n + 1$ equations, with the same number of unknowns; but it is easy to foresee, from the method of obtaining it, that it cannot by itself determine completely all the unknowns; there ought to remain an element of indeterminateness arising from the arbitrary nature of the law of correspondence between the points P of B and M of g. More definitely, we can prove that the definition (51′) of λ, or rather the relation derived from it by differentiation

$$\frac{d}{d\sigma}\left\{\lambda - \overset{n}{\underset{1}{\Sigma}}_r\,(D\boldsymbol{\xi})^r\,b_r\right\} = 0 \quad . \quad . \quad . \quad (51'')$$

is a consequence of equations (57) themselves. To establish this, note first that, for any vector $\mathbf{v}$ whose contravariant components are v^r, we have

$$\frac{d}{d\sigma}\overset{n}{\underset{1}{\Sigma}}_r\,v^r\,b_r = \overset{n}{\underset{1}{\Sigma}}_r\,\frac{dv^r}{d\sigma}\,b_r + \overset{n}{\underset{1}{\Sigma}}_r\,v^r\,\frac{db_r}{d\sigma}.$$

But the derivatives $\frac{db_r}{d\sigma}$ of the moments of a geodesic B satisfy the equations (Chapter V, § 24 and § 26 (52′))

$$\frac{db_r}{d\sigma} = \overset{n}{\underset{1}{\Sigma}}{}_{ih} \{ir, h\} b^i b_h,$$

which express, we may say, the autoparallelism of the geodesic B in terms of its moments b_r. The preceding identity, after interchange of the indices h and r in the last sum, therefore takes the form

$$\frac{d}{d\sigma} \overset{n}{\underset{1}{\Sigma}}{}_r v^r b_r = \overset{n}{\underset{1}{\Sigma}}{}_r (D\mathbf{v})^r b_r. \qquad . \quad . \quad . \qquad (58)$$

In virtue of this equation, the first member of (51″) now becomes (if we replace the vector $\mathbf{v}$ by $D\boldsymbol{\xi}$)

$$\frac{d\lambda}{d\sigma} - \overset{n}{\underset{1}{\Sigma}}{}_r (D^2\boldsymbol{\xi})^r b_r.$$

That this expression vanishes we can easily prove from equation (57), making use of the properties of Riemann's symbols, as follows. Multiply both sides of (57) by b_r and sum with respect to r, noting that $\overset{n}{\underset{1}{\Sigma}}{}_r b_r b^r = 1$. The right-hand member can be written

$$- \overset{n}{\underset{1}{\Sigma}}{}_{ihkrp} \{ir, hk\} a_{pr} b^p b^i b^h \xi^k.$$

We now sum with respect to r, thus changing the Riemann symbol to the symbol of the first kind, and then make use of the antisymmetry of (ip, hk) in i and p (§ 4), from which it follows that the sum is zero.

Equation (51′) is therefore simply a particular integral (or invariant relation) of the system (57); its role reduces to that of fixing one of the constants of integration. As the system (57) contains $n + 1$ unknowns, to make it determinate it is necessary to associate with it some other condition—a circumstance easy to understand from the geometrical point of view, since we have still to fix the law of punctual correspondence between g and the base.

From a formal point of view the easiest way to complete the system (57) is to cut out the unknown λ by putting

$$\frac{d\lambda}{d\sigma} = 0.$$

The equations (57) are thus reduced to the normal form (Chapter III, § 2)

$$(D^2\boldsymbol{\xi})^r = -\sum_{1}^{n}{}_{ihk}\{ir, hk\}\, b^i b^h \xi^k \qquad (r = 1, 2, \ldots n); \quad \text{(I)}$$

and we see that, on account of the identity (51″), *the system* (I) *admits the first integral*

$$\sum_{1}^{n}{}_r (D\boldsymbol{\xi})^r b_r = \lambda = \text{constant}, \quad . \quad . \quad . \quad \text{(II)}$$

expressing the fact that there is a constant linear dilatation when we pass from any arc of B to the corresponding arc of g.

Since, on account of the identity (58), the first member of the integral (II) is simply the derivative of $\sum_{1}^{n}{}_r \xi^r b_r$, it follows that every solution of the differential system (I) gives also

$$\sum_{1}^{n}{}_r \xi^r b_r = \lambda\sigma + C, \quad . \quad . \quad . \quad . \quad \text{(III)}$$

where C is a second constant.

If in particular we take $\lambda = 0$, we see that we can associate with the differential system the relation

$$\sum_{1}^{n}{}_r \xi^r b_r = C.$$

This gives the translation into analysis of the obvious geometrical fact that we can assign the correspondence between the points M of g and P of B in such a way that the (infinitely small) vector PM will have its orthogonal projection upon the tangent $\mathbf{t}$ to the base at the point P equal to a constant C. Such a law of correspondence implies, in virtue of (II), that there is no alteration of length ($\lambda = 0$) as between the arcs of B and the corresponding arcs of g. To particularize still further, if $C = 0$, we arrive at the orthogonal law of correspondence (PM perpendicular to B) considered in § 13.

It is scarcely necessary to add that, in order to substitute other geometrical laws of correspondence, we have only to associate with the system (57) the analytical translation of the law chosen, instead of the law $\frac{d\lambda}{d\sigma} = 0$. For example, if we wish PM to be inclined to B at an angle ψ (constant or a given function of σ) the additional equation will be

$$\sum_{1}^{n}{}_{r}\, \xi^{r} b_{r} = \xi \cos\psi,$$

where
$$\xi = \left| \sqrt{\sum_{1}^{n}{}_{ik}\, a_{ik}\, \xi^{i} \xi^{k}} \right|$$

represents the length of the vector $\boldsymbol{\xi}$.

In a case like this, some slight supplementary discussion of the complete system will be needed—its reduction to the normal form, determination of the number of constants of integration, &c.

17. Reduced form of the differential system (I) in terms of the co-ordinates y.

We now return to the co-ordinates y, and fix definitely on the orthogonal law of correspondence between the base B and any geodesic in its neighbourhood. As we have just seen, such a correspondence is expressed analytically by the differential system (I), with the specifications $\lambda = C = 0$ of the constants of integration connected with (II) and (III).

As remarked in § 14, the co-ordinate y_n of M is identical with that of P. Since the other co-ordinates y_α $(\alpha = 1, 2, \ldots n-1)$ of P are 0, the variations η^i of the co-ordinates y are respectively

$$\eta^{\alpha} = y_{\alpha} \quad (\alpha = 1, 2, \ldots n-1), \quad \eta^{n} = 0,$$

thus justifying the name of Cartesian components of the normal displacement or *deviation* $PM = \boldsymbol{\eta}$ which we give to the y_α's.

Moreover, the parameters $b^i = \frac{dy_i}{d\sigma}$ of the base B vanish for $i = 1, 2, \ldots n-1$; and $b^n = 1$. Christoffel's symbols also vanish along B, as well as their first derivatives with respect to

σ (or, what comes to the same thing, to y_n), and consequently

$$(D\boldsymbol{\eta})^r = \frac{d\eta^r}{d\sigma}.$$

Equations (I) thus become

$$\frac{d^2y_\alpha}{d\sigma^2} = -\sum_1^{n-1}{}_\beta \{n\alpha, n\beta\} y_\beta \quad (\alpha = 1, 2, \ldots n-1), \quad \text{(I')}$$
$$0 = -\sum_1^{n-1}{}_\beta \{nn, n\beta\} y_\beta,$$

where, in both sums, we have suppressed the term corresponding to the value n of the index, since every Riemann's symbol which has its last indices equal vanishes (§ 3).

The first group (I′) (comprising $n-1$ linear equations of the second order) *defines the* n — 1 *Cartesian components of the* (*normal*) *deviation* PM. The last equation reduces to an identity, as may be seen as follows. Riemann's symbols of the second kind are in all cases connected to those of the first kind by the relations

$$(ij, hk) = \sum_1^n{}_r\, a_{jr} \{ir, hk\};$$

we have, moreover, for the symbols of the first kind (§ 4),

$$(ij, hk) = -(ji, hk).$$

In our case the coefficients a_{jr} of ds^2 reduce, *on B*, to 0 (for $r \neq j$) and to 1 (for $r = j$). We have therefore, on the base, equality between symbols of the two kinds whose indices are the same; and, in particular,

$$\{nn, n\beta\} = (nn, n\beta) = 0. \qquad \text{Q.E.D.}$$

Of course, the integral relations (II) and (III) are of no further account, being now identities on account of the vanishing of the b^i's ($i = 1, 2, \ldots n-1$) and of the nth component $\xi^n = \eta^n$ of the displacement PM.

18. Case of $n = 2$ — formula of Jacobi.

For $n = 2$, that is to say for an ordinary surface, if B is the geodesic base, $y_2 =$ the arc σ, and y_1 ($= y$) the normal distance from M to B, the system (I′) reduces to the single equation

$$\frac{d^2y}{d\sigma^2} = -\{21, 21\} y.$$

Now (§ 9) for any co-ordinates whatever, the Gaussian curvature K of a V_2 is expressed by the ratio

$$\frac{(12,\,12)}{a} = \frac{(21,\,21)}{a},$$

a denoting the discriminant of the ds^2 of V_2.

For our co-ordinates, which are Cartesian along B, $a = 1$, and Riemann's symbols of the second kind are (§ 17) the same as their homologues of the first kind. The equation defining y is therefore none other than the equation of Jacobi (§ 13)

$$\frac{d^2y}{d\sigma^2} + Ky = 0.$$

CHAPTER VIII

RELATIONS BETWEEN TWO DIFFERENT METRICS REFERRED TO THE SAME PARAMETERS; MANIFOLDS OF CONSTANT CURVATURE

1. **Differences between Christoffel's symbols relative to two different metrics assigned to the same analytical manifold.**

We introduced in Chapter IV notions of *tensor*, *covariance*, &c., relative to an analytical manifold V_n, i.e. to the aggregate of n variables $x_1,\ x_2,\ \ldots\ x_n$; we then, in the third part of the following chapter, considered the metrical manifolds obtained by associating with an analytical manifold V_n a specified (but arbitrary) positive and definite differential quadratic form.

There is clearly no reason against assigning in turn to the same analytical manifold two distinct metrical determinations, defined by the two quadratic forms[1]

$$ds^2 = \sum_1^n{}_{ik}\, a_{ik}\, dx_i\, dx_k, \quad . \quad . \quad . \quad . \quad (1)$$

$$ds'^2 = \sum_1^n{}_{ik}\, a'_{ik}\, dx_i\, dx_k \quad . \quad . \quad . \quad . \quad (1')$$

---

[1] As a geometrical interpretation, we can think of two distinct V_n's whose points are in one-to-one correspondence, so that a set of n values assigned to $x_1, x_2, \ldots x_n$ can be represented either by a point P of one, or by the corresponding

Chapter 8

GÖDEL'S THEOREMS ON THE INHERENT LIMITATIONS OF FORMAL SYSTEMS

1 Gödel's new metamathematical method

We come now, in this chapter, to the celebrated metamathematical theorems of Gödel, which first revealed a fundamental disparity between formal axiomatic theories, of the type considered by Hilbert, and the intuitive mathematics that they are constructed to represent. The phase of formalism that lasted until 1930, and that was dominated by Hilbert's constructive work on metamathematics or theory of proof (*Beweistheorie*), can now be seen as a comparatively naive phase—intensely creative, and productive of the basic conceptions and techniques on which most later work has been based, but at the same time relatively uncritical of its own foundations and ignorant of its inherent limitations. By 1930, however, enough progress had been made on the constructive side for the process of formalization itself to be a possible object of critical study; and in a terse but incisive paper,[1] distinguished alike by astonishing originality, profundity of conception, and mastery of intricate detail, Gödel carried metamathematics over at a single stride into its second and more reflective phase.

Hilbert himself, in originally conceiving the idea of the formalist programme, had already taken a decisive step in the study of the formal aspect of mathematics. Even before this, the desirability of formalizing mathematical theories had been recognized by Peano, who had evolved a suitable technique for the purpose, but for Peano formalization was no more than an essential aid to rigour within mathematics. Hilbert, on the contrary, formalized mathematical theories in order to turn them into well-defined objects of discussion, thus making possible the new kind of investigation to which he gave the name 'metamathematics'. In his *Beweistheorie*, which we have outlined in the previous chapter, the mathematics is treated formally while the metamathematical discussion, though kept strictly within the bounds of finitary argument, proceeds in a more intuitive way. The further step which Gödel took was to devise a treatment of metamathematics that is itself essentially formal in character; and this new advance was made possible by a simple but ingenious device that he introduced for the 'arithmetization' of metamathematical reasoning.

---

[1] K. Gödel: 'Über formal unentscheidbare Sätze der Principia Mathematica und verwandter Systeme I', *Monatsh Math. Phys.*, **38** (1931), 173–198.

A formalized mathematical theory, as understood by Hilbert, is an edifice of symbolic expressions, made up of standard symbols that are used again and again, and such that the constitution of its component expressions (the well-formed formulae) and the manner in which these expressions may be assembled into derivations are regulated by precisely formulated syntactic rules. What Gödel realized was that, from a theoretical point of view, the particular nature of the signs that are chosen is totally irrelevant, so that we may as well adopt a standard system of 'coding', in which each symbol that is used is represented by a fixed natural number. Any formula, which is simply a finite string of symbols, will then be represented by a corresponding string of numbers; and by using the key to the code we shall be able to get back from the string of numbers to the formula. The coding can be arranged, moreover, in such a way that the rules which govern both the formation of well-formed formulae and the arrangement of such formulae in derivations can be expressed in terms of simple arithmetical operations on the representative numbers. When this is done, the metamathematical assertions that we are mostly interested in no longer require formulation in terms that refer specifically to the particular formal theory to which they relate, but they are all of a single uniform type, being without exception arithmetical propositions. Thus metamathematics, no less than the mathematics which forms its object, can be formalized, and it then becomes much more sharply defined than it was previously, when no limitation was imposed on it beyond that of being finitary.

When the new metamathematical technique is applied with formalized arithmetic itself as the primary theory, the way is made open for a most significant development. Since the metamathematics is now of the same nature as the mathematics, both of them consisting of arithmetical propositions, every metamathematical assertion can be expressed within the primary theory (provided that this is sufficiently comprehensive); and in this way the metamathematics of the formal system becomes formalizable within that system itself. A situation is thus created which allows of the sort of exploitation of self-reference that formed the basis of Cantor's proof that no class is equipotent with the class of all its subclasses, and also of Richard's paradoxical argument (see p. 127) and of the even simpler paradox of the man who declares 'The statement that I am now making is untrue'. Seizing upon this circumstance, Gödel was able to show that, if a system of formalized arithmetic is wide enough, then (i) the system is necessarily incomplete, in the sense that there exists a formula $\mathfrak{A}$ of the system such that neither $\mathfrak{A}$ nor its negation is derivable, and (ii) if the system is consistent, then no proof of its consistency is possible which can be formalized within it.

2 Gödel's heuristic argument

In the introduction to his paper of 1931, Gödel explained the general idea of his method by means of the following heuristic argument, formulated in relation to the logico-mathematical system of *Principia Mathematica*.

Consider all the formulae $R(x)$ which involve a single free variable x of the same type as the natural numbers. These formulae can be arranged, lexicographically for example, as a sequence $\{R_n(x)\}$.[1] Now the statement 'The formula $R_n(n)$, obtained when "n" is substituted for "x" in the nth formula of the sequence, is not derivable within the system' can itself be formalized within the system, and it is accordingly represented there by some formula $S(n)$. But the formula $S(x)$ then involves a single free variable x of the same type as the natural numbers, and therefore $S(x)$ coincides with $R_q(x)$ for some q. Thus $R_q(n)$ is a formal equivalent of 'The formula $R_n(n)$ is not derivable'; and consequently the formula $R_q(q)$ means 'The formula $R_q(q)$ is not derivable'. We therefore have, in $R_q(q)$, a formula that asserts its own underivability.

It now readily follows that this formula $R_q(q)$ is undecidable in the formal system. For suppose, first of all, that $R_q(q)$ were derivable. Then the proposition '$R_q(q)$ is underivable', expressed by this derivable formula, would be true. The assumption that $R_q(q)$ is derivable is therefore untenable. But now let us suppose that the negation $\sim R_q(q)$ of $R_q(q)$ were derivable. In that case the corresponding proposition 'not-[$R_q(q)$ is underivable]' would be true, and $R_q(q)$ would thus be derivable. If we assume that the formal system is consistent, we once again have an impossibility. Thus neither $R_q(q)$ nor $\sim R_q(q)$ can be derivable, and $R_q(q)$ is accordingly an undecidable formula of the system.

As Gödel says, this heuristic argument is plainly lacking in rigour, not only because we take for granted in it that the metamathematics of *Principia Mathematica* can be formalized within the *Principia* itself, but also because essential use is made of the non-formal semantic concept of truth of a proposition. In order to eliminate these deficiencies, Gödel proceeded in the body of his paper to develop the same line of argument fully and in a strictly formal manner, basing it not on *Principia Mathematica* itself but on a slightly different formal system, namely an arithmetical system P that he constructed by combining together the extended calculus of predicates (with the simple theory of types) and Peano's axioms for the natural numbers.

---

[1] The convention on the use of symbols that we have adopted in earlier chapters would require $\{R_n(x)\}$ to be written as $\{\mathfrak{R}_n(x)\}$; but in this chapter we prefer to adhere closely to the usage of Gödel in order to facilitate comparison of our summary with his original paper.

3 The formal system P and its arithmetized metamathematics

In summarizing Gödel's main argument, we must begin with the specification of the formal system P on which it is based. The primitive symbols of this system include both constants and variables, as follows:
I. Constants: '$\sim$' (not), '$\vee$' (or), 'Π' (for all), '0' (zero), 'f' (the successor of), and the two brackets '(' and ')'.
II. Variables: variables of the first type 'x_1', 'y_1', 'z_1', . . . (for individuals, i.e. natural numbers); variables of the second type 'x_2', 'y_2', 'z_2', . . . (for classes of individuals); variables of the third type 'x_3', 'y_3', 'z_3', . . . (for classes of classes of individuals); and so forth.[1]

In place of the symbolic expressions ϕx and $(x)\phi x$ that are used in *Principia Mathematica* for the propositional function 'x has the property ϕ' and the proposition 'Every individual has the property ϕ', we have in the system P the expressions $x_2(x_1)$ and $x_1\Pi(x_2(x_1))$.

The primitive symbols are to be supplemented by further constant symbols used as abbreviations. In particular, the symbols '.', '$\supset$', '$\equiv$', '(Ex)', '$=$' are used as '.', '$\supset$', '$\equiv$', '$(\exists x)$', '$=$' are used in *Principia Mathematica.*

By an *expression (Zeichen) of the first type* is meant an expression of one of the forms $a, fa, ffa, fffa, \ldots$, where a is either 0 or else a variable of the first type. An *expression of the nth type* ($n > 1$) can only be a variable of that type.

An *elementary formula* is an expression $a(b)$, where b is an expression of some type n and a is an expression of the next higher type $n + 1$.

The class of *formulae* is the smallest class that contains all the elementary formulae and is closed with respect to negation, disjunction, and universal quantification. By this we mean that, if a and b are formulae and x is any variable, then $\sim(a)$, $(a) \vee (b)$, and $x\Pi(a)$ are also formulae.

A formula with no free variables is said to be a *propositional formula.* A formula with exactly n free individual variables and no other free variable is said to be a *relation-formula with n arguments.* A relation-formula with one argument is also called a *class-formula.*

If a is any formula, v is a variable, and b is an expression of the same type as v, we are to understand by

$$\text{Subst } a \begin{pmatrix} v \\ b \end{pmatrix}$$

---

[1] No primitive symbols are needed for predicates. A predicate with one argument can be interpreted as a class of individuals, a predicate with two arguments as a class of ordered pairs of individuals, and so on; and an ordered pair $a \downarrow b$ can in turn be identified with a class of classes, namely $\{\{a\},\{a, b\}\}$ (cf. p. 171).

the formula which results when b is substituted for all the free occurrences (if there are any) of v in a.

A formula a is said to be obtained from a formula b by *elevation of type* if it is obtained when the type of every variable that occurs in b is raised by the same amount.

The axioms of the system P are arranged in five groups as follows:

I. 1. $\sim(fx_1 = 0)$,
2. $fx_1 = fy_1 \supset x_1 = y_1$,
3. $x_2(0) . x_1\Pi(x_2(x_1) \supset x_2(fx_1)) \supset x_1\Pi(x_2(x_1))$.

II. Every formula that can be obtained from the following schematic forms by substituting arbitrary formulae for p, q, r:

1. $p \vee p \supset p$,
2. $p \supset p \vee q$,
3. $p \vee q \supset q \vee p$,
4. $(p \supset q) \supset (r \vee p \supset r \vee q)$.

III. Every formula that can be obtained from the following schematic forms by making substitutions of the kind specified below for a, b, c, v, and, in the case of 1, carrying out the substitution indicated:

1. $v\Pi(a) \supset \text{Subst } a \begin{pmatrix} v \\ c \end{pmatrix}$,
2. $v\Pi(b \vee a) \supset b \vee v\Pi(a)$.

For a we may substitute an arbitrary formula, for v an arbitrary variable, for b a formula in which v does not occur free, and for c an expression of the same type as v, provided that c contains no variable that is bound in a where v is free.

IV. Every formula that can be obtained from the schematic form

1. $(Eu)(v\Pi(u(v) \equiv a))$

by substituting for v and u variables of types n and $n + 1$ respectively, and for a a formula in which u does not occur free. (This axiom, which is related to the 'principle of comprehension' for classes, as formulated below on p. 285, takes the place in the system P of the axiom of reducibility in *Principia Mathematica*.)

V. The following formula, and every formula that is obtainable from it by elevation of type:

1. $x_1\Pi(x_2(x_1) \equiv y_2(x_1)) \supset x_2 = y_2$.

This axiom asserts that a class is completely determined by its members; cf. the axiom of determination in the theory of sets, as stated on p. 288 below.

No rule of substitution is required, since substitutions are already taken care of by the adoption of axiom-schemata in preference to specific axioms (cf. p. 44). The other rules of procedure are incorporated in the system P in the following manner: A formula c is said to be an *immediate consequence* of a and b (or of a) if a is the formula $(\sim(b)) \vee (c)$ (or if c is the formula $v\Pi(a)$, where v is any variable). The class of *derivable formulae* is defined as the smallest class of formulae which contains the axioms and is closed with respect to the relation of immediate consequence.

Exercise. Rewrite the specification of Gödel's system P in the notation of the present book, using German letters as syntactic variables. Compare Gödel's axioms with those of (a) *Principia Mathematica*, (b) Peano's treatment of arithmetic, (c) Hilbert's formalization of logic and arithmetic, as given above in Chapters 3 and 7.

In order to arithmetize the metamathematics of the system P, Gödel had first of all to rewrite the entire formal system, using numbers everywhere in place of the special symbols $\sim$, $\vee$, Π, 0, f, $(\,,)$, x_1, $y_1, \ldots$; and this he did in principle by defining what has since come to be known as a *Gödel numbering* of the formal expressions. He first attached numbers to the constant primitive symbols in accordance with the following table:

Symbol	0	f	$\sim$	$\vee$	Π	(	)
Number	1	3	5	7	9	11	13

Then, making use of the natural sequence of prime numbers $p_1, p_2, p_3, \ldots$ (i.e. the sequence $2, 3, 5, \ldots$), he assigned to the variables $x_n, y_n, z_n, \ldots$ of the nth type the numbers $p_7^n, p_8^n, p_9^n, \ldots$, i.e. the numbers $17^n, 19^n, 23^n, \ldots$.

The coding of the symbols that is defined in this way is such that every primitive symbol of the system has a well-defined Gödel number, and distinct symbols always have distinct numbers. To any finite sequence $a_1, a_2, \ldots, a_k$ of primitive symbols there then corresponds a finite sequence $n_1, n_2, \ldots, n_k$ of natural numbers; and with this latter sequence we may associate in turn the single natural number $p_1^{n_1} p_2^{n_2} \ldots p_k^{n_k}$. By this process a one-one mapping is set up between the totality of finite sequences a of primitive symbols on the one hand, and a certain subset of the set of natural numbers on the other. We may denote this mapping by $a \longleftrightarrow \Phi(a)$. Then, since every formula a of the system P may be treated as a mere string of symbols, it has a well-defined Gödel number $\Phi(a)$.

EXAMPLE. Consider axiom I 2, which runs

$$fx_1 = fy_1 \supset x_1 = y_1.$$

Written in terms of primitive symbols only, without use of abbreviations, this becomes

$$\sim(x_2\Pi(\sim x_2(fx_1) \vee x_2(fy_1))) \vee x_2\Pi(\sim x_2(x_1) \vee x_2(y_1)),$$

which is a string of 34 symbols. From this string we obtain a sequence of 34 numbers 5, 11, 17^2, 9, 11, 5, $17^2, \ldots$, 13; and the Gödel number of the formula is therefore

$$p_1^5 p_2^{11} p_3^{17^2} \cdots p_{34}^{13}.$$

Not every integer corresponds to a well-formed formula, of which it is the Gödel number, or even to a string of primitive symbols; but if a number is the Gödel number of a formula, this formula can actually be found by resolution of the number into its prime factors.

The Gödel coding can readily be extended from single formulae to finite sequences of formulae—among which, of course, are included derivations. Let $a_1, \ldots, a_l$ be given formulae, and let the Gödel number $\Phi(a_i)$ of a_i be m_i, $i = 1, \ldots, l$. Then we assign to the sequence $\{a_1, \ldots, a_l\}$ the single number $p_1^{m_1} \ldots p_l^{m_l}$. When this has been done, every symbol, every formula, and every finite sequence of formulae in the system P is represented without ambiguity by a Gödel number.

Suppose now that we have some metamathematical predicate or relation $R(a_1, \ldots, a_n)$ that is defined for sets of n symbols, formulae, or sequences of formulae $a_1, \ldots, a_n$. In the special case $n = 1$ the 'relation' is to be understood, as usual, as a class of symbols, etc. Then the relation $R(a_1, \ldots, a_n)$ determines an 'induced' relation $R'(x_1, \ldots, x_n)$, defined for sets of natural numbers. This induced relation holds for a particular set of numbers $x_1, \ldots, x_n$ if and only if there exist $a_1, \ldots, a_n$ in the formal system such that, for $i = 1, \ldots, n$, a_i has Gödel number x_i—in the appropriate sense—and $R(a_1, \ldots, a_n)$ is true. Gödel represents the arithmetical relation R' that is derived in this way from any particular metamathematical relation R by putting the name of R into italics. Thus, for example, *formula* is the class (i.e. predicate) whose members are the Gödel numbers of formulae; and 'm is a *derivation* of n' is the relation between two numbers m and n which holds whenever m is the Gödel number of a sequence of formulae that is a derivation, the end-formula of which has Gödel number n.

When Gödel had set up his numbering in the manner described, he had to go on to show that the arithmetized metamathematics of P was all contained in P; that is to say, he had to show that the various italic relations between numbers that are obtained from such metamathematical relations as 'formula', 'immediate consequence', and 'derivable' admit of formalization within P. He was able to do this with the aid of recursive arithmetic. Only the elements of recursive arithmetic were needed for this purpose, and Gödel gave the following explanation of what he understood by recursive functions and recursive relations. The explanation is expressed intuitively, of course, not formalized within the system P.

An arithmetical function $\varphi(x_1,x_2,\ldots,x_n)$ is said to be *recursively defined* in terms of a pair of given functions $\psi(x_1,x_2,\ldots,x_{n-1})$ and $\mu(x_1,x_2,\ldots,x_{n+1})$ if, for all $x_2,\ldots,x_n$, k,

$$\varphi(0,x_2,\ldots,x_n) = \psi(x_2,\ldots,x_n),$$
$$\varphi(k+1,x_2,\ldots,x_n) = \mu(k,\varphi(k,x_2,\ldots,x_n),x_2,\ldots,x_n).$$

A *function* φ is said to be *recursive*[1] if there exists a finite sequence of functions $\varphi_1, \varphi_2, \ldots, \varphi_n$ such that $\varphi_n = \varphi$, and every function φ_k of the sequence is either recursively defined in terms of two of its predecessors, or is obtained by substitution in one of its predecessors, or else is either a constant or the successor function $x + 1$.

A *relation* $R(x_1,\ldots,x_n)$ between natural numbers is said to be *recursive* if there exists a recursive function $\varphi(x_1,\ldots,x_n)$ such that, for any numbers $x_1,\ldots,x_n$, the relation $R(x_1,\ldots,x_n)$ holds if and only if $\varphi(x_1,\ldots,x_n) = 0$.

Recursiveness having thus been defined, the demonstration that the metamathematics of the system P can be formalized in P proceeds in two stages. First it is shown that all the relevant metamathematical relations are recursively expressible in terms of the Gödel numbering; and then recourse is had to a general theorem which asserts that every recursive relation is representable in P (cf. the definition of formal representability on p. 222 above).

Gödel states and proves from first principles for his formal system P the following theorem, which may be compared with the corresponding theorem for Hilbert's system (Z), which we give in Chapter 10 (p. 269):

THEOREM 1. *If* $R(x_1,\ldots,x_n)$ *is any relation in recursive arithmetic, there exists in* P *a relation-formula* $\varrho(x_1^{(1)},\ldots,x_1^{(n)})$, *with n free variables, such that, for any set of n numbers* $m_1,\ldots,m_n$, (*i*) *if* $R(m_1,\ldots,m_n)$ *holds then* $\varrho(m_1',\ldots,m_n')$ *is derivable in* P, *and* (*ii*) *if* $R(m_1,\ldots,m_n)$ *does not hold then* $\sim\varrho(m_1',\ldots,m_n')$ *is derivable in* P, m_i' *denoting the symbol* $ff\ldots f0$ *that corresponds in* P *to the number* m_i.

This theorem appears in Gödel's paper as *Satz* V (p. 186).

That all the relevant metamathematical relations are recursive was shown by Gödel in a series of 46 lemmas. Typical of the relations that he considers are those which we can express (using the device of italic names to which we referred on p. 235) by the words 'x is a *variable of the nth type*', 'x is an *axiom*', and 'x is a *derivation* of the *formula* y'.

---

[1] I.e. primitive recursive in current terminology (cf. Chapter 10, §6).

4* The central argument of Gödel's paper

In attempting to summarize Gödel's argument in such a way that we can give some indication of the essential steps without going into too many formal details, we shall adopt a device of denoting the sequence of symbols (i.e the expression) that has a given Gödel number x by $\tilde{x}$, and the sequence of expressions that has a given Gödel number x by $\tilde{\tilde{x}}$. Then the statement 'x is a *derivation* of the *formula* y', for instance, can be expressed in the alternative form '$\tilde{\tilde{x}}$ is a sequence of formulae that is a derivation of the formula $\tilde{y}$'. We shall also use the notation 'x'', as in the theorem stated at the end of §3, for the expression $ff\ldots f0$ which represents the number x in the formal system P.

Gödel found it necessary to postulate that the system P is *ω-consistent*, or consistent in a stronger sense than that which is ordinarily envisaged, and the concept of ω-consistency must be explained before we can state his main theorem. An arithmetical formalism is consistent in the ordinary sense—or *simply consistent*—if no two formulae $\mathfrak{A}$ and $\overline{\mathfrak{A}}$ are both derivable in it; but consistency in this sense does not exclude the more subtle kind of contraction that occurs when, for some formula $\mathfrak{A}(n)$ that contains a free variable n, $\mathfrak{A}(\mathfrak{n})$ is derivable for each particular number $\mathfrak{n}$, and $\overline{(x)\mathfrak{A}(x)}$ is also derivable. This possibility was first pointed out by Alfred Tarski. It is easily seen that a system that is ω-consistent is also simply consistent, for if it were not simply consistent then every formula would be derivable in it (cf. p. 211); but Tarski has shown by an example that a system can be simply consistent without being ω-consistent.[1]

Gödel formulated his main argument in terms of any formal system that can be obtained by supplementation of the axioms of the basic system P by an arbitrary recursive class $\varkappa$ of additional formulae. He first defined the *consequential set* (*Folgerungsmenge*) of $\varkappa$ as the smallest set of formulae that contains the axioms of P and the formulae belonging to $\varkappa$, and is at the same time closed with respect to the relation of immediate consequence. If $\varkappa$ is empty, its consequential set plainly reduces to the set of derivable formulae of P.

The two senses of consistency can now be redefined, with reference to such a class $\varkappa$, as follows: A class of formulae $\varkappa$ is said to be *simply consistent* if its consequential set does not contain any formula together with its negation; and $\varkappa$ is said to be *ω-consistent* if there does not exist any class-formula $a(v_1)$ such that (i) $a(n')$ belongs to the consequential set of $\varkappa$ for every natural number n, and (ii) $\sim(v_1\Pi(a(v_1)))$ also belongs to this consequential set.

---

[1] A. Tarski: 'Einige Betrachtungen über die Begriffe der ω-Widerspruchsfreiheit und der ω-Vollständigkeit', *Monatsh. Math. Phys.*, **40** (1933), 97–112. In this paper Tarski claims priority in the introduction of the concept of ω-consistency though not in the use of this name for it.

We can now state Gödel's key theorem (his *Satz* VI) in the following terms:

THEOREM 2. *If $\varkappa$ is any ω-consistent recursive class of formulae of the system* P, *there exists a formula $\varrho(x_1)$, which determines a recursive class of numbers, and which is such that neither $v_1\Pi(\varrho(v_1))$ nor $\sim(v_1\Pi(\varrho(v_1)))$ belongs to the consequential set of $\varkappa$.*

Proof. In outlining Gödel's proof, we shall use the term '$\varkappa$-derivation' to mean a derivation in which any formulae belonging to $\varkappa$ may be used as initial formulae.

We consider first of all the metamathematical propositional function '$\tilde{\tilde{x}}$ is not a $\varkappa$-derivation of the formula which results when y' is substituted for y_1 in the formula $\tilde{y}$'. The 'y_1' that is here referred to is the particular symbol of the system P that has Gödel number 19, and the letter 'y' in it has no connexion with the 'y' that is one of the variables involved in the propositional function. This propositional function is a relation, $Q(x,y)$ say, built up out of constituent notions such as 'im mediate consequence' and 'substitution', whose italic counterparts ar proved in the lemmas of Gödel's paper to be recursive; and it is therefore represented in P by a relation-formula $\tilde{q}(x_1,y_1)$, in such a way tha (i) if $\tilde{\tilde{x}}$ is not a $\varkappa$-derivation of $\tilde{y}(y')$, then $\tilde{q}(x',y')$ is derivable, and (ii) i $\tilde{\tilde{x}}$ is a $\varkappa$-derivation of $\tilde{y}(y')$, then $\sim(\tilde{q}(x',y'))$ is derivable.

We now put

$$\tilde{p}(y_1) \equiv x_1\Pi(\tilde{q}(x_1,y_1))$$

and

$$\tilde{r}(x_1) \equiv \tilde{q}(x_1,p').$$

Then

$$\tilde{p}(p') \equiv x_1\Pi(\tilde{q}(x_1,p'))$$
$$\equiv x_1\Pi(\tilde{r}(x_1)),$$

and

$$\tilde{q}(x',p') \equiv \tilde{r}(x').$$

Substituting p for y in (i) and (ii) above, we have: (i)$'$ if $\tilde{\tilde{x}}$ is not a $\varkappa$-derivation of $\tilde{p}(p')$, then $\tilde{q}(x',p')$ is derivable; and (ii)$'$ if $\tilde{\tilde{x}}$ is a $\varkappa$-derivation of $\tilde{p}(p')$, then $\sim(\tilde{q}(x',p'))$ is derivable. In other words, (i)$''$ if $\tilde{\tilde{x}}$ is not a $\varkappa$-derivation of $x_1\Pi(\tilde{r}(x_1))$, then $\tilde{r}(x')$ is derivable; and (ii)$''$ if $\tilde{\tilde{x}}$ is a $\varkappa$-derivation of $x_1\Pi(\tilde{r}(x_1))$, then $\sim(\tilde{r}(x'))$ is derivable.

At this point the argument divides into two parts:

1. We suppose that $x_1\Pi(\tilde{r}(x_1))$ is $\varkappa$-derivable. Then it follows that $\tilde{r}(n')$ is $\varkappa$-derivable for any number n whatever. But, in view of (ii)$''$,

there is an n such that $\sim(\tilde{r}(n'))$ is $\varkappa$-derivable. We thus have a $\varkappa$-derivable contradiction; and this proves, even if $\varkappa$ is assumed merely to be *simply* consistent, that the formula $x_1\Pi(\tilde{r}(x_1))$ is not $\varkappa$-derivable.
2. We have shown in 1. that $x_1\Pi(\tilde{r}(x_1))$ is not $\varkappa$-derivable, and thus, for any n whatever, $\tilde{\tilde{n}}$ is not a $\varkappa$-derivation of $x_1\Pi(\tilde{r}(x_1))$. Hence, by (i)'', $\tilde{r}(n')$ is derivable for every choice of n. If, therefore, $\varkappa$ is assumed to be ω-consistent, the formula $\sim(x_1\Pi(\tilde{r}(x_1)))$ is not $\varkappa$-derivable.

1. and 2. together show that neither the formula $x_1\Pi(\tilde{r}(x_1))$ nor its negation is $\varkappa$-derivable, and this proves the theorem.

Remarks (i) In the above version of the proof we have used the expression $\tilde{q}(x_1,y_1)$ to stand for the formula with Gödel number q, and to indicate at the same time that this formula contains x_1 and y_1 as free variables. We have then used $\tilde{q}(x_1,p')$ to stand for the formula

$$\text{Subst } \tilde{q}(x_1,y_1)\begin{pmatrix} y_1 \\ p' \end{pmatrix}.$$

(ii) It has been shown by Barkley Rosser (*J. Symb. Logic*, **1** (1936), 87–91) that Gödel's original proof can be modified in such a way that the existence of an undecidable formula is shown to follow merely from simple consistency of $\varkappa$, the heavier requirement of ω-consistency being in fact superfluous.

(iii) After proving his main theorem on the existence of undecidable formulae, Gödel made the following comment on its range of application:

'In the proof of Theorem VI, no properties of the system P were used except the following:
1. The class of axioms and the rules of inference (i.e. the relation of "immediate consequence") are recursively definable (as soon as the primitive symbols have been replaced in some way by natural numbers).
2. Every recursive relation is definable within the system P (in the sense of Theorem V).

It follows that, in every formal system that satisfies the hypotheses 1 and 2 and is ω-consistent, there are undecidable propositions of the form $(x)F(x)$, where F is a recursively defined property of natural numbers, and the same is true of every extension of such a system by means of a recursively definable ω-consistent class of axioms. The systems that satisfy the hypotheses 1 and 2 include, as may easily be verified, the Zermelo-Fraenkel and von Neumann systems of axioms for the theory of sets, and also the system of axioms for the theory of numbers that consists of the Peano axioms, recursive definitions, and the logical rules. Hypothesis 1 is satisfied by any system whatever that has the usual rules of inference and whose axioms arise (as in the case of P) by substitution in a finite number of schemata.'

5 The impossibility of an 'internal' proof of consistency

In §4 of his paper, Gödel turned his attention to the second of his famous theorems, the one that establishes the impossibility of proving certain formal systems consistent from within. The general idea of the argument (of which only the outline is sketched in the original paper) may be explained in the following terms.

The argument depends on the fact that in the system P we are able to formalize intuitive arithmetical reasoning. That is to say, given an intuitive arithmetical proof, we can construct in P a corresponding formal derivation. Suppose then, once again, that $\varkappa$ is an arbitrary recursive class of formulae of the system P. We already know, by 1. on p. 238, that from the hypothesis that $\varkappa$ is simply consistent it follows that the formula $x_1\Pi(\tilde{r}(x_1))$ is not $\varkappa$-derivable. More precisely, we are able to give an intuitive proof (which is effectively arithmetical in view of our arithmetization of the metamathematics of the system P) that this conclusion follows. Hence we can establish, by intuitive reasoning, the implication

($\varkappa$ is consistent) $\rightarrow$ (the formula $x_1\Pi(\tilde{r}(x_1))$ is not $\varkappa$-derivable),
i.e. ($\varkappa$ is consistent) $\rightarrow$ (x)($\tilde{\tilde{x}}$ is not a $\varkappa$-derivation of $x_1\Pi(\tilde{r}(x_1))$),
i.e. ($\varkappa$ is consistent) $\rightarrow$ (x)($\tilde{\tilde{x}}$ is not a $\varkappa$-derivation of $\tilde{p}(p')$),
i.e. ($\varkappa$ is consistent) $\rightarrow$ $(x)Q(x,p)$.

The intuitive proof of this implication can now be formalized by an equivalent derivation in P. The metamathematical proposition '$\varkappa$ is consistent' will be formalizable in P by a certain propositional formula $\tilde{w}$; and since $Q(x,p)$ is formalizable, as we already know, by $\tilde{r}(x')$, it follows that $(x)Q(x,p)$ is formalizable by $x_1\Pi(\tilde{r}(x_1))$. The derivation in P will accordingly be a derivation of the formal implication

$$\tilde{w} \supset x_1\Pi(\tilde{r}(x_1)).$$

If, now, $\tilde{w}$ were to be derivable in P, we would at once have a derivation of $x_1\Pi(\tilde{r}(x_1))$—and this we know to be impossible if $\varkappa$ is consistent. Thus $\tilde{w}$ is not derivable in P, and so we have the following theorem:

THEOREM 3. *If $\varkappa$ is any simply consistent recursive class of formulae in* P, *there does not exist any proof, formalizable in* P, *of the consistency of the system which results when the formulae in $\varkappa$ are adjoined to* P *as additional initial formulae.*

If, in particular, we take for $\varkappa$ the empty class, we see that Theorem 3 applies to the system P itself.

It was the publication of this theorem that effectively brought to a close the initial phase of the formalist movement, as we have indicated in §1 of this chapter. Although, as Gödel was careful to point out, the theorem only rules out *formalizable* proofs of consistency, and does not say anything directly about *finitary* proofs, it does not seem likely that a finitary procedure could ever be devised that was not also formalizable.

Hilbert and Bernays have discussed Gödel's theory and its implications at length in the second volume of their *Grundlagen der Mathe-*

matik (1939). They modify the details of Gödel's paper, using an alternative way of arithmetizing metamathematics which brings the theory into more immediate relation with Hilbert's treatment of formalized arithmetic, but the basis of the theory remains substantially unchanged. The proofs are, of course, given in full; and for each of Gödel's theorems precise conditions are formulated which are sufficient to ensure that a formal system is one to which the theorem applies. It is eventually shown (*Grundlagen*, II, §5, 2, e) that the theorem on the impossibility of an internally formalizable proof of consistency holds, in particular, for the system (Z) of formalized arithmetic, as specified on p. 223 above.

We see, then, that the consistency of formalized arithmetic can only be proved by methods which are more general than any that are provided for in the arithmetical system itself. When Gödel had established this fact, it was natural that attempts should be made to prove the consistency of arithmetic by means which did not go too far beyond the previously recognized limits of strict finitariness, and in 1936 Gentzen succeeded in constructing a proof of consistency which depended on the application of transfinite induction. For this further development of metamathematics see Note 1, immediately following, and also Section 2 of the Appendix, p. 385.

SUPPLEMENTARY NOTES ON CHAPTER 8

1. *Gentzen's proof of the consistency of arithmetic.* It follows from Gödel's theorem on proofs of consistency (Theorem 3, p. 240) that, for any reasonably adequate formalization of arithmetic to be proved consistent, more powerful types of metamathematical argument must be allowed than those originally envisaged by Hilbert. The proof of consistency will then no longer provide the clear justification of arithmetic as a 'significant' formal theory that was at one time hoped for, and its value in this respect will vary inversely with the power of the methods of demonstration which it employs. But, whatever weight may now be given to proofs of consistency as an ultimate guarantee of the validity of mathematical theories, any precise indication of means that are sufficient to establish the consistency of formalized arithmetic is of major interest in its own right. In the proof of consistency which Gentzen constructed, finitary reasoning of the earlier kind was supplemented by a limited use of transfinite induction.

Gentzen's argument depended on the introduction of a process of reduction (cf. p. 211) which can be applied to any derivation in the arithmetical system that he considered. This process was defined in a recursive manner, and to complete the specification Gentzen had to show that the reduction of any given derivation can be accomplished in a finite number of steps. To show that the process of reduction always terminates, he introduced ordinal numbers as measures of the complexity of formulae and then applied transfinite induction to these ordinal numbers. For this purpose he needed transfinite induction for a certain segment of Cantor's second number class, namely the series of all ordinals below the first ε-number, i.e. the smallest ordinal number α such that $\omega^\alpha = \alpha$. A different proof of the consistency of arithmetic, also dependent on transfinite induction up to the first ε-number, has been given by Ackermann [2]. This proof makes essential use of the selection operator ε_x, which Hilbert originally introduced with the aim of extending to the arithmetical system (Z) the proofs of consistency that he had already constructed for weaker systems.

2. *Alternative accounts of Gödel's investigation.* A detailed presentation in English of the substance of Gödel's fundamental paper is contained in the mimeographed notes [3] of lectures which Gödel gave at Princeton in 1934. These notes were compiled by Kleene and Rosser. Rosser has published also, in the *Journal of Symbolic Logic* in 1939, an informal paper [2] which gives the gist of Gödel's work.

Gödel's theory is presented afresh by Mostowski in his book [1], again in considerable detail. A more elementary summary is that of N. R. Hanson [1]; and there is also a popular account by Nagel and Newman [1].

FORMALIZED MATHEMATICS AND METAMATHEMATICS

1 Hilbert's new approach to the foundations of mathematics

For all the inspiration that *Principia Mathematica* has communicated to the logicians and philosophers of mathematics of the twentieth century, and for all its rich fecundity as a source of concepts and symbolic devices, this great work remains, in the literature of the foundations of mathematics, a lone classic without progeny.[1] That such should be the case may well seem puzzling; and indeed there does not appear to be any simple reason why the impetus of the logistic movement should have failed with the publication of the third volume of the *Principia*. It is an undoubted fact, however, that the leadership of research into the foundations of mathematics passed at that time from Russell to Hilbert, and that it is from Hilbert that most of the subsequent developments directly derive. Before turning to the details of Hilbert's work we must try to see, as best we can, how this sudden change came about.

The Russell of the *Principia* was both a mathematician and a logician, though inclining, as we may infer from the outlook revealed in *The Principles of Mathematics*, more to the side of logic and philosophy than to that of mathematics, whereas Hilbert was one of the most professional of mathematicians. This difference may go a long way towards accounting for the greater readiness of mathematicians interested in the foundations of mathematics to align themselves with Hilbert than to follow Russell into the unfamiliar territory of philosophy.

There were also certain specific deficiencies in *Principia Mathematica* which must have made it appear that the solution there offered to the problems raised by the foundations of mathematics was not a complete or final one. The controversial nature of the theory of types, and in particular the intrusion of the admittedly arbitrary axiom of reducibility, constituted an obvious imperfection; and there was an even more fundamental weakness in the logistic view itself that had been shown up by the discovery of the vicious-circle paradoxes. The known paradoxes could indeed all be eliminated from the logistic system by the theory of types, but this still did not ensure that no other paradoxes would arise in the future, and the most that could be claimed was that the logic of the *Principia* was as rigorous as anyone then knew how to make it. But if Russell had not happened to stumble upon his contradiction, the *Principia* would presumably have been written (as indeed was Frege's *Grundgesetze der Arithmetik*) without any separation of types, and it is unlikely that logicians would have suspected that there might be something wrong with it. Elimination of known fallacies is therefore not by itself a sufficient safeguard, and the ultimate logical justification of mathematics must include some more positive guarantee of its consistency. The main concern of Hilbert, in the decades following the publication of *Principia Mathematica*, was with the search for such a guarantee.

---

[1] On the logical side, the *Principia* has a direct descendant in Quine's *Mathematical Logic* (1940, revised 1951).

The approach of Hilbert to the problems of the foundations of mathematics was so closely bound up with his personal experience of the activity of mathematical creation that we can scarcely hope to understand it unless we see his work as a whole. By good fortune we are in a position to trace the mathematical origin of his preoccupation with questions of foundations, for we possess an early though fully mature work of his in which we can see this interest in process of development. This work is the famous *Grundlagen der Geometrie* [Foundations of Geometry] of 1899, which we shall have to consider in some detail. But before turning to Hilbert's writings we must first summarize the main facts of his career.

David Hilbert was born in 1862 at Königsberg in East Prussia—the native city of Immanuel Kant, the great philosopher—and he became in turn a student, a lecturer, and a professor at the university of Königsberg. In 1895 he went as professor to Göttingen, where he remained until his death in 1943; and he thus spent more than half his life at the university whose fame as a centre of mathematical research had begun with the presence there of the illustrious figure of Gauss and had been maintained by a succession of mathematicians of the highest eminence, from Dirichlet and Riemann to Klein. Indeed, Hilbert himself must be numbered among the greatest creative mathematicians since Gauss, for besides making discoveries of fundamental importance in many different branches of mathematics, he influenced decisively the mathematical outlook of his whole generation.

In some fields of study Hilbert introduced concepts and methods that enabled research to go forward in entirely new directions, as with his theorem, described by Hermann Weyl[1] as 'one of the simplest and most important theorems in the whole of algebra', which asserts that every ideal in a polynomial ring has a finite basis, and also with the concept that is now known by the name of 'Hilbert space'. In the case of the classical theory of invariants he was able, by solving a fundamental problem that had been the ultimate objective of a vast amount of earlier work, to bring research virtually to an end. Among the most important and influential of his publications (excluding those devoted specifically to the foundations of mathematics) are the book on geometry that we are about to discuss; the famous *Zahlbericht* of 1897, a report on the state of knowledge in the theory of algebraic numbers, drawn up for the *Deutsche Mathematiker-Vereinigung*; a book, *Grundzüge einer allgemeinen Theorie der linearen Integralgleichungen* (Leipzig and Berlin, 1912), in which are reprinted six fundamental papers on integral equations, originally published in the *Göttinger Nachrichten* between 1904 and 1910; and the two volumes of *Methoden der mathematischen Physik* (Berlin, 1924 & 1937), written in collaboration with Richard Courant, in which essentially algebraic methods are made the basis of a unified treatment of partial differential equations, integral equations, and the calculus of variations.

2 Hilbert's 'Grundlagen der Geometrie'

Hilbert's epoch-making book of 1899 was offered as a new presentation of euclidean geometry, written with the intention of taking fully into account the enhanced understanding of the axiomatic method that mathematicians had achieved in the centuries that had elapsed since the time of Euclid, and more particularly in the closing decades of the nineteenth century. Not only did Hilbert profit by this recently acquired insight, but he himself raised the axiomatic method to a new level of efficiency; and of his book Hermann Weyl subsequently wrote as follows:

'The soil was well prepared, especially by the Italian school of geometers. Yet it was as if over a landscape, wherein but a few men with a superb sense of orientation had found their way in murky twilight, the sun had risen all at once. Clear and clean-cut we find stated the axiomatic concept according to which all geometry is a hypothetical deductive system; it depends on the implicit definitions of the concepts of spatial objects and relations which the axioms contain, and not on a description of their intuitive content. A complete and natural system of geometric axioms is set up. They are required to satisfy the logical demands of consistency, independence, and completeness, and by means of quite a few peculiar geometries, constructed *ad hoc*, the proof of independence is furnished in detail.'[1]

---

[1] H. Weyl: 'David Hilbert, 1862–1943', *Obituary Notices of Fellows of the Royal Society*, **4** (1942–1944), 547–553. In this notice, Weyl gave an account of Hilbert's mathematical achievements and showed clearly why it was that his influence on the development of mathematics was so great. A more detailed survey of Hilbert's work is contained in the longer obituary notice [5] that Weyl wrote for the American Mathematical Society

In the opening chapter of the *Grundlagen der Geometrie* Hilbert laid his foundation for a new axiomatic treatment of euclidean geometry that was intended to be absolutely rigorous, although expressed without the aid of any special symbolism and in language no more technical than that of Euclid. The later chapters of the book were then devoted to investigations, with the system of geometry itself as their object, of the kind described nowadays as *metamathematical*. Chief among these investigations was one that established the consistency of geometry; and the others were mainly concerned with general questions of logical dependence of propositions on other propositions—whether certain important theorems are deducible from such and such axioms, and whether the axioms themselves are independent.

The formal system was constructed in accordance with the principles of Peano, although this feature was somewhat masked by Hilbert's use of ordinary language in preference to logical symbolism. Hilbert had his reasons for this choice of language, the main consideration presumably being that he wished his work to be seen as a continuation of the age-old striving of geometers to evolve a purely rational theory of the spatial structure of the world. That this was his motive is confirmed by the following words from the introduction to the book:

> 'Geometry, like arithmetic, requires for its systematic development only a small number of simple basic principles. These principles are known as axioms of geometry. Setting up axioms for geometry and investigating the way in which they are connected is a problem that has been discussed ever since the time of Euclid in numerous admirable contributions to the literature of mathematics. The problem in question amounts to logical analysis of our intuition of space.'

The concluding sentence of this paragraph was no merely conventional remark, but a deliberate affirmation of ultimate intention. Hilbert made this quite clear by placing at the head of the introduction, as a motto for the whole book, these famous words from Kant's *Critique of Pure Reason*: 'Thus all human knowledge begins with intuitions, goes from there to concepts, and ends with ideas.' It had been Kant's firm conviction that theoretical knowledge and immediate intuition are inseparable, and that even the most abstruse scientific reasoning derives its significance and its objectivity from its continuity with the basic intuitions of the active mind. In a rather similar way Hilbert believed that, although geometry is entirely self-sufficient as a deductive system, it is nevertheless dependent on the immediacy of intuition for the interest that makes it a recurrent challenge to the human mind instead of merely one among a whole infinity of arbitrary intellectual exercises.

Thus the language of the *Grundlagen* was the traditional language of elementary geometry; and where this language offered convenient synonyms, such as 'lies on' or 'belongs to' for 'is a point of', Hilbert used them freely to denote one and the same abstract concept. From the point of view of the strict logician, however—and this was one of the points of view that Hilbert so skilfully kept distinct and yet at the same time never entirely separated—the concepts denoted by the geometrical terms were primitive concepts in the sense of Peano. Among such concepts were 'point', 'line' (*Gerade*), and 'plane', conceived as three separate kinds of entity, and a number of basic relations such as 'belongs to' (i.e. 'is incident with'), 'is between', 'is congruent to', and 'is parallel to'. The axioms or primitive propositions which comprised the implicit definitions of the primitive concepts were twenty in number, and they were classified in five sets as follows: I, 1–8, axioms of connexion; II, 1–4, axioms of order; III, 1–5, axioms of congruence; IV, the axiom of parallels; V, 1–2, axioms of continuity. These axioms are a sufficient foundation for a strictly deductive treatment of Euclid's system of geometry, in which stated axioms take over the ill-defined function of such semi-intuitive procedures as establishment of congruence by the method of superposition. We shall now give them in full.

I. *The axioms of connexion:*

1. If A and B are two points, there is always a line a that is incident with both of them.
2. If A and B are two points, there is not more than one line that is incident with both of them.
3. On a line there are always at least two points. There are at least three points which do not lie on a line.
4. If A, B, C are any three points which do not lie on one and the same line, there is always a plane α which is incident with them all. For every plane, there is a point that is incident with it.
5. If A, B, C are any three points which do not lie on one and the same line, there is not more than one plane that is incident with them all.
6. If two points A, B of a line a lie in a plane α, then every point of a lies in the plane α.
7. If two planes α, β have a point A in common, then they have at least one other point B in common.
8. There are at least four points which do not all lie in a plane.

II. *The axioms of order:*

1. If a point B lies between a point A and a point C, then A, B, C are three distinct points of a line, and B then also lies between C and A.
2. If A and C are two points, there is always at least one point B on the line AC which is such that C lies between A and B.
3. For any three points of a line, there is not more than one that lies between the other two.
4. Let A, B, C be three points which do not lie on a line, and let a be a

line in the plane ABC which does not pass through any of the points A, B, C. Then if the line a goes through a point of the segment AB [i.e. a point between A and B] it must go also through a point of the segment AC or through a point of the segment BC.

III. *The axioms of congruence:*
1. If A and B are two points on a line a, and if, further, A' is a point on the same or another line a', then a point B' can be found on the line a', on a given side of A', which is such that the segment AB is congruent or equal to the segment $A'B'$; in symbols:

$$AB \equiv A'B'.$$

2. If a segment $A'B'$ and a segment $A''B''$ are congruent to the same segment AB, then the segment $A'B'$ is congruent to the segment $A''B''$; in short, if two segments are congruent to a third, then they are congruent to each other.
3. Let AB and BC be two segments, without any points in common, on a line a, and also let $A'B'$ and $B'C'$ be two segments on the same or another line a', again without common points. If $AB \equiv A'B'$ and $BC \equiv B'C'$, then $AC \equiv A'C'$ also.
4. Let $\sphericalangle\,(h,k)$ be an angle in a plane α, and let a line a' in a plane α' and also a particular side of a' in α' be given. If h' denotes one ray of the line a' which issues from a point O', then in the plane α' there is one and only one ray k' such that the angle $\sphericalangle\,(h,k)$ is congruent or equal to the angle $\sphericalangle\,(h',k')$, and at the same time all the internal points of the angle $\sphericalangle\,(h',k')$ lie on the given side of a'; in symbols:

$$\sphericalangle\,(h,k) \equiv \sphericalangle\,(h'k').$$

Every angle is congruent to itself, i.e. always

$$\sphericalangle\,(h,k) \equiv \sphericalangle\,(h,k).$$

5. If, for two triangles ABC and $A'B'C'$, the congruences

$$AB \equiv A'B', \quad AC \equiv A'C', \quad \sphericalangle\,BAC \equiv \sphericalangle\,B'A'C'$$

all hold, then the congruence

$$\sphericalangle\,ABC \equiv \sphericalangle\,A'B'C'$$

is always satisfied also.

IV. *The axiom of parallels (Euclidean axiom):*
Let a be an arbitrary line and let A be a point that is not on a. Then, in the plane that is determined by a and A, there is at most one line that passes through A and does not meet a.

V. *The axioms of continuity:*

1. (*Axiom of measurement* or *Archimedean axiom.*) Let AB and CD be any segments whatever. Then there is a natural number n such that, if the segment CD is stepped off n times in succession along the ray from A which passes through B, a point beyond B will be reached.
2. (*Axiom of linear completeness.*) The system of points on a line, with its relations of order and congruence, does not admit of any extension that preserves all relations between existing elements, and also all the fundamental properties of linear order and congruence which follow from the axioms I–III, and that preserves V, 1.

The twenty axioms have been stated here in the original sequence, but the later ones will be seen to involve concepts that have not been formally introduced. This is because Hilbert himself interspersed between the separate sets of axioms various deductions of theorems and discussions of derivative notions. For details of these, and of the way in which Euclid's basic theorems were deduced from the new set of axioms, the original memoir must be consulted. It will be found that, despite its appearance of comparative informality, Hilbert's system of euclidean geometry is developed with great formal rigour. In any case, important as was Hilbert's achievement of rewriting Euclid in the spirit of Peano, the *Grundlagen der Geometrie* was to prove even more significant as a metamathematical essay than as a treatise on geometry; and it is this aspect of the book that we need chiefly to discuss at present.

The first metamathematical topic that Hilbert considered was the consistency of his axioms, that is to say the freedom from contradiction of the deductive theory that is built upon them. The method that he adopted for proving consistency was one of constructing an arithmetical model of the abstract system; and the use of models has since come to be very important in metamathematical investigations. By a *model* of a formal axiomatic theory we understand a realization of that theory, constructed in some mathematical domain which is already available. The formal theory will be based, as always, on one or more postulated totalities of entities, certain constant predicates and functions, and suitable axioms which define these predicates and functions implicitly; and to construct a model of it we replace the postulated totalities of entities by certain specific mathematical totalities, and the constant predicates and functions by specific predicates and functions defined for these totalities. If we are then able to show that, with this particular identification of the primitive elements of the formal theory, all the axioms become true propositions, we have succeeded in producing a model of the original theory. A model of a formal theory is thus a well-defined mathematical system with the particular structure that is characterized by the theory.
